Having constructed the body of the best material, teak being more preferable than ash, and sufficient time having been allowed for the hardening of the last coat of varnish, we should expect to find a well-designed body with the majority of the following details.

Seats and Seating Accommodation. Each inside passenger should have at least 17½ in. of sitting-room, and a brass rail should be supplied to divide the passengers into two divisions in order that the proper seating accommodation may be easily obtained without recourse to individual divisions.

The overall width of the roof should be not less than 7 ft. 6 in., which will not exceed in most cases the overall of the hind mudguards, and the garden seats each seating three persons might be placed in the centre of the roof, a gangway being provided on each side. This garden seat should be made so that a slight dip tends to keep the passenger centrally rather than towards the gangways. Much of the discomfort caused to outside riders might be minimised if a set of springs, painted or covered with waterproof material, were placed between the seat laths proper and a foundation. If the usual method of roof seating with central gangway be adopted the same overall width should be maintained. The height of the roof in the centre being kept the same, the sides should be higher, so that less arch and consequent less discomfort may be given to the passengers, besides allowing of more ventilation inside. A fare table should also be visible to the outside passengers. The cross seating has been tried for the interior, but while the drivers and his levers etc., are between the passenger and the view, not much comfort is added. It is certainly a favourable method when the body is open-sided, as in some patterns of tramcars, or if of the *char-a-banc* type.

Staircase. Again we plead for a few more inches, this time in the width of the treads. If one or two more risers and treads were inserted, the difference in comfort, especially for ladies, would be appreciated. But the staircase, whatever its pattern, is, after all, only a necessity owing to the public demand for a roof seat, as the omnibus and tramcar have become a means of pleasure in the form of an enjoyable ride. The proper development of the single decker has much before it, especially for country roads. We might add 12 in. to the head room of existing types and go on devising drop sashes till they do not rattle.

Curtains and Other Fittings. Such items as curtains are best in the spring roller type, and as there are firms who have supplied them in their tens of thousands to railway companies, there is no need to argue that a proper fitting has not been devised. Small electric pushes may be fitted as in tramcars to arrest the vehicle when the conductor is on the roof. Advertisements should be entirely banished from the interior, and illustrations and descriptions of places of interest en route allowed to take their places.

Lighting and Heating. The lighting of the interior should allow each inside passenger to read with comfort after dark, an electric lamp over the shoulder being best. Heating is easier with steam systems than with the petrol type. We have yet to see the evolution of heating systems in road vehicles.

Suspension. The châssis being hung on springs strong enough to take the maximum load and of sufficient length to absorb vibration easily, there is no reason why the body should not be suspended on a set of springs of its own. In steam rail motor coaches we see the front end of the passenger body resting on a movable bolster provided with springs, the whole resting on knife edges. This tends to isolate the body from the vibration of the engine. Possibly this can be adopted on the motor 'bus.

Announcement of Destinations. Where the 'bus goes, where it comes from, and the direction in which it is travelling should be made quite clear by day and night. The two sides of the vehicle should be taken up with the names of the chief places passed through during the journey, each side reading the same, except that the near side should always read from left to right and from top to bottom, the different roads and streets in the order that they are passed in the way the 'bus is travelling should be recorded. The front should be simply inscribed with a visible sign announcing the terminus, and the rear should be similarly fitted. Both should be capable of illumination at night.

Advertisements must be kept above the roof line, and should not be placed on the windows. If this were done, advertisements would not be confused with the destinations, and light would be allowed free ingress into the interior.

The route naming that is becoming fashionable with motor omnibus companies is to be upheld if it does not confuse the stranger. "Vanguard," "Ensign," "Pioneer," "Arrow," and such words denoting enthusiasm and enterprise should not take up the best part of the side panel and crowd valuable space which should be allotted to the destinations. The public are quite likely to associate a certain name with a certain route, and as the cars are continually being transferred to other routes confusion is caused.

Improvement of Motor 'Buses Possible. The old omnibus companies that have used the horse for many years past find that the expensive quadruped has brought them better dividends than railways. They should be able to adopt all the improvements suggested on a motor omnibus service without decreasing their returns or the pay of their employees, as the new form of traction is cheaper.

The mechanical omnibus is in its infancy, and is certain to develop into comparatively general use. This will come all the sooner if the newly formed society of Motor Omnibus Engineers has among its members a moderate proportion whose thoughts are not confined to sparking plugs, silencers, and such things.

Influence of Motors on Other Vehicles. The coachbuilder has in some instances copied the motor body types in his latest productions for horse traction. Governess cars, from which the tonneau was partly evolved, have been made with top panels carrying the back squabbing very similar to the motor body types. Bucket-shaped seats have been adopted in phaetons—including victorias—as well as in sociables, and the revival of the motor landaulette has seen an awakening among the horse-drawn types. The tonneau phaeton is practically a tonneau motor body on the coachbuilder's undercarriage, and it might be yet more successful as a novelty if it were hung lower and made easier to enter.

The railway companies have felt the presence of the automobile. Not only are they adopting motor omnibuses and *char-a-bancs* to bring customers to the railway stations, but they are bringing up to date an old type which is now known as the *rail motor coach.* In the majority of cases it is driven by the much tried steam power, and we yet have to see the adoption of the petrol motor, such as the Great Northern Railway Company are trying, to this new type of body. The influence has been felt even among mail carts, for the youngster can now be provided with a pedal-driven motor car, and if its parents can afford them, such details as lamps, goggles, horn, etc., may be included, in order that "playing at motors" may be carried out thoroughly.

The Old Compartment Trailer. We notice with pleasure that the rolling stock of the new motor coaches is either of the saloon or corridor type. The renouncement of the compartment type in these vehicles as well as in tube trains and other new electric rolling stock, will help to expel them from the main and suburban lines. In public service vehicles, safety lies in company. It has been shown time and again that the compartment system is fraught with danger.

Weight Cutting. The motor-car trade has revived the use of constructional metal work in vehicles. Aluminium panels, framework angle and moulding, when of good quality, are lighter, and necessitate less labour in the painting, although, perhaps, they do not give quite so durable a finish. The metal panel is also better adapted to quick turns. yet in some cases, where we have a return curve in the turn-under together with a side sweep, we find that such a panel keeps its shape better if of mahogany. The side panel in a curricle-shaped body is an illustration of this.

Still, the experienced metal-worker who is used to the eccentricities of the material will more likely be successful in turning out a piece of work that does not offend the eye whichever way it be viewed. Perhaps the most aggravating part of a thin metal panel is when it has a slight dent, not enough to warrant an expensive repair, yet sufficient to spoil the beauty of an otherwise good surface.

Metal hoopsticks may be seen in motor omnibuses carrying the roof, and the use of aluminium castings will do much to reduce the dead weight.

Metal Railway Waggons and Coaches. Railway waggons are now sometimes built entirely of metal. This applies not only to the medium types, but also to the new varieties of high capacity waggons with the varying method of discharging the load. The passenger railway vehicles are also being designed with panels and other parts of metal. By carefully apportioning the various sheet thicknesses and sectional strengths of the various members, not only have we obtained a fireproof carriage, but the total weight has been reduced. This is a consideration in the tremendous weight which corridor carriages have attained during the last eight or nine years. Increase of comfort has done this, for cooking stoves, dining tables, refreshment bars, sleeping berths, especially one-berth compartments, heating and lighting apparatus cannot be provided without adding to the weight. They all, more or less, take up room that might be occupied by a passenger.

As far back as 1898, American railway carriage designers came to the conclusion that 100,000 lb. was an enormous weight for a car, even if it were some 79 ft. in length. British builders, less eager to crowd their stock with every comfort, have not erred so greatly as have the Americans. The Brush Electrical Engineering Company, Limited, are to be congratulated on the new type of steel coach they have built for the Great Northern and City Railway, the electric tube railway running from Finsbury Park to Moorgate Street. Here, the weight per passenger has been reduced to 657 lb. A modern dining coach seating 20 will often weigh nearly double as many tons, while even a saloon carriage holding 56 passengers will work out at nearly half a ton per passenger.

Pleasure or Private Motor Vehicle Design. In a commercial vehicle we naturally expect the interior to be as useful as possible. The exterior, bounded mostly by straight lines, will fulfil its purpose in ordinary cases if neatly finished without any recourse to excess of decoration. Probably the enterprising and up-to-date tradesman will get better value out of his motor vehicle if he paints and inscribes it in a striking manner, as previously suggested, but this does not require curved boundaries for its display. In a gentleman's touring car we may be excused if we desire further to embellish the body after the seating and other accommodation has been properly arranged.

We must have a straight line if the panel ends at the seat line and where the rocker joins the top of the frame, if it be of the ordinary pattern, but there are many instances where a flowing curve may be used with advantage. Some designers have considered that any line deviating from the stiff straight line and an abundance of scrolls and dub ends gives a beautiful effect. But anyone who has the slightest artistic pretensions will allow that the fewer and simpler the lines necessary to carry out a body, the more pleasing is the effect and the more lasting the pleasure so created.

French Taste. Without being accused of want of patriotism, we do well to closely notice the style of outline which the best French taste dictates. We find that the lines flow. As we follow the outline, it never seems to lie still or remain flat in any place. We shall find in a Roi des Belges tonneau that the line that bounds the top extremity of the seat panels is a beautiful curve the whole way. There is scarcely a spot where a straightedge would find a resting place, even for an inch, and yet there is nothing exaggerated in the appearance.

Owing to its shape, a ¾ in. half-round moulding gives more reflection to the varnish, thereby imparting a lighter appearance, and the size suggested, when increased, is inclined to give a heavy effect to the whole.

Front Seats and Doors. The position of the chauffeur's seat is generally determined by the pedals and steering wheel. The occupant of the seat beside him, not being bound by any mechanical considerations, may encroach a little on the space between the front of the seat and the dash, thereby securing a more roomy seat, yet keeping the backs of the two front seats in line. Lightly constructed doors are useful in keeping the draught from the legs of those on the front seats. In designing the top line of the doors, it is desirable that it should not be a continuation of the front seat line, but swept gently upwards.

A doorway less than 20 in. wide gives little comfort to the passenger or quitter, and 22 in. is the normal width with the horse-drawn type for side entry. The engineer's designing of the châssis often results in the right-hand bottom corner of the door being cut away, owing to the nearness of the hind wheel and wing.

Lighter Appearance of the Body. Round corners at the back give a pleasing and lighter appearance, although they are, no doubt, a little more expensive to construct, especially when a piece of curved glass is included. Glass itself gives a light appearance, but it must not be forgotten that a sheet of plate glass is heavier than a corresponding area of mahogany or aluminium. The use of imitation cane-work, if it coincides with the customer's taste, is also useful in doing away with a heavy appearance. But it must be put on with due regard to bevels and round corners, otherwise it will be unsightly. It is a pity that the hand method has been superseded, for in it there was more chance of every allowance being made for the direction of the surface. Striping and shamsticks must be quiet, otherwise attention is detracted from the outline of the body.

Demand for New Types of Bodies. The automobile salesman is asked by some of his customers to construct bodies involving wonderful ideas, many of which are practically impossible of realisation. Although some foolish designs have been the result where the purchaser has insisted against the advice of those who are experienced, yet the effect, as a whole, has been to invent many fresh designs in seating and other arrangements, as well as in the general conformation of the body.

The Future. Towards the end of the year 1906 we find that Great Britain is turning out automobiles equal in performance to those made in France. As yet, the pleasure car is in the ascendancy; but no doubt time will bring proportions of other vehicles. The Show at Olympia is an evidence of the popularity as well as the prosperity of the new method of locomotion, and already the technical Press, the finest in the world of its kind, as well as newspapers and magazines, show what a tremendous hold it has.

It is, from the automobile point of view, a foregone conclusion that the man of the future will be more of an engineer than his father. Cycling developed mechanical thought; railways, interesting thousands more than they actually employ, have fostered it, so automobilism will find a prepared field upon which to work, and a wide scope.

We cannot believe that the horse will be entirely superseded, for it has already withstood the advent of the "iron road," but it may be safely prophesied that few omnibuses, tramcars, medium and heavy vans, will be horse-drawn some ten or fifteen years hence.

We have seen that the railway is primarily a carrier of merchandise. Is the automobile to develop in the same direction ?

Coachbuilder's Machinery. We have seen that in factories with large output, and especially in those where repetition work is turned out in quantities, wood-working machinery is an absolute necessity. Apart from the different tools, each doing their own special work, we find several types of motive power. In medium sized and large factories the steam engine has for some time held its own, but lately it has been used to drive a dynamo, so that neat little electric motors may be coupled up to each machine. Anyone who has seen an old factory converted from direct steam power, with its endless bands and pulleys, to electric power, will appreciate the saving of space, the better light, and the cheaper working gained by the newer practice. It may be that the manufactory can draw power from an electric main, in which case the steam engine is not wanted in the factory. Gas engines find favour in small shops, and need no boiler, chimney, or coal. Also the power is set in motion or arrested as required, and is specially valuable where the work is intermittent.

Petrol Stationary Engines. The petrol explosion motor by no means finds the only outlet for its energy in propelling road vehicles. It is unnecessary here to consider motor boats and flying machines, but as a stationary engine we cannot overlook the fact that this near relation of the gas engine is destined to do much useful work. Already it has been adapted with success, and eminent engine makers are providing types designed in frames suitable for the work, sometimes with attached dynamo in the event of electric power being required. The manufacturer is fortunate who is conveniently situated to a waterfall where he can utilise this cheapest of power. But Niagaras, even modest ones, are few and far between in this country.

Log Saws. The first machine that deserves notice is naturally that attacking the log and converting it into planks. A vertical log band saw effects this by means of an endless saw passing over pulleys, the timber being laid on a travelling metal table. The machine takes its name from the position in which the saw works. The latest method of treating with the log is by machines with horizontal band saws.

These log saws are continuous in their action, and the timber may be examined after each cut, that the man in charge may see if the next cut should be made as close as originally intended. Log saws are also arranged in sets whereby a log may be slabbed completely into planks or boards at one operation. It is well to remember that the thinner the saw blade the less the waste in conversion. The young timber student is often liable to forget allowance for saw cuts when, say, a 3 in. deal has to be cut up.

The Ordinary Band Saw. A coachbuilder must have a very small and unusual business not to warrant the adoption of an ordinary band saw. This tool is very useful for work with curved outlines, and can be fitted with an adjustable fence for straight work. For dealing with stuff on the bevel the table can be swung down to accommodate the angle of the work under treatment.

Another useful machine is the circular saw, which may be hand or machine fed. The fence may be removed for cross cutting when the capacity of the shop does not warrant a separate machine.

Circular saws are also fixed to the beams overhead as well as to the ordinary table. The former are known as pendulum saws. Fret saws are useful for cutting out internal work, a hole being drilled for the start.

Planing Machines. Planing machines are often more in evidence than is comfortable to the hearing. Yet when one sees a machine facing the four sides of a heavy piece of timber in a few minutes he is, perhaps, reconciled to its noise. Machine planing can be given a higher finish by passing the stuff through scraping machines, after which process little is necessary on the part of the bodymaker.

The various joints are quickly and accurately shaped on matchboarding, mortising, boring, and tenoning machines. The function of irregular moulding machines is to form rebates on pillars and rails, and mouldings of various shapes where required. Wood lathes are necessary for any work of a circular character. A very useful class of machinery is that set apart for the manufacture of wheel parts. Spokes are made and copied, stocks bored and mortised, felloes planed, and rims bent and dressed.

Metal-working Machines. The smith as well as the bodymaker has his mechanical appliances. His fire may be blown, his tyres bent, his work forged and upset—all without manual labour. In constructional steel work we should expect to see in the railway shops riveting and punching machines, a class of tool which is often operated by pneumatic power.

The Elevator. Although present practice does not favour many-storied factories for vehicular work, yet it is general to find an elevator or lift which carries up the body in the wood and iron to the paint shop, or brings down the finished vehicle ready to be sent away. The lift must be suited to the load it has to carry. Coachbuilders find that motor-cars, when being sent to the paint shop with châssis complete, need a more powerful lift than has hitherto been necessary. Travellers on the Central London Railway are familiar with the hydraulic and electric types, and there are also the older patterns coupled up to the factory steam engine or worked by hand.

Technical Education. The technology of vehicle building has received most attention in the road and rail carriage building departments, but during the last two or three years, van-building and wheelwrighting have been included in the syllabus of our large institutes. Evening classes are held during the winter months in such centres as Birmingham, Bristol, Newcastle, Liverpool, and Wolverhampton, while London, which lately had three classes in road carriage building, has now only one. At Stratford there is a large class in railway work, the natural outcome of the factory in the vicinity.

Official Examinations. The City and Guilds of London Institute recognise all these three subdivisions of the trade (road, rail, and van), and separate examinations are held annually, generally about May.

Vehicle Day School. London possesses the only English practical day school in vehicle work in the world, and although the evening classes are well appreciated, it is a great pity that the day school is not better supported by the trade.

The motor body is classified officially with the horse-drawn carriage, and as yet no separate syllabus has been in operation for the different principles governing automobile coachwork.

Literature of the Trade. Considering the importance to the community of vehicles generally, the scantiness of the textbooks available is surprising.

Rail carriage building is, however, well represented by the "Car Builders' Dictionary," 1903 ("Railroad Gazette," New York), price $5 ; "Railway Carriages and Waggons," by Stone ; parts 1 and 2, 1905-6 ("Railway Engineer," Ludgate Circus, E.C.), 10s. 6d. each part. The "Locomotive Magazine," 2d. monthly, contains many useful articles on railway coachbuilding from time to time.

Road Carriage Books. There are many small textbooks and pamphlets published, but none can be considered manuals. Among the best are Philipson on "The Art of Coach Body Making" (John Kemp) ; Philipson on "Suspension of Carriages" ("Hub," New York), and "Coachbuilding" (Bell), by the same author ; Thrupp on "History of Coaches" (Kerby & Endean) ; "Handbook for Coach Painters," by Simpson (Cooper) ; "Coach Trimming," by Farr & Thrupp (Chapman & Hall).

A useful collection of essays is the volume of papers read before the Institute of British Carriage Manufacturers (1883-1901), published by the Powage Press. The subjects embrace all departments of the trade.

As regards trade journals, we have the "Automobile and Carriage Builders' Journal" (16, Eldon Street, E.C.), 10s. per annum, and the "Coachbuilders' Art Journal" (64, Long Acre), 25s. per annum. Both are monthly periodicals, and embrace all departments, including automobile work and van-building.

Illustrations and general details of motor-car bodies are well set out in the numerous motor-car weeklies, such as the "Autocar," 3d., "Automotor," 3d. ; "Motoring Illustrated," 1d.; "Motor Car Journal," 1d. ; "The Car," 6d. ; etc., but their actual province is, of course, motor engineering.

Cycles. Books on cycle construction include "Modern Cycles," by A. J. Wallis-Taylor, 10s. 6d. (Lockwood), "Cycling," by H. Graves, etc., 1s. (Suffolk Sporting Series), "Cycling" (Ward, Lock & Co., Ltd.), 1d., are useful little works on the popular pastime. Periodicals such as "Cycling" and the "Motor" (formerly "Motor Cycling") are representative of the periodicals.

PRACTICAL WEAVING

Drawing-in or Healding. Practical Points in Jacquard Tying. Making Cloth. Linen, Jute, and Silk Looms

Continued from page 3686

By W. S. MURPHY

HAVING acquired an understanding of the structure and fittings of the loom, we can now proceed to make use of it. The warp is healded before it is put on the loom; but the method of drawing is founded on both a knowledge of the loom and the plan of the designer. For every design there is a treading plan, or draft. The former term points to the treadles of the hand loom which direct the motions of the healds; the latter term applies to harness of all kinds—to the jacquard, the dobbie, the lappet, and other contrivances. It is by the management of the warp and its relation to the weft that the loom is patterned.

Plain cloth presents no problem; the treading plan is straightforward. Say that we have two healds. The weaving beam [**174**], with the warp on it, is slung, and the healds are hung before it. The healder's boy helper stands at the warp and feeds the threads in proper order. Through heald No, 1 the first, third, fifth, and all the odd-numbered threads are drawn; through heald No. 2, the second, fourth, and other even numbers are drawn. The healder has a tool like a long crocheting needle, with which he pulls through the threads at a rapid rate.

When one plain web succeeds another, the former warp leaves ends in the healds, and then the duty of the healder is to twist the ends of the new warp on to the threads of the old one. The trade designation of the old order of men who did the healding was *drawers and twisters.*

Treading Plan. It is when we take up twills and fancy weaves that the treading plan becomes important. For every change in the relation of warp and weft we must have a heald. The three-leaved twill, for instance, is only one remove from plain weaving, and is applied to sheetings, blankets, and other cloths of that nature. With the three leaves we can obtain only a single variation in the warp — two threads up and one down, one up and two down, alternately, though the weft may effect other variations.

Four-leaved twill begins complexity. With four healds we can make a fairly large variety of patterns, limited only by the general rule that "when two threads differ from each other in their order of weaving or interweaving at any point, they cannot be actuated by the same heald." Three threads over and one under the weft is cashmere; two under and two over gives a two-sided twill. We may reverse the order of the first, and vary in several other ways which are obvious.

Dimity and Diaper. Five leaves add still further to the resources of the designer. The simplest use of the five leaves is in the production of dimity, in which the weft passes over four warp threads and under one. Diaper alternates the action, four threads of warp and four threads of weft coming up in turn to the surface, with, of course, one intermediate thread.

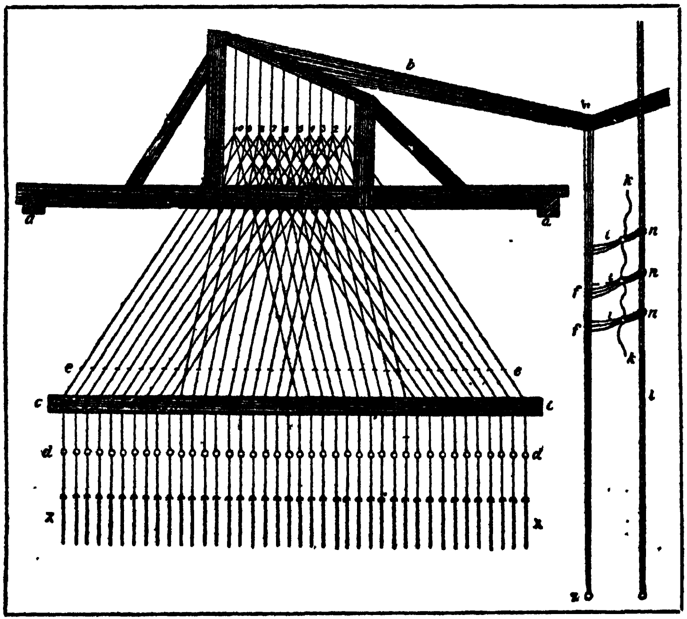
With the five-leaved harness, the satin surface can be produced, and, in heavy cottons such as jeans, or woollens, is commonly adopted.

Numerous fine patterns are woven with the set of five healds; some weavers contend that the finest cloth effects require no more; but the numbers run up to eight, ten, twelve, and even sixteen in some fabrics. Silk weavers often

174. DRAWING-IN OR HEALDING (H. Bannerman & Sons, Ltd., Manchester)

prefer the large number of healds to any other form of harness. We think, however, that ten healds mark the limit where the use of healds ceases to be of any advantage over the jacquard and the dobbie in any circumstance, and highly skilled weavers even refuse to allow more than five where the jacquard can be brought into requisition. Into this debate we do not invite the student. Experience will enable him to form an opinion of his own.

Harness. Great as the French inventor was in genius, he did not originate a single important feature in the jacquard machine. Like Shakespeare, he took the material at hand, and put it into his idea. The jacquard, in short, is simply the old loom harness [175] made automatic. Detailed study of the harness would not be of much practical value, and we therefore note only those features it has in common with the jacquard to assist the student in understanding the operation of *tying*. A board (*c*) perforated throughout was hung over the loom, and through this the cords of the harness were passed to the number required, amounting in many cases to thousands. The cords (*e*) were looped to take up the warp threads, according to the design; these, again, were knotted together at the neck, and from each group a single cord passed through a series of pulleys across to a fixed piece of wood, called the *table* (*o*), and firmly fastened. From each cord (*w*) a cord was let down to a fixture in the floor (*f*), and at the side of these another stout cord (*l*) was fastened from floor to ceiling. Next, small cords called *lashes* (*i*) were bound in the order of the design from the harness cords to the fixed cord. The drawer pulled the first set of lashes tight, bringing out the proper vertical cord from the rest; these he pulled by themselves, and thus acted on the set of harness cords he designed to call into action, lifting the warp threads in the order the weaver required.



175. LOOM HARNESS

Tying up the Jacquard. The student has made acquaintance with the mechanism of the jacquard, and it now remains for us to inquire into the methods to be adopted in bringing it into practical use. In the old harness loom we had a certain freedom which is limited in the newer apparatus. We could put as many or as few cords as we liked into a row on the harness; but in the jacquard, because it is a machine applicable all round, the cords and needles corresponding must be definitely numbered. Jacquards are known as 300, 400, 500, or 600, according to the number of hooks they contain. The hooks are ranged in rows of 8 and 12, and each row must be complete; therefore a 300 jacquard contains either 304 or 308 hooks, just as the hooks are ranged in rows of 12 or 8. Suppose our pattern occupies 18 threads, what is to be done? The number 18 is not a multiple of 304. We must cast out, as the saying is, 16 hooks. This is not such a simple matter as may seem. We have to keep the whole web in due proportion; the vacancies must be so distributed as to leave no gaps in the warp. For the sake of simplifying the matter, let us suppose that we are working with healds. If our healds give 60 threads of warp to the inch, and we find it impracticable to give more than 50 threads to the inch, our plan would be to miss one loop in 30 in the heald of 300 cords. Similarly, in our jacquard we must reduce the number of threads per inch in the warp if the pattern does not come out even with the number of hooks on the machine. In designing we have this to consider and provide for. Should it be necessary to put a large number of threads into the inch, the process must be reversed, and the extent of pattern woven at each revolution, or the total use of all the hooks, reduced. At this point we sight the vast range of problems which the designer deliberately faces when he undertakes to work with the jacquard.

Cards. The cards are the most valuable idea in the jacquard apparatus. By means of these the work of tying-up is simplified. Making the cards is a mechanical operation. From the designer the card cutter gets the design, marked on pointed paper to correspond with the hooks of the jacquard. On each line those squares are marked black, which shows that a warp thread is to be lifted. Perforations are cut in the card corresponding to the black squares on each line. Automatic machines have now been invented which do all but read the design, and cut the perforations with an accuracy the most skilful workman could hardly hope to equal. When the cards are cut, they are sewn together by another machine, modelled on the common sewing machine.

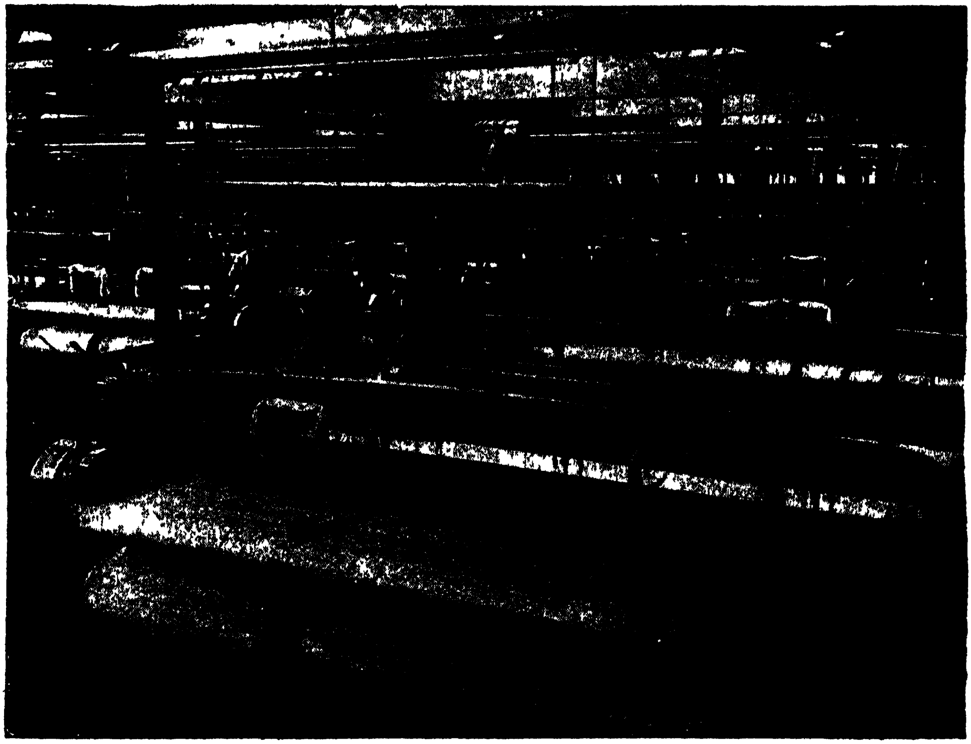
The cards are folded together and set on the cylinder, a few slips requiring to be let out for the purpose. Considerable variation occurs at this point, some sheaves of cards being arranged so that they merely fall over from one position to another, while others make a wide circle, as many as twenty cards flying loose like a slack belt. This and other minor details signify little to the student.

Now let us see the connection of warp and jacquard. Every cord has a small weight at the end and an eyelet where the warp passes through. To each warp thread there is a cord, and we draw the threads through in the same way as has been done on the healds. The cords pass through what is called the *cumber board*, and those which belong to the same hooks—that is, those attached to warp threads interweaving in one way throughout the pattern—are joined, and from them single threads pass up to the hooks of the jacquard.

In dealing with this wonderful machine we have tried to keep strictly to the side of simplicity. Into the manifold uses of the jacquard we cannot enter. At the present day every textile industry utilises the jacquard in one form or another. Understanding of the machine takes us a considerable way towards making intelligent use of it, whether as weaver or designer, as managers or workers. If the student could always remember that the jacquard is little more than an aggregation of healds, and think of each neck cord as a heald cord, he would not be led astray by the seeming complexity of the contrivance.

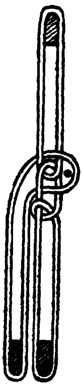
Making Cloth. Having examined the main parts of the loom, let us try to obtain a clear view of its general working in the weaving-shed [176]. The shedding of the warp, the crossing of the weft, and the beating of the reed in the slay, are the principal actions of the loom, and we can look at them in order. At the moment when the reed comes up against the cloth, the loom is in balance, and ready for another operation. The slay swings back, and the parts begin to act. The tappets, or the jacquard, shed the warp, opening it till the slay has reached the centre of its stroke. Then the shuttle comes flying through. The warp closes, while the slay comes forward, and, before the shed is shut, drives home the weft.

All the other parts move in harmony with these, being governed more or less directly by them. It is in the adjustment of part to part that the harmony of the loom is obtained, and a good cloth woven. The shuttle must be directed



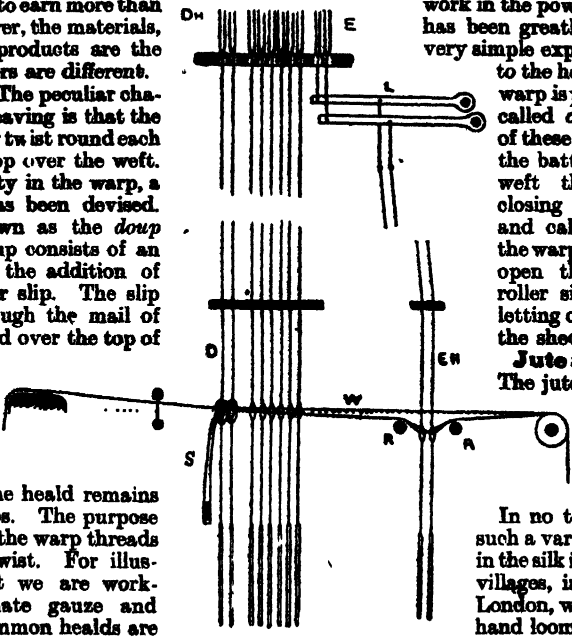
176. A SHEETING WEAVING-SHED (Horrockses, Crewdson & Co., Ltd., Preston)

by picker and spindle, so that it will fly straight, and the reed must be in direct line with the shuttle-box. The adjustment of the warp calls for the closest attention. While the under half of the shed should lie level on the shuttle race to give the shuttle a free flight, the least pressure on the race will alter the balance of the tension and cause slackness. The taking-up motion needs to be watched, for the least variation in the leverage alters the whole character of the cloth. On looms with numerous mountings the duties of the over-looker and weaver are correspondingly increased. We have developed the loom to a high degree, and made it almost automatic, as we have seen in the Northrop loom; but human skill and attention can by no means be dispensed with. The weaver is the cloth-maker still. Broken picks, flakes, twists, and other faults may occur in any web if the weaver is not careful; even with the greatest care they do occur, and must be neatly and quickly repaired. To get a fine skin on the cloth is the supreme object of the satin weaver; but the weaver of the coarsest jute should not be unmindful of the same. A perusal of the wages-book of any weaving factory would startle many who lightly think of the weaving craft. Some weavers earn an average of 29s. per week, where others, working under exactly equal conditions, fail to earn more than 14s. The driving power, the materials, the looms, and the products are the same; but the weavers are different.



177. DOUP HEALD

Gauze Loom. The peculiar characteristic of gauze weaving is that the warp threads partially twist round each other, and form a loop over the weft. To obtain this mobility in the warp, a special mechanism has been devised. This is what is known as the *doup* heald [176]. The doup consists of an ordinary heald, with the addition of another half heald, or slip. The slip may either pass through the mail of the ordinary heald and over the top of it, or it may pass entirely through it. In the latter case, the slip is held in position by the thread of warp passing through it; in the former case, the heald remains in position at all times. The purpose of the doup is to raise the warp threads so as to produce a twist. For illustration, suppose that we are working strips of alternate gauze and plain cloth. Two common healds are required, and the warp is drawn through them in the usual manner. The doup heald is placed in front, and one thread of each pair crossed under the other and passed through the slip of the doup. In weaving plain cloth, the loose slip rises and falls into harmony with the other healds, to avoid changing the position of the warp threads passed through it, the main part of the doup heald remaining stationary. But when gauze is to be made the whole doup heald lifts, bringing the thread it carries to the contrary side of its neighbour, and forming a crossing which the passage of the weft renders permanent. One difficulty in this operation has always troubled weavers, and that is the sudden pull of the doup heald; lifting the threads it carries above the ordinary tension causes many breaks if not otherwise prevented. Slackeners of various kinds have been invented. The one thing to be demanded from any slackener is that it should act only with the doup heald and let the slack back when the need for it has ceased. In the diagram [178] the whole action of the warp (W) is shown. The heald (D) carrying the doup (S) appears in its proper relation to the slackener heald (E H). The rest of the mechanism drawn has already been described.



178. GAUZE HEALDS
(From Ashenhurst's "Practical Weaving")

Linen Loom. The looms used in linen manufacture are almost identical with those of the cotton-weaver. In the linen weaving shed there are plain looms, looms equipped with the jacquard and dobby fittings, and many looms of great weight. One feature, however, is special to the linen loom, and that is the slackening beam. In spite of every device, linen remains a hard thread, with little elasticity, and the lack of that quality makes it difficult to work in the power loom. The defect has been greatly minimised by a very simple expedient. On its way to the heddles, or healds, the warp is passed over what are called *carrier beams*. One of these is lifted by a cam as the batten drives home the weft thread between the closing shed of the warp, and calls up the slack of the warp. When the healds open the shed again the roller sinks into its place, letting out the warp to form the shed.

Jute and Silk Looms. The jute loom has about it no special features; its size alone marks it out from all other textile weaving machines.

In no textile trade is there such a variety of looms used as in the silk industry. In country villages, in the very heart of London, we find silk woven on hand looms with and without jacquard apparatus. In the great centres of silk manufacture, such as Coventry and Macclesfield, we find the fine adaptations of all the highest forms of loom. The lappet, the swivel, the jacquard, and all the other fancy devices are utilised. The student of silk may not omit the study of any form of weaving machine.

THE PROGRESSIONS

Arithmetical, Geometrical, and Harmonical Progressions. Insertion of Means between Two Given Quantities. Summation of Series

Group 21
MATHEMATICS
27
ALGEBRA

continued from page 3898

By HERBERT J. ALLPORT, M.A.

ARITHMETICAL PROGRESSION

143. If we have a series of quantities such that the difference between any one of them and the preceding one is the same throughout the series, the quantities are said to be in *Arithmetical Progression.*

We shall use the letters A.P. as an abbreviation for Arithmetical Progression.

Examples.

(i.) 1, 4, 7, 10 .... are in A.P.
(ii.) 5, 3, 1, -1............ are in A.P.
(iii.) a, $a+d$, $a+2d$. .... are in A.P.

The difference between each term and the preceding term is called the *common difference.* In the first of the given series, by subtracting any term from the term which follows it, we see that the common difference is 3; in the second series it is -2; in the third series it is d.

144. Series (iii.) in the last Article represents the *general* form of an A.P. The coefficient of d in the different terms should be noticed. Thus, in the 2nd term the coefficient of d is 1; in the 3rd term it is 2; in the 4th term it is 3, so that *the coefficient of* d *is always less by unity than the number of the term.*' Hence, in the nth term, the coefficient will be $(n-1)$, and the nth term $= a + (n-1)d$.

Therefore, we can write down *any* term of an A.P. when we know the first term and the common difference.

Example. The 24th term of the series whose first term is 17 and common difference -3, is $17 + (24-1)(-3)$, or $17-69$, *i.e.*, -52.

145. When *any* two terms of an A.P. are known, any other term of the series can be found.

Example. The 8th term of an A.P. is 25 and the 21st term is 51. Find the 3rd term.

Let $a =$ the 1st term, $d =$ the common difference. Then,

$$\text{the 8th term} = a + 7d = 25, \quad . \quad . \quad (1)$$
$$\text{the 21st term} = a + 20d = 51. \quad . \quad . \quad (2)$$

Solving the equations (1) and (2) we find $a = 11$, $d = 2$. Hence,

$$\begin{aligned}\text{the 3rd term} &= a + 2d\\ &= 11 + 4 = 15 \ \textit{Ans.}\end{aligned}$$

146. If three quantities are in A.P., the middle one is called the *Arithmetic Mean* between the other two.

The arithmetic mean between two given quantities, a and b, is easily found. For, if x be the required mean, a, x, b are in A.P., so that $x-a$ and $b-x$ are each equal to the common difference. Hence,

$$x - a = b - x,$$

from which we obtain

$$x = \frac{a+b}{2}.$$

Thus, *the arithmetic mean of two quantities is half their sum.*

147. In a similar way, if we have any number of quantities in A.P., the intermediate terms are called arithmetic means between the first and last. An example will make clear the method of inserting any required number of means between two given quantities.

Example. Insert 4 arithmetic means between 7 and -8.

Having inserted 4 means between 7 and -8, we shall then have *six* terms in A.P. We have, therefore, to find the common difference of a series in which the 6th term is -8 and the 1st term is 7.

Let d be the common difference. Then,

$$-8 = 7 + 5d \ [\text{Art. } \mathbf{144}];$$

therefore,

$$d = -3.$$

The series is therefore 7, 4, 1, -2, -5, -8.

148. *To find the sum of any number of terms of an A.P.*

Let $a =$ the first term, $d =$ the common difference, and $l =$ the last term. Clearly the term before the last will be $(l-d)$, and the next preceding one will be $(l-2d)$. Suppose we are required to find the sum of n terms. We cannot write down *every* term of the series, since we do not know the actual values of a, d, and n; but writing a few of the terms at each end of the series we have, if s be the required sum,

$$s = a + (a+d) + (a+2d) + \ldots + (l-2d) + (l-d) + l.$$

Writing the series in reverse order we get

$$s = l + (l-d) + (l-2d) + \ldots + (a+2d) + (a+d) + a.$$

Hence, adding corresponding terms,

$$\begin{aligned}2s &= (a+l) + (a+l) + (a+l) + \ldots \text{to } n \text{ terms},\\ &= n(a+l).\end{aligned}$$

Therefore,

$$s = \frac{n}{2}(a+l). \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

Now,

$$\begin{aligned}a + l &= a + a + (n-1)d \ [\text{Art. } \mathbf{144}],\\ &= 2a + (n-1)d.\end{aligned}$$

Hence,

$$s = \frac{n}{2}\{2a + (n-1)d\}. \quad . \quad . \quad . \quad . \quad . \quad (2)$$

Of these two formulæ (2) is perhaps more useful than (1), but both should be remembered.

Example 1. Sum the series 1, 3, 5, 7, 9 ... to 20 terms.

Here $a = 1$, $d = 2$, $n = 20$.
Therefore,

$$s = \frac{20}{2}\{2 + (19 \times 2)\}$$
$$= 10 \times 40 = 400 \ \underline{Ans.}$$

Example 2. How many terms of the series 28, 24, 20 ... must be taken in order that their sum may be 88?

Let n be the required number of terms. The common difference of the series is

$$24 - 28 = -4.$$

Hence, using formula (2) of the present article, we have

$$88 = \frac{n}{2}\{56 - 4(n-1)\},$$

or, on simplification,

$$n^2 - 15n + 44 = 0.$$

The solution of this equation gives

$$n = 4 \text{ or } n = 11.$$

Hence, the sum of 4 terms or of 11 terms will be 88.

NOTE. Where *two* values of n satisfy the question, the sum of the extra terms in the second case is zero. This is easily seen by writing down 11 terms of the given series, *viz.*, 28, 24, 20, 16, 12, 8, 4, 0, -4, -8, -12. Evidently the sum of the last 7 terms is zero, so that the sum of 4 terms is the same as the sum of $4 + 7$, or 11 terms.

GEOMETRICAL PROGRESSION

149. A series of quantities is in *Geometrical Progression* when the ratio of any term to the preceding term is the same throughout the series. This ratio is called the *common ratio* of the series.

Examples.

(i.) 2, 4, 8, 16 ... is a G.P. whose common ratio is 2.

(ii.) $\frac{1}{3}, -\frac{1}{6}, \frac{1}{12}, -\frac{1}{24}$ ... is a G.P. whose common ratio is $-\frac{1}{2}$.

(iii.) a, ar, ar^2, ar^3 ... is a G.P. whose common ratio is r.

150. In the series whose 1st term is a and common ratio r, the 2nd term is ar, the 3rd term is ar^2, the 4th term is ar^3, and so on, *the index of r always being less by unity than the number of the term.* Thus, the *general term*, or nth term, of the series is ar^{n-1}. Hence we can write down *any* term of a G.P. when we know the first term and the common ratio.

151. When any *two* terms of a G.P. are known, the series itself is easily found.

Example. Find the 2nd term of a G.P. whose 4th term is -2 and whose 7th term is $\frac{1}{4}$.

Let a be the 1st term and r the common ratio of the series. Then (Art. 150) the 4th term is ar^3 and the 7th term is ar^6.

Hence,

$$ar^3 = -2 \quad . \ . \ . \ . \ . \quad \text{(i)},$$

and

$$ar^6 = \frac{1}{4} \quad . \ . \ . \quad \text{(ii)}.$$

Dividing the second equation by the first we have $r^3 = -\frac{1}{8}$, and therefore $r = -\frac{1}{2}$. Substituting in (i) we get $a = 16$. Hence, the required 2nd term

$$= ar$$
$$= 16 \times \left(-\frac{1}{2}\right) = -8. \ \underline{Ans.}$$

152. When three quantities are in G.P. the middle one is called the *geometric mean* between the other two.

Suppose a, b, c are in G.P. Then,

$$\frac{b}{a} = \frac{c}{b},$$

since each of these ratios is the common ratio of the series.

Therefore, $\quad b^2 = ac$,

or $\quad b = \sqrt{ac}$.

Hence, *the geometric mean between two quantities is the square root of their product.*

153. When any number of terms are in G.P. the intermediate terms are called *geometric means* between the first and last terms.

Example. Insert 3 geometric means between 6 and 96. We have here to find the series of 5 terms (consisting of 6, 96, and the three means), of which the 1st term is 6, and the 5th 96.

Let r be the common ratio. Then, since the 5th term of the general series is ar^4, we have

$$6r^4 = 96.$$

Therefore, $\quad r^4 = 16$;

therefore, $\quad r = \pm 2$.

The series is therefore 6, ± 12, 24, ± 48, 96, and the required means are ± 12, 24, ± 48.

154. Sum of n Terms of a G.P.

Let a be the 1st term, r the common ratio. Then the nth term is ar^{n-1}, the $(n-1)$th term is ar^{n-2}, and so on. Hence, if s be the required sum, we have

$$s = a + ar + ar^2 + \ldots + ar^{n-2} + ar^{n-1}.$$

Multiply both sides of this equation by r, putting the terms of the right-hand side one place to the right. Then,

$$rs = \quad ar + ar^2 + \ldots + ar^{n-2} + ar^{n-1} + ar^n.$$

Subtract corresponding sides of the two equations.

Therefore, $\quad s(1-r) = a - ar^n$;

therefore, $\quad s = \frac{a(1-r^n)}{1-r}$.

Example. Sum the series 1, 3, 9 ... to 6 terms. In this case $a = 1$, $r = 3$, $n = 6$.

Therefore,

$$s = \frac{1-3^6}{1-3} = \frac{3^6-1}{2} = \frac{728}{2} = 364. \ \underline{Ans.}$$

155. Sum of an Infinite Number of Terms of a G.P. When the common ratio of a G.P. is less than unity, there is a limit to the value of the sum of its terms; that is, we cannot make the sum as great as we please by taking a very large number of terms. For example, suppose we have a line 3 in. long. First take away half the line, then take away half the remainder, then half of the new remainder, and so on. The lengths of the parts taken away will be $\frac{3}{2}, \frac{3}{4}, \frac{3}{8}, \frac{3}{16}$, etc. Now, the sum of the parts taken away can evidently never be greater than 3 in; also, since the remainder diminishes indefinitely as the number of parts taken away is indefinitely increased, the sum of the parts taken away can be made to differ from 3 in. by an indefinitely small length. Hence, the sum of an infinite number of terms (or, the *sum to infinity*) of the series $\frac{3}{2}, \frac{3}{4}, \frac{3}{8} \ldots$ is 3.

The formula for the sum to infinity is deduced from that of Art. **154**.

$$s = \frac{a(1 - r^n)}{1 - r}$$

$$= \frac{a}{1 - r} - \frac{ar^n}{1 - r}.$$

Now, when r is less than unity, numerically (whether it be + or −), the numerical value of r^n decreases as n is made larger, and can be made as small as we please by sufficiently increasing the value of n. Hence, s can be made to differ from $\frac{a}{1 - r}$ by as small a quantity as we please.

The sum of an infinite number of terms of the series $a, ar, ar^2 \ldots$ is therefore $\frac{a}{1 - r}$.

It must be particularly noted that the "sum to infinity" can only be found in cases where r is less than unity.

HARMONICAL PROGRESSION

156. A series of quantities is in *Harmonical Progression* if, when any three consecutive terms are chosen, the difference between the first and second is to the difference between the second and third as the first is to the third.

Thus, $a, b, c, d \ldots$ are in H.P. if

$$a - b : b - c :: a : c,$$

$$b - c : c - d :: b : d,$$

and so on, for every three consecutive terms.

157. A more easily remembered definition is the following: *Quantities are said to be in H.P. when their reciprocals are in A.P.* This relation is easily deduced from the definition of the last article. For, if a, b, c are in H.P., we have

$$\frac{a - b}{b - c} = \frac{a}{c}.$$

Therefore, $ac - bc = ab - ac.$

Divide both sides by abc. Then,

$$\frac{1}{b} - \frac{1}{a} = \frac{1}{c} - \frac{1}{b},$$

which shows that $\frac{1}{a}, \frac{1}{b}, \frac{1}{c}$ are in Arithmetical Progression.

158. When three quantities are in H.P., the middle one is the *harmonic mean* between the other two.

If a, b, c, are in H.P., we have proved that $\frac{1}{a}, \frac{1}{b}, \frac{1}{c}$, are in A.P., and therefore,

$$\frac{2}{b} = \frac{1}{a} + \frac{1}{c} \text{ [Art. 146].}$$

Hence, $b = \frac{2ac}{a + c}.$

159. *The geometric mean of two quantities is the geometric mean between their arithmetic mean and their harmonic mean.*

Let a, b, be the two quantities, and A, G, H, their arithmetic, geometric, and harmonic means, respectively.

Then, $A = \frac{a + b}{2}$ [Art. **146**],

$G = \sqrt{ab}$ [Art. **152**],

$H = \frac{2ab}{a + b}$ [Art. **158**];

therefore,

$$A \times H = \frac{a + b}{2} \times \frac{2ab}{a + b} = ab = G^2,$$

or $G = \sqrt{AH},$

so that G is the geometric mean between A and H.

160. No general formula can be found for obtaining the sum of a number of terms in H.P.

Many questions in H.P. are solved by considering the corresponding problem in A.P.

Example. Insert 3 harmonic means between 1 and 3.

We insert 3 *arithmetic* means between 1 and $\frac{1}{3}$. Their reciprocals will be the required harmonic means.

As in Art. **147**, we find the arithmetic means are $\frac{5}{6}, \frac{2}{3}, \frac{1}{2}$. Hence, the required harmonic means are $\frac{6}{5}, \frac{3}{2}$, 2.

EXAMPLES 34

1. The 3rd term of an A.P. is 72 and the 8th term is 37. Find the 1st term.

2 Insert 4 arithmetic means between 2 and 17.

3. The sum of the 1st and 2nd terms of a G.P. is 10, and the sum of the 3rd and 4th terms is 160. Find the 5th term.

4 Sum the following series:

(i.) $3 + 6 + 9 + \ldots$ to 15 terms

(ii.) $6 + 5\frac{1}{2} + 5 + \ldots$ to 20 terms.

(iii.) $\frac{1}{3} + \frac{3}{4} + \frac{3}{2} + \ldots$ to 5 terms.

(iv.) $1 + \frac{1}{\sqrt{3}} + \frac{1}{3} + \ldots$ to infinity.

SINGLE ENTRY & ROYALTIES

Profit and Loss Account by Single Entry. Hire Purchase Accounts. Interest. Mining Royalties. Chartered and Incorporated Accountants

By J. F. G. PRICE

LITTLE has been said hitherto upon the subject of keeping books by what is known as single entry. The reason has been that no accountant would recommend the keeping of books by these means in a business of any size. Having regard to the fact, however, that there are many small traders who do keep their books in this way, it is necessary that some description of the process should be given. The great drawback of the method is the impossibility of proving the accuracy of the records kept under it.

Single Entry Methods. The books in use vary in different businesses, but usually there are a cash book and a ledger; sometimes there is a day book. What semblance of a system there is in keeping books by this method consists in entering in the cash book all cash received, from whatever source, and all cash paid away, for whatever purpose, and in keeping accounts in the ledger for customers owing money to the business. Sometimes the ledger contains also the accounts of wholesale dealers from whom goods have been purchased on credit. The "system" is usually a mixture of double entry and single so far as the practice observed in keeping the books is concerned. No goods account is kept, and the only way in which purchases and sales are recorded is on the cash and personal accounts. When a cash sale is made the cash received is merely entered on the debit side of the cash book, but no posting is made to the ledger. This is mere single entry, there being a debit entry, but no corresponding credit.

Ledger Entries. In a sale on credit the customer's account in the ledger is debited, but there is no credit to a goods or sales account. This is single entry. But when cash is received from a debtor in respect of goods previously sold on credit with which he has been debited, the amount received is not only entered on the debit side of the cash book, it is posted to the credit of the customer's account. This is complete double entry. Similarly, when payments are made for cash purchases the payments are recorded on the credit side of the cash book, but are not posted to a ledger account. Further, cash paid for rent, wages, and other expenses of the business, although entered on the credit side of the cash book, are not posted to nominal accounts in the ledger. Where no ledger accounts are kept for creditors the same principle is applied, and payments made to persons who have supplied goods on credit are not posted to the ledger. But where ledger accounts have been opened for persons who have supplied goods on credit the payments to them are posted to their debit, as well as being entered on the credit side of the cash book. This, of course, is again complete double entry. There is thus very little system about single-entry bookkeeping, and this failing is particularly felt when a trader desires to know the result of his operations at the end of a year's transactions. To meet his wishes in this respect a means has to be devised for arriving at the desired result with some degree of accuracy; but although errors of magnitude can be avoided by the exercise of common-sense, it is not possible to place absolute reliance upon the result obtained.

Single Entry Profit and Loss. The first step to be taken is to dissect the cash book. Taking the debit side, the receipts will probably be found to consist entirely of cash sales and receipts from debtors on credit sales. There may be also some items in respect of further capital introduced by the proprietor. The credit side will consist of payments for cash purchases, to persons for credit purchases, rent, wages, rates, carriage and miscellaneous trade expenses. There will be also the proprietor's drawings, and these must be carefully inquired into, for money is frequently withdrawn from a business by the proprietor without a record of the fact. The ledger accounts must then be analysed to ascertain the amount of the credit sales, which will consist of the posting of goods to the debit of the personal accounts. These can be approximately checked by comparing the total of the entries with the cash received from debtors during the year plus the debts outstanding. After providing for any discounts or other allowances made to debtors, the two totals should agree. The same course must be pursued with the credit purchases, and a similar comparison made.

The value of the stocks at the beginning and end of the period will be required, and if these are obtainable a trading and profit and loss account can be prepared. There is, as a rule, no difficulty in obtaining the stock at the close, but that at the beginning is not usually so readily procurable unless it is a new business. The initial stock is generally the most uncertain element in the accounts prepared on this plan, and if it was not taken in a proper manner at the beginning of the trading period it must be estimated.

Inasmuch as the whole result will depend upon the estimate formed, it must be very carefully made, and the usual means adopted is to take the closing stock at cost, add to this the total sales, less a percentage for gross profit, and then deduct the purchases. Here, of course, everything depends upon the trustworthiness of the percentage of gross profit, and if any other means are available the result should be tested by them. Care must be taken to ascertain if there are any outstanding liabilities not recorded in the books, in respect of rent, rates, wages, or other expenses, as these may materially affect the result. Having taken the above steps, a profit and loss account and balance-sheet can be prepared in the usual form.

Conversion to Double Entry. The trader, after the trouble he will have experienced in obtaining these results, will probably desire to revise his methods of keeping his accounts in the future. If so, the first steps to be taken will be to bring into use purchases and sales books for the recording of all goods bought and sold on credit. The periodical posting of these books and the cash book into the ledger, together with the opening of a goods account and the various nominal accounts, will make his books capable of proof, and the results of accounts showing his trading operations thoroughly reliable.

If he decide to keep his books on double-entry principles in future, all that need be done to record in his books the position shown in the balance-sheet is to open ledger accounts for his stock, for his capital, and for the creditors if there are not accounts for them already. This having been done and the purchases and sales books brought into operation, the record of his transactions will proceed upon ordinary double-entry lines.

Hire - purchase Accounts. Many businesses are now conducted upon the instalment plan—*i.e.*, they sell their goods upon the terms that they may be paid for by the purchasers gradually by periodical payments. When this is the case, the price at which the goods are sold is naturally higher than that at which they would have been sold for cash. This increased price is due to the fact that the seller does not receive the purchase price at once, but only a small portion of it, and he, therefore, charges interest on the part unpaid. It is this factor of interest that occasions the necessity of keeping the accounts of such businesses—known as *hire-purchase accounts*—on special lines.

Formal agreements are entered into when sales of this nature take place, and for the protection of the seller they generally treat the transaction as one for the hire of the goods, which are to be made over to the hirer at the end of a stated period (provided the instalments are regularly paid), either without further payment or upon payment of a trifling amount. But, although the agreements usually treat the transaction as one of hire, it would not be correct for the seller to treat the periodical payments he receives as income which he is entitled to take to credit in full in his profit and loss account and yet at the same time treat the goods as his property, although in the hands of another. He must deal with the matter on the basis of a sale. But he must not take credit for the full amount charged to the purchaser, since that price includes interest which is only accruing due over a more or less lengthened period.

Manufacturer's Books. Business is conducted on these lines in connection with railway waggons, house furniture, pianofortes, cycles, etc., all over the kingdom, and it was principally in relation to railway waggons that accounts were first specially designed to meet the facts of this particular class of transaction. To take the case of the manufacturer first, it will be necessary for him to have his sales book ruled with two money columns—one for principal, the other for interest. When a sale is made on the hire-purchase system the manufacturer knows how much of the total price is for interest, and he enters the amounts in the two columns accordingly. The total price will be debited to the customer, the sales account will be credited with the amount of the principal or cash price, and the interest account with the balance.

The sold ledger will be ruled with two columns on each side—one for principal, the other for interest. A note will be made at the head of each customer's account as to the manner in which the price is to be paid. The debit to the customer will be divided into principal and interest, and the two amounts entered in the appropriate columns. As he pays the instalments cash will be debited and he will be credited with the full amount, the proportion attributable to principal being entered in the principal column and that to interest in the other column. The earlier instalments will, of course, include a greater proportion of interest than the later, owing to there being a large amount of principal outstanding upon which interest has to be charged.

When the manufacturer is making up his accounts at the close of a trading period, he must not take credit for the full amount of interest which has, during the period, been credited to the interest account, as sales were effected. Although interest has been charged to the hirers or purchasers it has not all been earned, and a rebate, or allowance, must therefore be made in respect of interest charged on the various purchasers' accounts, but which has not yet accrued due.

He should also make provision for the fact that if some of the goods were returned by the purchasers they would probably not be worth the amount at which they stand to the debit of the various customers' accounts. In some businesses this might not be so after a few payments had been made, but the manufacturer must, after taking all the circumstances into consideration, make such allowance as is in his opinion sufficient under this head. In order that the student may follow the working of this system the specimen of a customer's account in a manufacturer's ledger is given on the next page.

Hirer's Books. The matter has now to be considered from the view of the hirer or purchaser. When the agreement is entered into he does not credit the manufacturer with the full amount of the purchase price, as the latter becomes a creditor only when the instalments fall due. The method adopted, therefore, is to

debit an account opened for the article purchased—waggons, furniture, or as the case may be, with each instalment as it becomes due, and credit the manufacturer. When the instalment is paid the manufacturer is debited and cash credited. The result is that, provided the instalments are paid promptly, there is no balance on the manufacturer's account, as the credit of the instalment is immediately extinguished by the debit of cash. As the price of the goods, as we have seen, includes a considerable sum for interest, care must be taken to ensure that the articles purchased are included in the annual balance-sheet at not more than their actual value. This value will be the portion of the price which has been paid in respect of the principal amount due, irrespective of interest.

The purchaser must ascertain how much of the price payable under the agreement is for interest. He can generally obtain the information from the manufacturer, or can arrive at it by finding out the cash price as compared with that which he is paying. The difference will, of course, be interest, of which, as already stated, the larger proportion will fall against the earlier years. At balancing time an adjustment must be made by debiting the interest apportionable to the year to the profit and loss account and crediting the account of the articles purchased, which will thus stand at their cash price in the books.

Depreciation. In addition, provision must be made for the depreciation of the articles, and the allowance calculated, not upon the portion of the price actually paid, but upon the full cash price. This depreciation is put through the books in the ordinary way by debiting depreciation account and crediting the asset account with the amount written off. The net result of these entries will be that the asset will stand in the books at the end of the period over which the payments have been spread at its actual value to its owner.

This method of dealing with articles bought on the hire-purchase system is obviously only necessary in the case of a trader who has made a purchase of considerable value by these means. The ordinary man who has bought a cycle or pianoforte by instalments does not keep an account at all, but it is of the utmost importance in the case of an hotel-keeper who has purchased a large quantity of furniture on the system, or a colliery proprietor who has bought a number of waggons. Unless both these individuals take steps to show the articles they have purchased at their cash value only they will be overstating their profits, since they will not be debiting the profit and loss account with the interest on what is in effect borrowed money for the purchase of the articles.

ROYALTIES

A *royalty* is an amount paid by a person for the right to use the property of another. Thus the lessee of a mine pays a royalty to the owners of the land on which the mine is situated; a theatrical manager pays a royalty to a dramatic author for the right to produce his play; a manufacturer to a patentee for the right to use his patent, and so on. The amount paid in respect of the royalty depends upon the extent of the use which is enjoyed by the lessee or concessionaire in each case. A rate is usually fixed per unit. In the case of a colliery it is either upon the tonnage output or the superficial or cubic area worked. In the case of a patent it will depend upon the number of articles produced, in the manufacture of which the patent has been used; and in the case of a play, it depends upon the number of performances.

It will be seen, therefore, that the amount paid in respect of a royalty is as much an expense of the particular business paying it as the rent, salaries, and other working expenses. It must be treated in the same way as the other expenses and debited to the profit and loss account. As the amount depends upon the extent of the user, a careful record must be kept, which must be available for inspection by the owner of the property, showing the output or production as the case may be. The form which the record will take must depend upon the nature of the property for the use of which the royalty is paid. In the case of a colliery, if the royalty is upon tonnage, the amount recorded in the pit books and agreed by the workmen's check weigher will be accepted by the landlord; while if it is upon area it will be fixed by survey. In most cases, when once the amount payable has been agreed, the entries to be made in the books of the business having the use of the property are simply a debit to the profit and loss account under the head of royalties, and a credit to the owner. When he is paid he is debited and cash credited, and this will close the matter until the next periodical payment becomes due.

Mining Royalties. But in the case of a colliery a slight complication frequently arises. The form which the concession usually takes is a lease of the land for the purpose of working the mining rights subject to the payment of a minimum annual sum. An amount of royalty is also fixed, which we will assume is payable upon the amount of coal raised. The fixed minimum is usually known as *dead rent*. If it exceeds the royalty upon the coal raised in a particular year, then nothing beyond the dead rent is payable; but if, on the contrary, the royalty exceeds the dead rent, the latter becomes merged in the royalty and only the royalty on the tonnage is paid.

Redeemable Dead Rents. There is often a further provision in the lease that payments of dead rents in excess of royalties may be recovered by deduction from future royalties when these exceed the dead rent in a particular year. But the operation of this right is usually limited as to the time within which it may be exercised. The time limit is frequently five years. Thus, unless by the end of the fifth year the royalties exceed the dead rents, any excess dead rent on the first year will become irrecoverable, while if that state of things continued for another year, the excess on the second year would be lost to the lessee. So long as the right of recovery exists, the excess of dead rent paid is carried forward as an asset, the only charge to the profit and loss account in respect of the sum payable under the lease being the royalty on the coal actually raised. But so soon as the period has gone by within which it could have been deducted from excess royalties, it must be written off to profit and loss.

The working of the following example will show the student how the redeemable dead rent and the royalty accounts are dealt with in the books of the person working the colliery: A lease of a colliery is granted at a minimum dead rent of £600 per annum, merging into a royalty of 1s. per ton, with a right to recover dead rents out of royalties paid within five years. The quantity of coal raised was 800 tons the first year, 4,600 tons the second year, and 75,000 tons the third year.

It will be observed that the amount received by the landlord for the three years—*viz*, £4,020—is the amount of the royalty on actual output.

Investigation and Audit. Our method in dealing with the subject has necessarily been to describe the process of recording transactions of different kinds in the books of an undertaking. The organisation of accounts on such a basis as to facilitate the keeping of the financial records of the business, and to give the proprietor of the concern the information he requires in the best possible way, is an important branch of the accountant's profession, but one not less so is that dealing with the investigation of accounts, including their audit. The business man is well advised who leaves investigation and audit to a skilled accountant, for no man who has not been specially trained to the work can be regarded as a reliable investigator and auditor of accounts. There are two societies of professional accountants in England and Wales—*viz.*, the Institute of Chartered Accountants, which confines its operations to the countries named, and the Society of Accountants and Auditors, which has branches in other parts of the world. The members of the former body

are known as chartered accountants, those of the latter as incorporated accountants. The chartered institute dates from 1880, the incorporated society from 1885, and both have large memberships. It will be seen from the dates mentioned that, as compared with medicine and the law, the organisation of the profession of accountancy is comparatively young; but it should be mentioned that societies of earlier foundation were merged in the institute on its formation, and, of course, the practice of accounting in a more or less primitive state dates back to the early ages. There are accountants' societies in Scotland and Ireland, the former being older than the English bodies.

Professional Accountants. The conditions for admission to membership of the various societies are practically the same, the principle rule being that intending members must serve five years' articles of apprenticeship to a practising member. During the period under articles the would-be accountant is learning his business in its various aspects, a considerable portion of his time in the earlier years being occupied in acting as junior clerk on audits. In the later years he is, naturally, doing more important work, and gradually acquiring a knowledge of the different branches of his profession. He is required to pass a preliminary examination before admission to articles, and during his service he has to pass an intermediate examination. At the expiration of his articles he presents himself for his final examination, and if he satisfies the examiners is admitted to full membership of his society. The subjects of examination are, of course, those of which a knowledge is required by the accountant in his profession. They are set out in full on pages 148 and 149.

The proper training and examination of a body of men capable of investigating the financial books of a concern, with a view to ascertaining the accuracy or otherwise of the records in them, is a work of immense value to the commercial community generally, having regard to the dependence which has to be placed upon such records.

Merchants and others are not slow to avail themselves of the opportunity afforded them of checking the work of their employees by means of the audit of their accounts conducted by a professional accountant.

The class of work upon which incorporated and chartered accountants are largely employed is the audit of the accounts of private concerns and limited companies. The reason of the non-discovery of many of the frauds which have been exposed of recent years, particularly in connection with the accounts of Friendly Societies, has been the failure to employ professional men as auditors. Reliance has, instead, been placed upon the well-meant but quite incompetent examination of the accounts conducted by men who, in some cases, were quite ignorant of the first principles of bookkeeping. This condition of things still exists to a large extent, although matters are improving.

From what has been said, it will be apparent that, although certain principles and rules might be laid down in connection with the investigation of accounts for the guidance of the ordinary business man who wishes to know that his bookkeeping arrangements are satisfactory, or for the young clerk who desires to be more than a recording machine, it is not possible to give in the shape of an article the knowledge that is required to make the practical auditor and complete accountant. Something can be done in that direction, but the only satisfactory course for the beginner is to enter the office of a chartered or incorporated accountant, and go through the whole routine necessary to fully qualify himself; while for the business man engaged in his own affairs all the year round the only safe course is to employ a properly qualified accountant to safeguard his interests by auditing his books periodically.

Work of a Professional Accountant. Professional accountants, in addition to their work as auditors, are largely engaged in examining into and reporting upon the accounts of businesses which it is proposed to convert into limited companies. This function, to which reference was made in the article on company work, is of the utmost importance, as the public probably place more reliance upon the certificate of the accountant as to the past working of the concern than upon any other statement in a prospectus. They are further extensively employed as trustees in bankruptcies and under deeds of arrangement, as liquidators in the winding up of companies, and as receivers of properties on behalf of mortgagees and debenture holders. In any of these capacities they may be required to carry on a business for a more or less extended period, or their duties may be confined to the realisation of the property to the best advantage, and the distribution of the proceeds amongst the persons entitled.

From this brief summary of some of the more important duties of the professional accountant the reader will see that a training in the office of an incorporated or a chartered accountant with a varied practice affords a splendid opportunity of becoming familiar with the working of all kinds of businesses. This fact is of considerable value, for many young accountants, after serving their articles, seek positions as secretaries, managers and accountants of important companies and public bodies, and their prospects of success are greatly enhanced if they hold the diploma of one of the recognised societies.

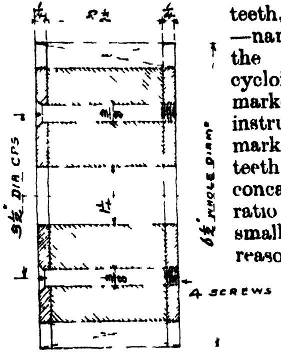
TECHNICAL DRAWING

continued from page 3880

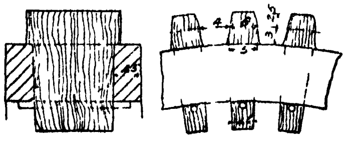
By JOSEPH W. HORNER

Raw-hide Gears. Pinions which run at high speeds, such as those on electric motor spindles, are frequently made of raw hide. Discs of ox hide are cemented together in layers under pressure in order to form the rough blank, which is then machined all over to finished sizes; side plates—usually of gunmetal—are fitted as shown in section **104**, and the teeth are cut through the hide and through the metal plates. Sometimes one of the side plates has cast with it a bush, which passes through the pinion and forms a stronger driving medium for the key than can be afforded by the hide and plates alone. Wheels have been made of raw hide up to 3 ft. diameter, the rim being of hide and the arms and boss of cast iron. Such wheels are, however, unusual, it being the more common practice to make pinions only of hide and the wheels with which they gear of metal. The object in using raw hide is to ensure noiseless running.

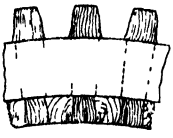


104. RAW-HIDE PINION

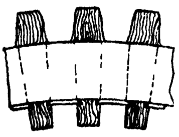
Mortise Teeth. Another and an older device to ensure a quiet running gear is to make the wheel teeth of wood; such teeth are termed *cogs*, are made separately by hand labour, and are fitted into slots cast in the wheel rim. Fig. **105** shows a good method of securing the teeth as well as the proportions for tooth and wheel rim; the figures given are to be multiplied by the circular pitch in order to obtain actual dimensions. Mortise wheels are used in flour mills, cotton mills, etc. The cogs are made of well-seasoned oak, acacia, hornbeam, or apple-tree, and the grain must run in a radial sense as shown in the illustration [**105**]. Instead of holding the teeth by means of pins, wooden wedges, as **106**, or steel plates, as **107**, may be used, and pins are used where the arms occur, as in **108**. This class of gear is expensive, and is gradually falling into disfavour.



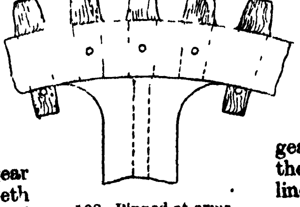
105. Pinned



106. Wedged



107. Plated



108. Pinned at arms

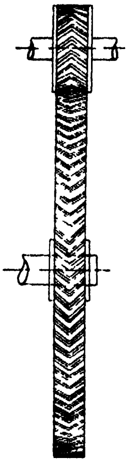
105-8. MORTISE TEETH

Helical Teeth. A quiet gear drive is obtained by making the teeth short lengths of a right and left hand screw or helix, as shown in **109**; the theory of construction is based upon an almost obsolete form of gear termed *stepped gear*, where the width of the teeth is divided into a number of equal parts and each part is moved slightly in advance of its fellow. The merging of these steps into a straight line gives a helical curve to the tooth; it is necessary to make it right and left, or *double helical*, as it is termed, in order to avoid end thrust on the shafts. These gears are usually cast, but can be machine-cut. They are used largely for rolling-mill engines where reversal under load occurs. The usual angle for the teeth is 30 deg. measured from a horizontal line parallel with the shaft.

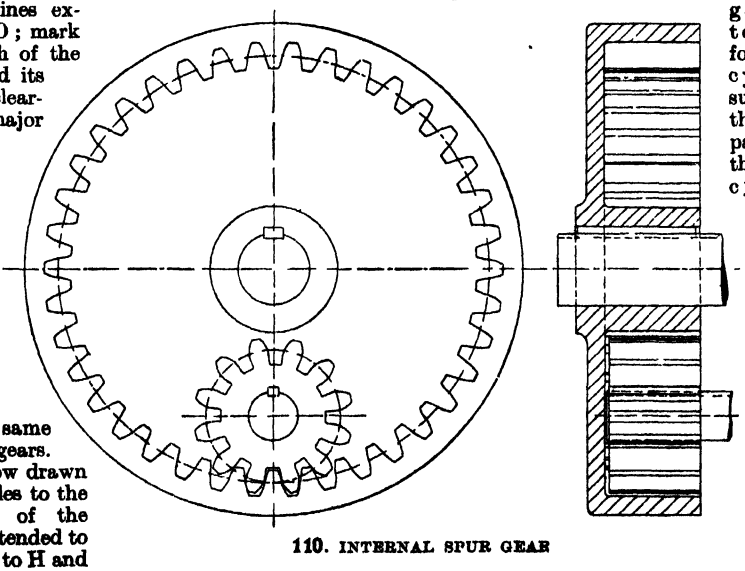
Internal Gears. These gears are made by forming the teeth upon the inside of the wheel rim as indicated in **110**. The principle of tooth formation is the same as for outside teeth, but the spaces become the teeth—namely, the tooth curve is reversed; the odontograph can be used for cycloidal teeth, but the face curve is marked from the flank data on the instrument, while the flank curve is marked from the face data. If involute teeth be struck, then the curve becomes concave instead of convex. When the ratio of wheel and pinion becomes very small, difficulties are encountered by reason of the teeth fouling each other. Normally, there should be at least a difference of 15 teeth between wheel and pinion. Internal gears are used on lathe headstocks, revolving gears on cranes, and so forth, or in cases in which both driving and driven shaft must rotate in the same direction.

Rack. A rack is a straight line of teeth as **111**. It is used to produce rectilinear motion from rotary motion, or vice versâ; it is applied to the tables of planing machines, the operation of sluice-doors, and so forth. The teeth may be marked out with the odontograph for cycloidal curves. If a rack be required to gear with an involute pinion, then the face and flank become a straight line drawn at right angles to the angle of obliquity, as in **111**. A rack is in effect part of a circle of infinite diameter; the circumference of a circle approaches a straight line as the diameter increases, and when the diameter is infinite any part of the circumference is a straight line. Cycloidal curves are formed by the rolling of generating circles upon a straight line as well as upon a curved line, but an involute struck from a straight line becomes a straight line.

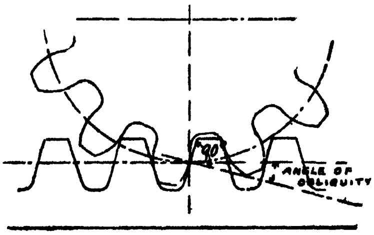
Bevel Gears. We have hitherto only dealt with gears having their teeth formed upon parallel surfaces; bevel gears have their teeth formed upon conical surfaces, and are used for connecting shafts which are not parallel. Fig. 112 gives three views of a pair of conical cylinders in contact, having their axes at right angles and intersecting at O; considering the lines of contact A, B, and C as pitch lines, ordinary cycloidal or involute teeth may be formed upon them; the pitch circle, the pitch, and the section of tooth are reduced from the "major" diameter D to the "minor" diameter E, following radial lines to O. A section of a pair of bevels is given in 113, together with the method of marking out the teeth at the major and minor diameters. Draw the axes or shaft centre lines, O A and O B, intersecting at O, then the major diameters C and D, then the pitch lines extending to O; mark off the width of the tooth E, and its depth and clearance; the major diameter is counted as the true pitch diameter, and the ordinary proportions of teeth, etc., apply there; the width of the tooth may be taken as the same as in spur gears. Lines are now drawn at right angles to the pitch lines of the teeth and extended to F and G and to H and J; arcs are then struck from F and G, the outer arc in each case being the developed pitch circle at the major diameter, and upon which the teeth are marked out as in spur gears, the inner arc being the developed pitch circle at the minor diameter. The radius of the inner arc for the bevel wheel is taken from H K, and is transferred to F L; radial lines are then drawn from the outer arc to centre, F, and upon these lines the pitch and the tooth section diminish regularly. The corresponding depth of tooth is taken by compasses from the minor diameter in the sectional view. The development of the teeth on the inner arc of the pinion is dealt with in the same manner as for the wheel.



109. HELICAL-TOOTHED SPUR GEAR



110. INTERNAL SPUR GEAR

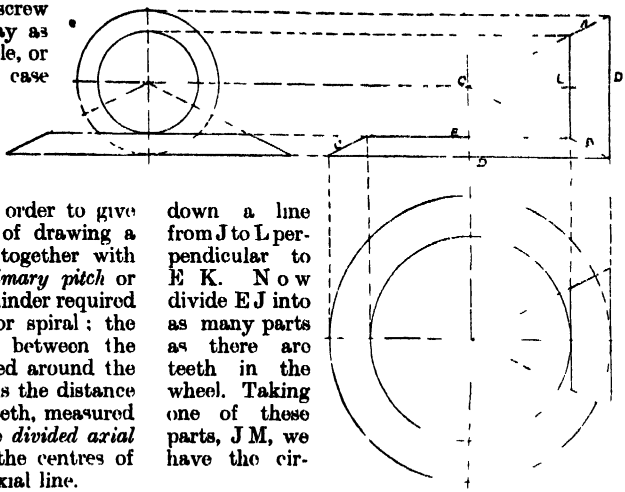


111. RACK AND PINION

When bevel gears are made with equal diameter wheels they are termed *mitre gears* from the fact that the pitch lines make an angle of 45 deg. with the axes of the shafts. Bevel gears may be made with axes at other than right angles; if the angle be greater than 90 deg. they are frequently termed *angle spur gears*.

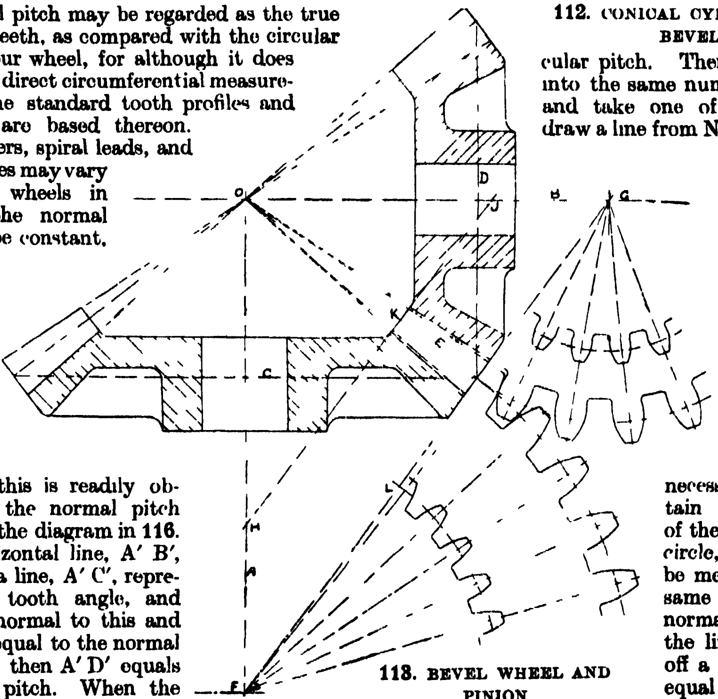
The thickness of the rims of bevel gears is made about ·56 of the pitch at the major diameter and decreases radially to the minor diameter. The arms are usually made T section, as in 114, and to the proportions given for cross arms for spur wheels. The strength of a bevel tooth is calculated at the mean pitch. Bevel gears may be half shrouded or fully shrouded, and they may be made with helical teeth or with mortise teeth or of rawhide.

Screw Gears. When the axes of wheels gearing together are not in the same plane, recourse is had to *screw* or *spiral* gears. The teeth are formed upon cylindrical surfaces, but they are not parallel with the axes of the cylinders; each tooth is a portion of a spiral thread or helix. A screw wheel may have any number of such teeth from one upwards; a one-toothed screw wheel is termed a *worm*, and corresponds to a single-thread screw; a many-toothed wheel corresponds to a multiple-thread screw. The section of these screw threads is a standard tooth form, generally the involute. Fig. 115 shows a pair of screw wheels gearing together, their axis being at right angles. The screw threads on both wheels are the same hand; the number of teeth is counted as the number of screw threads involved, in the same way as we would speak of a double, triple, or quadruple thread screw. In the case illustrated there are 12 threads, or teeth, in each wheel; they will, therefore, transmit motion at equal velocities. But such gears can be made with different diameters and numbers of teeth, in order to give different velocities. The method of drawing a screw wheel is shown in **116**, together with explanatory projections. The *primary pitch* or *lead of spiral*, A, is the length of cylinder required to complete a turn of the screw or spiral; the *circular pitch*, B, is the distance between the centres of adjacent teeth measured around the circumference; the *normal pitch* is the distance between the centres of adjacent teeth, measured at right angles to the spiral; the *divided axial pitch*, C, is the distance between the centres of adjacent teeth measured on the axial line.



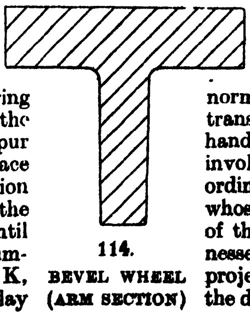
112. CONICAL CYLINDERS FOR BEVELS

The normal pitch may be regarded as the true pitch of the teeth, as compared with the circular pitch of a spur wheel, for although it does not represent direct circumferential measurement, yet the standard tooth profiles and proportions are based thereon. Pitch diameters, spiral leads, and circular pitches may vary in any two wheels in gear, but the normal pitch must be constant, otherwise they will not work together. In order to set out a screw wheel it is convenient to start with the circular pitch, and this is readily obtained from the normal pitch by means of the diagram in **116**. Draw a horizontal line, A′ B′, and extend a line, A′ C′, representing the tooth angle, and draw a line normal to this and of a length equal to the normal pitch, D′ E′; then A′ D′ equals the circular pitch. When the axes of the shafts intersect at right angles, as in **115**, it is essential that the sum of the respective tooth angles be 90 deg., and it is, of course, convenient to make each one 45 deg.

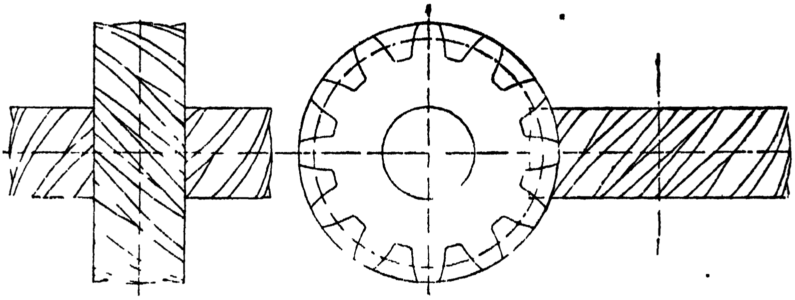


113. BEVEL WHEEL AND PINION

Delineating the Spiral. Having obtained the circular pitch, calculate the pitch diameter, as in the case of spur gears, and draw the pitch circle, D in face elevation [**116**], and also in side elevation E F G H, which latter may be termed the *pitch cylinder*. Unroll this cylinder until the length, E J, represents its circumference, and then draw the diagonal, E K, which is the developed spiral, and lay down a line from J to L perpendicular to E K. Now divide E J into as many parts as there are teeth in the wheel. Taking one of these parts, J M, we have the circular pitch. Then divide J K into the same number of parts and take one of them, J N; draw a line from N to M, cutting J L at O, and then J O is the normal pitch, and J N is the divided axial pitch. The next step is to develop the end elevation of the teeth in order to draw the face view. To do this it is first necessary to ascertain the diameter of the normal pitch circle, and this must be measured in the same plane as the normal pitch. Upon the line E J, mark off a distance, E P, equal to the radius of the pitch cylinder, and draw a horizontal line, P R, cutting E K at R; then lay down a line, R G, perpendicular to E K, and E G is the radius of the normal pitch circle. To develop the teeth, transfer the radius, E G, to the lower left hand view [**116**], and upon it mark out involute teeth of the pitch required, as in ordinary spur gears. Selecting a tooth whose centre line coincides with the angle of the spiral, we project its various thicknesses upon a vertical line, S T, and reproject them upon a horizontal line, U V, the depth of the tooth remaining the same



114. BEVEL WHEEL (ARM SECTION)



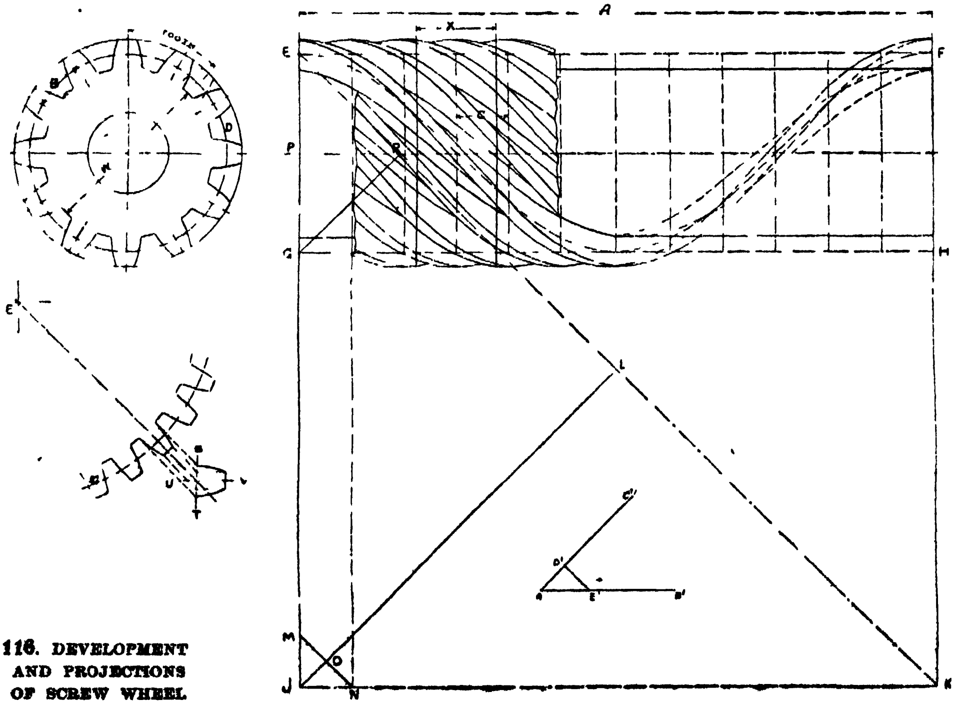
115. SCREW GEARS

in each case. We may now transfer the tooth developed on line U V to the face elevation of the wheel. The teeth and the spaces look abnormally wide, but this is, of course, due to the fact that they are not perpendicular to the face of the wheel.

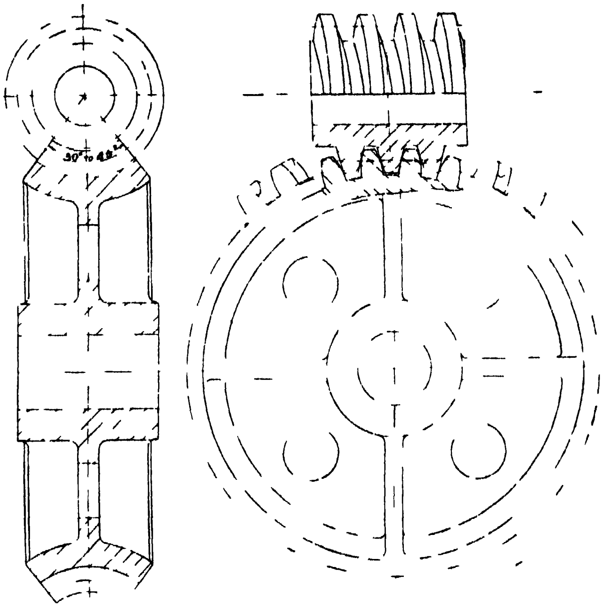
The pitch line is now projected upon the cylinder in the same manner as we projected the helix and the screw thread on page 3003. A tooth may be also projected in a similar way by considering it to be coiled on a cylinder of a diameter equal to that of the wheel measured under the teeth, as W. There is no necessity to draw the complete helix in actual practice, but it is shown so in 116 in order to present the principle in as clear a manner as possible. Further teeth may be drawn without the labour of projecting each one. Make a tracing of one half helix, and move it successively one axial pitch, pricking off the tooth points in turn; the tooth curves may then be drawn through the points so obtained. A slice may be taken from the cylinder of projected spirals, as X, and this slice is the screw wheel required. The width, X, should be sufficient to ensure at least one pair of teeth being well in contact before the next pair leave contact. This is attained if the width be made to contain a pitch and a half measured circumferentially, as shown in the face elevation.

Screw gears may be made with their axes at various angles, and with wheels of various diameters; the teeth of helical gears, as mentioned earlier in this lesson, are portions of similar spirals.

The Worm and Wheel. This is a true screw gear, with axes usually, though not necessarily, at right angles [117]. The worm may be single thread or multiple thread, the wheel containing many portions of internal threads, formed on an external surface. The sections of the threads are involute teeth, those of the worm having straight faces and flanks similar to a rack. The projection of the worm presents no difficulty, since it is a true spiral. The number of threads on the worm affects the speed of the worm wheel in direct ratio—that is to say, a single, double,



116. DEVELOPMENT AND PROJECTIONS OF SCREW WHEEL



117 WORM AND WORM WHEEL

or triple thread worm driving a wheel having, say, 33 teeth would have to make 33, 16½, and 11 revolutions respectively to each revolution of the wheel. Worm gears are generally used for the purpose of speed reduction on account of the great difference obtainable in a small space. Fig. **118** shows a typical example of a worm gear reduction in an oil tight case. The worm wheel itself has a phosphor bronze rim, out of which the teeth are cut, this rim being fitted tightly on to a cast iron centre, and secured thereon by means of four set screws, spaced circumferentially. The worm is of mild steel, triple thread, left hand; the wheel has 60 teeth. The worm shaft is coupled to an electric motor spindle running at 500 revolutions per minute, and the speed of the worm wheel shaft is therefore $\frac{500 \times 3}{60} = 25$ revolutions per minute. The casing is of cast iron, and has a circular bracket cast on as shown, in order to support it. This bracket may be arranged in any position desired to suit the application of the gear reduction—that is, it may be cast underneath or on one side, if necessary. The casing forms an oil bath for the gear to run in, and the worm should preferably be arranged underneath the wheel, so as to ensure plenty of oil getting at the working teeth. Ball bearings are fitted to the worm spindle to reduce the friction due to the end thrust of the worm, these bearings being carried in a gland shaped casting, which enables them to be removed bodily with the worm. It will be noticed that the worm is solid with the spindle, which is usual with small worms, as there would not be sufficient metal left under the threads if they were bored out for the reception of the spindle. A small oil bath is also arranged for the worm spindle, and an oiling ring rests on the spindle and dips into the oil; this is a common device adopted to secure the proper lubrication of high speed shafts in connection with motors and dynamos, etc.

The diameter of a worm is generally from three to five times the circular pitch, and the angle of engagement which determines the width of a worm wheel is usually 30 deg. to 45 deg., as indicated in **117**.

finirò	*finiremo*
finirai	*finirete*
finirà	*finiranno*

Future Perfect

I shall have finished, etc.	We shall have finished, etc.
avrò finito	*avremo finito*
avrai finito	*avrete finito*
avrà finito	*avranno finito*

IMPERATIVE MOOD

Present

Finish, etc.	Let us finish, etc.
—	*finiamo*
finisci	*finite*
finisca	*finìscano*

SUBJUNCTIVE MOOD

Present

That I finish, etc.	That we finish, etc.
finisca	*finiamo*
finisca	*finiate*
finisca	*finìscano*

Perfect

That I have finished, etc.	That we have finished, etc.
àbbia finito	*abbiamo finito*
àbbia finito	*abbiate finito*
àbbia finito	*àbbiano finito*

Imperfect

If I finished, etc.	If we finished, etc.
finissi	*finìssimo*
finissi	*finiste*
finisse	*finìssero*

Pluperfect

If I had finished, etc.	If we had finished, etc.
avessi finito	*avèssimo finito*
avessi finito	*aveste finito*
avesse finito	*avèssero finito*

CONDITIONAL MOOD

Present

I should finish, etc.	We should finish, etc.
finirei	*finiremmo*
finiresti	*finireste*
finirebbe	*finirèbbero*

Perfect

I should have finished, etc.	We should have finished, etc.
avrei finito	*avremmo finito*
avresti finito	*avreste finito*
avrebbe finito	*avrèbbero finito*

INFINITIVE MOOD

Present—finire, to finish
Perfect—aver finito, to have finished
Past Participle—finito, -*a*, -*i*, -*e*, finished

1. The majority of the verbs of the third conjugation are conjugated like *finire* (second class), as:

capire (*cahpeèreh*), to understand
asserire (*ahssehreè-reh*), to assert
ardire (*ahrdeè-reh*), to dare
contribuire (*contreeboo-eèreh*), to contribute
preferire (*prehfehreè-reh*) to prefer
proibire (*pro-eebeè-reh*), to prohibit, to forbid
punire (*pooneè-reh*), to punish
spedire (*speh-deèreh*), to forward, to dispatch
unire (*ooneè-reh*), to unite
differire (*deeffehreè-reh*), to differ, etc.

2. The following verbs are conjugated like *vestire* (first class).

avvertire (*ahvvehrteè-reh*), to advise
bollire (*bolleè-reh*), to boil
convertire (*convehrteè-reh*), to convert
divertire (*deevehrteè-reh*), to amuse
dormire (*dormeè-reh*), to sleep
fuggire (*foodgeè-reh*), to escape
invertire (*eenvehrteè-reh*), to invert
partire (*pahrteè-reh*), to start
seguire (*sehgueè-reh*), to follow
sentire (*sehnteè-reh*), to feel
servire (*sehrveè-reh*), to serve
tossire (*tosseè-reh*), *to cough*

3. The following verbs may be conjugated either with or without the addition of the syllable *isc* (third class):

aborrire (*ahborreè-reh*), to abhor
applaudire (*ahpplah-oodeè-reh*), to applaud
assorbire (*ahssorbeè-reh*), to absorb
inghiottire (*eenkee-òtteè-reh*), to swallow
languire (*lahngu-eèreh*), to languish
mentire (*mehnteè-reh*), to lie
nutrire (*nootreè-reh*), to feed
pervertire (*pehrvehrteè-reh*), to pervert

The verbs *partire* and *divertire* may also be conjugated like *finire*, but then assume a different meaning: *parto*, I start; *partisco*, I divide in parts, I portion out; *diverto*, I amuse; *divertisco*, I cause to diverge.

NOTE: Besides the verbs of the first and third classes mentioned above, there are only a few others, which will be given among the irregular verbs.

OBSERVATIONS.

1. By no means all the verbs of the third conjugation have a present participle (termination *-nte*). Some of the verbs having the present participle retain the characteristic vowel *i* before the termination, as: *nutriente*, *ubbidiente*. The present participle of *sentire* is *senziente*; of *patire*, *paziente*; of *venire*, *vegnente*. The verb *dormire* has *dormente* and *dormiente*; *morire*, *morente* and *moriente*.

2. In ordinary conversation, the third person singular, preceded by *si*, may be used instead of the first person plural, particularly in the Past Definite and in the Present Conditional, as: *noi si comandò* for *noi comandammo*; *noi si crederebbe* for *noi crederemmo*.

3. The first person singular of the Imperfect of the Indicative may also have a termination *va*, but the form in *vo* is more common.

CONVERSAZIONE.

Finalmente! Credevo che non venissi più. Son due ore che t'aspetto. Perchè così tardi?

Mi dispiace di èssere in ritardo, ma degli affari importanti mi hanno impedito di venir prima.

Ebbene (*well*), l'hai veduto? Gli hai parlato?

Gli ho parlato, ma ne so meno di prima. Egli non ha voluto dir tutto, ma pare che àbbia intenzione di seguire l'esèmpio del suo compagno e partire anche lui per l'Amèrica.

Credi che riuscirà a far niente?

Io non credo; Giorgio è un giòvane troppo leggiero; avrebbe bisogno di un amico sincero che lo guidasse, che gli desse dei consigli . . .

Gli scriverò io e lo pregherò di venire da me. Gli darò io dei consigli che accetterà di tutto cuore, vedrai.

Hai ragione; Giorgio in questo momento ha più bisogno di danari che di consigli.

EXERCISE XXIX.

1. Parlate più lentamente, per piacere, perchè non vi capisco. 2. Non lo chiamate ancòra, lasciate che finisca di scrìvere. 3. Fate silènzio, vi proibìsco di parlár male di un amico in mia presenza. 4. Quale preferite di questi due? 5. Preferisco il primo, perchè è più a buon mercato. 6. Se egli lo asserisce, vuol dire (it means) che è vero. 7. Quella pòvera bambina non fa che (*does nothing but*) tossire tutto il giorno. 8. Avete dormito bene questa notte? 9. Questo tè non è buono; vi avete versato l'acqua prima che bollisse. 10. Dite alla domèstica di vestire i ragazzi, perchè è ora di andare. 11. Se gli artisti canteranno bene, li applaudiremo. 12. È già la terza volta che mi domandate se è vero; vi avverto che io non mentisco mai. 13. Non dite questo, vi prego, perchè avete mentito tante volte, che non credo più a quello che dite. 14. Le uova e la carne sono molto nutrienti. 15. Non capisco perchè vogliate avèr sempre ragione voi.

KEY TO EXERCISE XXV.

1. We shall meet them. 2. They will give us. 3. They sent (to) him. 4. What did he tell you? 5. What did you answer him? 6. Where are the flowers that we have gathered? 7. I have put them in water. 8. As soon as I see him I will speak to him of you. 9. I have seen him from the window, and I have called loudly to him twice, but he has not heard me. 10. Mary told us that she would have gone to Italy this year. 11. They have bought heaps of books; they have read them and re-read them, but I am sure that they have not understood anything in them.

KEY TO EXERCISE XXVI.

1. How much did you pay for those gloves? 2. I have paid rather dearly for them, but they are of an excellent quality. 3. Did you find them at home? 4. Her, yes; but not him. 5. When will you give me what you have so many times promised me? 6. If you give me some toys I will be good. 7. Have you any more writing paper? I wish to write to my bookseller to send me the books that I have ordered of him. 8. I am sorry; I have no more. I have given you all the paper that I had left. 9. No matter; I will write to him later.

KEY TO EXERCISE XXVII.

1. We shall receive. 2. Have you drunk? 3. If we lost. 4. They feared. 5. They would not have believed. 6. Would you have sold? 7. We would sell. 8. We sold. 9. Has he received? 10. I have not yet received, but I shall receive. 11. He is always without money, yet he always receives some. 12. How much do you think he has received lately? 13. He

received five hundred francs last week, but he will receive as many to-morrow. 14. We sold our garden, and shall also sell our house. 15. I cannot believe that he has not received our invitation. 16. Let us go, if not we shall lose our time uselessly. 17. If we are not careful, I fear that we shall lose what we have already gained. 18. The leaves begin to fall. 19. Those brave men all fought to the death.

KEY TO EXERCISE XXVIII.

1. We shall start. 2. If we had started. 3. Do not open. 4. Listen. 5. If they had followed. 6. They would suffer. 7. That poor woman suffered so much when her son left! 8. If the shopmen served us badly, we should have a right to take our custom elsewhere. 9. Open the window, it is too hot. 10. I would leave to-morrow if I had finished my business. 11. These children sleep too much. 12. As soon as they saw the danger, they all ran away and left him alone. 13. How many times have we heard them say that they were tired of studying! 14. Come with me. 15. Shun bad company, and follow the example of good men.

VERBS—continued

Third Conjugation

Recevoir, to receive. Principal Parts: *recevoir, recevant, reçu, je reçois, je reçus.*

INDICATIVE

SIMPLE TENSES	COMPOUND TENSES
Present	*Past Indefinite*
I receive, am receiving, etc.	I have received, etc.
je reçois	*j'ai reçu*
tu reçois	*tu as reçu*
il, elle reçoit	*il, elle a reçu*
nous recevons	*nous avons reçu*
vous recevez	*vous avez reçu*
ils, elles reçoivent	*ils, elles ont reçu*
Imperfect	*Pluperfect*
I was receiving, used to receive, etc.	I had received, etc.
je recevais	*j'avais reçu*
tu recevais	*tu avais reçu*
il, elle recevait	*il, elle avait reçu*
nous recevions	*nous avions reçu*
vous receviez	*vous aviez reçu*
ils, elles recevaient	*ils, elles avaient reçu*
Past Definite	*Past Anterior*
I received, etc.	I had received, etc.
je reçus	*j'eus reçu*
tu reçus	*tu eus reçu*
il, elle reçut	*il, elle eut reçu*
nous reçûmes	*nous eûmes reçu*
vous reçûtes	*vous eûtes reçu*
ils, elles reçurent	*ils, elles eurent reçu*
Future	*Future Anterior*
I shall receive, etc.	I shall have received, etc.
je recevrai	*j'aurai reçu*
tu recevras	*tu auras reçu*
il, elle recevra	*il, elle aura reçu*
nous recevrons	*nous aurons reçu*
vous recevrez	*vous aurez reçu*
ils, elles recevront	*ils, elles auront reçu*

CONDITIONAL

Present	*Past*
I would receive, etc.	I would have received
je recevrais	*j'aurais reçu*
tu recevrais	*tu aurais reçu*
il, elle recevrait	*il, elle aurait reçu*
nous recevrions	*nous aurions reçu*
vous recevriez	*vous auriez reçu*
ils, elles recevraient	*ils, elles auraient reçu*

IMPERATIVE

Present

reçois, receive (thou)
qu'il reçoive, let him receive
qu'elle reçoive, let her receive
recevons, let us receive
recevez, receive (ye)
qu'ils reçoivent, let them (m.) receive
qu'elles reçoivent, let them (f.) receive

SUBJUNCTIVE

Present	*Past*
That I may receive, etc.	That I may have received, etc.
que je reçoive	*que j'aie reçu*
que tu reçoives	*que tu aies reçu*
qu'il, qu'elle reçoive	*qu'il, qu'elle ait reçu*
que nous recevions	*que nous ayons reçu*
que vous receviez	*que vous ayez reçu*
qu'ils, qu'elles reçoivent	*qu'ils, qu'elles aient reçu*
Imperfect	*Pluperfect*
That I might receive, etc.	That I might have received, etc.
que je reçusse	*que j'eusse reçu*
que tu reçusses	*que tu eusses reçu*
qu'il, qu'elle reçût	*qu'il, qu'elle eût reçu*
que nous reçussions	*que nous eussions reçu*
que vous reçussiez	*que vous eussiez reçu*
qu'ils, qu'elles reçussent	*qu'ils, qu'elles eussent reçu*

INFINITIVE

Present	*Past*
recevoir, to receive	*avoir reçu*, to have received

PARTICIPLE

Present	*Past*
recevant, receiving	*reçu, e*, received *ayant reçu*, having received

The so-called regular third conjugation consists of only seven verbs. With the exception of *devoir*, to owe, and its derivative *redevoir*, still to owe, all the third conjugation verbs belong to the same group. They are: *apercevoir*, to perceive; *concevoir*, to conceive; *décevoir*, to deceive; and *percevoir*, to perceive (receive impressions), and also to levy taxes.

It is to be noted that in these verbs the *c* takes a cedilla (*ç*) when it occurs before *o* or *u*. This is for the purpose of retaining the soft sound of *c* throughout the whole verb.

In *devoir*, the letter *d* takes the place of the *rec* of *recevoir*. Consequently, its principal parts are: *devoir*, *devant*, *dû*, *je dois*, *je dus*. The masculine form of the past participle takes a circumflex accent; the feminine form does not: *dû*, *due*; neither does the plural, *dus*.

Idiomatic Meanings of Devoir.

1. When *devoir* is used in the present, or the imperfect of the indicative, and followed by another verb in the infinitive, it is equivalent to the English "I am to," "I was to," "I have to." Examples: *Je dois prochainement recevoir de l'argent*, I am to receive some money shortly; *il doit y avoir demain une assemblée des actionnaires*, There is to be a meeting of the shareholders to-morrow; *Je dois aller demain à la campagne*, I have to go to the country to-morrow.

2. In the present indicative it sometimes expresses what is held to be a certainty, and is then to be translated by "must": *S'il a fait vingt milles, il doit être bien fatigué*, If he has walked (lit., done) twenty miles, he must be very tired.

3. In the same tense it may also express moral obligation. Example: *Un bon fils doit respecter son père*, A good son should respect his father.

4. In the present conditional (*je devrais*, etc.), *devoir* is to be translated by "ought"; and in the past conditional (*j'aurais dû*, etc.), by "ought to have." Example: *Vous devriez lui payer d'abord ce que vous lui devez*, You ought first of all to pay him what you owe him; *Vous n'auriez pas dû lui dire cela*, You ought not to have told him that.

5. In the past indefinite, and occasionally in the past definite and pluperfect (*J'ai dû*, *je dus*, *j'avais dû*), *devoir* implies obligation; *Jai dû lui donner quelque chose pour m'en débarrasser*, I had to give him something to get rid of him.

6. It is to be carefully noted that, in all these constructions, the verb following *devoir* is in the present infinitive.

EXERCISE XXVII.

1. We receive two papers every day.
2. She receives her friends on Thursdays (*le jeudi*).
3. We perceived a little white house at the foot of the hill.
4. Have you not yet received any reply (*réponse*, f.) to your letter?
5. It is easy to express (*énoncer*) clearly (*clairement*) what one conceives properly (*bien*).
6. When you receive this letter I shall no longer be in England.
7. About ten o'clock in the morning we perceived the hostile (*ennemi*) army in the distance (*lointain*, m.).
8. He owes his tailor fifty francs.
9. If you owe him so much, do you owe me nothing?
10. You ought to plant some trees along (*le long de*) that avenue (*allée*, f.).
11. When is there to be a meeting of the shareholders?
12. If good faith (*foi*, f.) were exiled from the rest of the earth, it ought to be found again (*se retrouver*) in the heart of kings.
13. You ought first of all to pay me what you owe me.
14. She must have been greatly astonished at (*de*) seeing you.
15. You ought to have returned (*rendre*) him the money which he has lent you.
16. If you have eaten nothing since this morning, you must be very hungry.
17. What time is it? It must be at least (*au moins*) half-past four.
18. I have received an invitation, but I have had to refuse it.

Fourth Conjugation

Vendre, to sell. Principal Parts: *vendre*, *vendant*, *vendu*, *je vends*, *je vendis*.

INDICATIVE

SIMPLE TENSES	COMPOUND TENSES
Present	*Past Indefinite*
I sell, am selling, etc	I have sold, etc.
je vends	*j'ai vendu*
tu vends	*tu as vendu*
il, elle vend	*il, elle a vendu*
nous vendons	*nous avons vendu*
vous vendez	*vous avez vendu*
ils, elles vendent	*ils, elles ont vendu*
Imperfect	*Pluperfect*
I was selling, used to sell, etc.	I had sold, etc.
je vendais	*j'avais vendu*
tu vendais	*tu avais vendu*
il, elle vendait	*il, elle avait vendu*
nous vendions	*nous avions vendu*
vous vendiez	*vous aviez vendu*
ils, elles vendaient	*ils, elles avaient vendu*
Past Definite	*Past Anterior*
I sold, etc.	I had sold, etc.
je vendis	*j'eus vendu*
tu vendis	*tu eus vendu*
il, elle vendit	*il, elle eut vendu*
nous vendîmes	*nous eûmes vendu*
vous vendîtes	*vous eûtes vendu*
ils, elles vendirent	*ils, elles eurent vendu*
Future	*Future Anterior*
I shall sell, etc.	I shall have sold, etc.
je vendrai	*j'aurai vendu*
tu vendras	*tu auras vendu*
il, elle vendra	*il, elle aura vendu*
nous vendrons	*nous aurons vendu*
vous vendrez	*vous aurez vendu*
ils, elles vendront	*ils, elles auront vendu*

CONDITIONAL

Present	*Past*
I would sell, etc.	I would have sold, etc.
je vendrais	*j'aurais vendu*
tu vendrais	*tu aurais vendu*
il, elle vendrait	*il, elle aurait vendu*

nous vendrions	*nous aurions vendu*
vous vendriez	*vous auriez vendu*
ils, elles vendraient	*ils, elles auraient vendu*

IMPERATIVE

Present

vends, sell (thou).
qu'il vende, let him sell
qu'elle vende, let her sell
vendons, let us sell
vendez, sell (ye)
qu'ils, qu'elles vendent, let them sell

SUBJUNCTIVE

Present	*Past*
That I may sell, etc.	That I may have sold, etc.
que je vende	*que j'aie vendu*
que tu vendes	*que tu aies vendu*
qu'il, qu'elle vende	*qu'il, qu'elle ait vendu*
que nous vendions	*que nous ayons vendu*
que vous vendiez	*que vous ayez vendu*
qu'ils, qu'elles vendent	*qu'ils, qu'elles aient vendu*

Imperfect	*Pluperfect*
That I might sell.	That I might have sold.
que je vendisse	*que j'eusse vendu*
que tu vendisses	*que tu eusses vendu*
qu'il, qu'elle vendît	*qu'il, qu'elle eût vendu*
que nous vendissions	*que nous eussions vendu*
que vous vendissiez	*que vous eussiez vendu*
qu'ils, qu'elles vendissent	*qu'ils, qu'elles eussent vendu*

INFINITIVE

Present	*Past*
vendre, to sell	*avoir vendu*, to have sold

PARTICIPLE

Present	*Past*
vendant, selling	*vendu, e*, sold
	ayant vendu, having sold

The stem of all regular verbs of the fourth conjugation, except *rompre*, to break, and its derivatives ends in *d*. In consequence of this these verbs do not take the *t*, which is the final letter of the third person singular of the present of the indicative: *il vend*. The *t* reappears in *rompre*: *il rompt*.

The fourth conjugation verbs used in the following exercise are:

attendre, to wait for
descendre, to come down, fall
entendre, to hear, understand
étendre, to stretch
fondre, to melt
mordre, to bite
perdre, to lose
rendre, to return, render, yield
répondre, to answer
rompre, to break, burst
tondre, to shear
vendre, to sell

EXERCISE XXVIII.

1. Do you hear what I tell you ?

2. Do not be afraid of the dog, it will not bite you.

3. You are always losing something.

4. Why have you not answered (to) his letter ?

5. We heard some noise (*bruit*, m.), upstairs (*en haut*).

6. Let them wait for us now, we have waited long enough for them.

7. Wait for them ; they are not ready (*prêt*) yet.

8. Do not lose so much time in (*à*) chattering (*bavarder*).

9. The enemy (pl.), coming down from their mountains, pillaged (*piller*) the whole district (*contrée*).

10 Those houses will be sold by auction (*aux enchères*) at eleven o'clock precisely.

11. I closed my eyes and I heard a frightful (*épouvantable*) din (*fracas*, m.).

12 You will lose nothing by (*pour*) waiting.

13. The discovery of America has greatly extended European commerce.

14. The Lord stretched out His hand over the sea, He shook (*ébranler*) the kingdoms.

15. The thermometer (*thermomètre*, m.) has fallen (*de*) four degrees since yesterday.

16. The young man thanked us without embarrassment for the service which we were rendering him.

17. Render unto Cæsar (*César*) that which belongs to Cæsar, and render unto God that which belongs to God.

18. The blows (*coup*, m.) which we feel (*sentons*) most are those which we can (*pouvons*) not return.

19. Some grains (*grain*, m.) yield a hundredfold (hundred for one), others sixty, and others thirty.

20. Samson broke his ropes (*corde*, f.) as one would break a thread (*fil*, m.).

21. To (the) shorn sheep God tempers (*mesurer*) the wind, says the proverb (*proverbe*, m.).

22. That dog is dangerous ; it bites.

23. There are some persons whose praises (*louange*, f.) bite, and whose caresses (*caresse*, f.) scratch (*égratigner*).

24. Gold melts at a less degree (*degré*, m.) of heat (*chaleur*, f.) than iron.

KEY TO EXERCISE XXVI.

1. Quand j'étais enfant, j'étais très honteux, je rougissais jusqu'aux yeux quand on me parlait.

2. La terre n'est jamais ingrate ; elle nourrit de ses fruits tous ceux qui la cultivent.

3. Ce n'est pas l'âge, c'est le chagrin qui a blanchi ses cheveux.

4. Si vous ne choisissez pas un bon endroit pour établir les fondations de la maison, vous serez obligé de la démolir.

5. La honte de cette action réfléchit sur tous ceux qui y ont participé.

6. Parmi les arbres, les amandiers fleurissent les premiers, et les néfliers les derniers.

7. Après tant de calamités il est étonnant que ce pays soit aujourd'hui si florissant.

8. Les armes qui ont été bénites par l'Église ne sont pas toujours bénies du ciel sur le champ de bataille.

9. Il y a des hommes dont il est glorieux d'être haï.

10. On ne hait pas toujours ceux que l'on rend malheureux.

11. Les bons livres guérissent les maladies de l'esprit.

12. Un peuple libre obéit, mais il ne sert pas.

GERMAN

Continued from page 3791

By P. G. Konody and Dr. Osten

LXXXV. Government of Adjectives. The following adjectives govern the genitive (answering the question weſſen? whose?):

anſichtig, gewahr,* aware
bar, ledig, frei, los,* free
bedürftig, in want of
unbedürftig, not in want of
bewußt, conscious of
unbewußt, unconscious of
eingedenk, mindful
uneingedenk, unmindful
fähig, able
unfähig, unable
froh, glad
gewärtig, expecting
gewiß, ſicher, certain, sure
gewohnt,* used to, accustomed
ungewohnt,* unaccustomed
gierig, begierig, eager, greedy
habhaft (werden),* to get possession of
kundig, expert
unkundig, unexpert
leer, empty
voll, full
mächtig, mighty
müde,* tired
ſatt,* überdrüſſig,* satiated, weary, tired
ſchuldig, guilty
verdächtig, suspicious
teilhaftig, participating, sharing
verluſtig, forfeited, deprived of
wert,* deserving, worthy
unwert, undeserving
würdig worthy
unwürdig, unworthy.

Examples: Ich bin meines Verſprechens eingedenk, I am mindful of my promise. Sie wurde meiner (genitive) anſichtig, She became aware of me. Die Polizei' wurde des Verbrechers hab'haft, The police got hold of the criminal. Ich bin dieſer Sprache mächtig, I am master of this language. Er war ſeiner nicht mächtig, He had no command over himself. Dies iſt nicht der Mühe (genitive) wert, This is not worth while. Der Arzt wurde ſeines Titels verluſtig, The physician lost his degree, etc.

The adjectives in above list marked with * are, in ordinary speech, also used with the accusative, where the genitive would sound affected, especially with neuters of pronouns, like es, it; das, that (instead of the genitive deſſen); dieſes or dies, this; jenes, that; and with the indefinite pronouns and numerals etwas, nichts, manches, alles

Examples: Ich hatte es (accusative) ſatt, I had enough of it. Ich wurde den unwillkommenen Genoſſen (accusative) los, I got rid of the unwelcome companion. Er iſt die Arbeit (accusative) nicht gewohnt, He is not accustomed to the work. But in some cases the adjectives are used with prepositions: thus it is preferable to say ich bin mit (preposition) allem (dative) zufrieden (I am content with everything), than Ich bin alles (accusative) zufrieden.

1. The following adjectives govern the dative (answering the question wem? to whom?):

ähnlich,* similar, like
an'geboren, inborn, innate
an'gehörig, related to
an'gelegen, important, pressing
an'gemeſſen,* commensurate, suitable
an'genehm,* agreeable
an'ſtößig, offensive
är'gerlich, annoying, vexatious, fretful
auf'fällig,* striking, conspicuous
bedenk'lich,* doubtful, suspicious
begreif'lich,* comprehensible
behag'lich,* comfortable
behilf'lich, serviceable, useful
bekannt,* known, acquainted
bequem',* convenient, comfortable
beſchwer'lich, cumbersome, troublesome
bewußt',* conscious
böſe, wicked, bad, ill
dank'bar,* grateful
deut'lich,* clear, distinct
dien'lich, serviceable
eigen, own, proper
eigentümlich, peculiar
ekelhaft (eklig), nasty
empfind'lich,* sensitive
entbehr'lich,* dispensable
erfreu'lich,* delightful, pleasing
erge'ben, devoted
erin'nerlich, present in one's mind
erwünſcht, wished for, welcome
feind (feindſelig), hostile
fern, far, distant
förderlich, useful, beneficial
fremd, strange
furchtbar, fürchterlich, terrible
gedeihlich, prosperous, thriving
gefährlich,* dangerous
gehor'ſam,* obedient
gewachſen, to be a match for
gleich, equal
gleichgültig, callous, indifferent
gemäß, according to
gemein, common, mean
gemeinſam, gemeinſchaftlich, common, mutual
geneigt, disposed, inclined
getreu,* faithful to
gnädig,* gracious
gram, averse, hostile
günſtig,* favourable
gut, good
heilſam, salutary, beneficial
hinderlich, impeding, troublesome
hold, amiable, sweet
klar,* clear, bright
kund, known, notorious
läſtig, burdensome
leicht, easy, light
leid, sorry
lieb, dear, beloved
möglich,* possible
nachteilig, disadvantageous
nahe, near
natürlich,* natural
nötig,* notwendig, necessary
nützlich, useful
rätſelhaft, enigmatic
ſchädlich, pernicious
ſchmeichelhaft,* flattering
ſchmerzlich, painful
ſchuldig, guilty
ſchwer, difficult, heavy
ſicher, certain
tauglich, fit
teuer, dear
treu,* true, faithful
treulos, untrue, faithless
überle'gen, superior
unausſteh'lich, insupportable
unerwartet, unexpected
untertan, subject (to)
unvergeßlich, unforgetable
unwiderſtehlich, irresistible
verant'wortlich, responsible
verderb'lich, pernicious
verhaßt, hated
verwandt, related
vor'teilhaft,* advantageous
wert, worth
wichtig, important
widrig, adverse, contrary
widerwärtig, repugnant
willfährig, compliant
willkommen, welcome
wunderbar, marvellous
zu'gänglich, accessible
zu'getan, devoted
zu'träglich, becoming

The adjectives marked in above list with * take the prefix un- to convey the opposite (negative meaning): ähnlich, like; un-ähnlich, unlike.

Examples: Er iſt ſeinem Bruder (dative) ähnlich, He resembles his brother. Die Botſchaft war dem König (dative) angenehm, The message was pleasing to the king. Ich bin Ihnen (dative) dankbar, I am grateful to you. Das Kind blieb ſeinem Verſprechen (dative) treu, The child remained true to its promise. Der Hagel iſt dem Getreide ſchädlich, The hail is harmful to the corn.

LXXXVI. Co-ordinate Clauses. Sentences or clauses that have the same grammatical value can be connected in different ways:

(*a*) The clauses agree in sense: Die Nacht war kalt, und die Straßen waren menſchenleer, The night was cold, and the streets were deserted.

(*b*) One clause modifies or limits the other: Der Regen war dem Wachstum förderlich, aber der Hagel zerſtörte Alles, The rain was beneficial to (the) growth, but the hail destroyed everything. Er wollte gehen, doch er konnte nicht, He wanted to go, but he could not.

(*c*) One clause is explained by the other: Das Waſſer iſt geſund, denn es enthält Eiſen, The water is wholesome, as it contains iron.

(*d*) One clause is the consequence of the other: Er iſt ſehr gutherzig, deshalb wird er von Bettlern umlagert, He is very kind-hearted, therefore he is besieged by beggars.

The connection of co-ordinate clauses is effected by the use of (*a*) copulative, (*b*) adversative, (*c*) causal, and (*d*) consecutive conjunctions.

LXXXVII. Subordinate Clauses. The auxiliary finite verb, which normally stands at the end of the subordinate clause in the compound tenses, may be transposed if the clause contains dependent infinitives: Ich wünſchte, daß du ihn hätteſt (finite verb) kennen lernen, I wished that you had got to know him, is better than the clumsy form: Ich wünſchte, daß du ihn kennen lernen hatteſt.

1. Subordinate clauses are never employed if the idea can be clearly expressed without them. Thus, Ich bat ihn, daß er mir ſage, wohin ſie gegangen ſei (literally: I begged him to tell me where she had gone) can be expressed far better and more briefly in the following way: Ich bat ihn mir zu ſagen, etc. Subordinate clauses are connected with the principal sentence by subordinative conjunctions, and relative pronouns.

2. The subordinate clause can be placed (*a*) at the beginning, (*b*) in the middle, (*c*) at the end of the compound sentence. (*a*) Daß die Nacht hereinbrach (subordinate clause), machte uns beſorgt, That the night set in made us uneasy; (*b*) Der Umſtand, daß die Nacht hereinbrach, machte uns beſorgt, The fact that night set in made us uneasy; (*c*) Es machte uns beſorgt, daß die Nacht hereinbrach, It made us uneasy that, etc.

3. Some ideas cannot be expressed by simple nouns, but require entire subordinate clauses to elucidate their meaning. At times, too, a noun is replaced by a subordinate clause for the sake of stress, euphony, rhythm, or clearness. Thus a subordinate clause always stands for some part of the principal sentence—the subject, the object, an attribute, or an adverbial adjunct, and according to its function, the dependent clause is either a *subject clause*, an *object clause*, an *attributive* (*adjective*) *clause*, or an *adverbial clause*.

EXAMINATION PAPER XXI.

Correct the following sentences by changing the nominative, which is employed throughout, into the correct cases required by the adjectives.

Ich war meine Pflicht eingedenk. Der Sohn
I was mindful of my duty. The son
iſt ſein Vater ähnlich. Die Lüge war
resembles his father. The lie was
die Athener angeboren. Die Sache ſchien
innate in the Athenians. The affair seemed
der Beamte bedenklich. Er hielt ihn
suspicious to the official. He thought him
ein ſolches ſchreckliche Verbrechen fähig.
capable of such a horrible crime.
Der Gefangene war das Urteil gewärtig.
The prisoner was expecting the verdict.
Die Eltern ſind die Sprache nicht mächtig
The parents have not command of the language.
Die Soldaten waren der Dienſt überdrüſſig.
The soldiers were weary of the service.
Die Soldaten war der Dienſt überdrüſſig
The service was wearisome to the soldiers.
Das Kind iſt ſeine Eltern Gehorſam ſchuldig
The child owes obedience to its parents.
Dieſe Handlung iſt du unwürdig. Man
This action is unworthy of you. They (people)
überhob mich die Mühe. Die Verfolger
spared me the trouble. The pursuers
wurden der Dieb habhaft. Dieſer Zwiſchenfall
got hold of the thief. This incident proved
erwies ſich ich günſtig. Das iſt ſie ganz gleichgültig.
favourable to me. This is quite indifferent to her.
Das Volk iſt der König untertan. Trotzdem
The people is subject to the king. Though
der Fall der Richter unklar war, fand er ihn
the case was not clear to the judge, he found him
das Verbrechen ſchuldig. Der Feldherr
guilty of the crime. The commander-in-chief
war dieſe große Überzahl nicht gewachſen,
was not equal to such overpowering numbers,
und ergab ſich, als er die heranrückende friſche
and surrendered when he got sight of the
Truppen anſichtig wurde.
approaching fresh troops.

CONVERSATIONAL EXERCISES

V. Laundry and Washing

I have some dirty linen, can it be washed?	Ich habe einige ſchmutzige Wäſche, kann ſie gewaſchen werden?
Oh, yes; give it to me, please.	O ja, bitte geben Sie ſie mir.
When can I get it back?	Wann kann ich ſie wieder haben?
In four or five days.	In vier bis fünf Tagen.

That is too late; I must have it to-morrow, as I start in the evening.	Das iſt zu ſpät; ich brauche ſie ſchon morgen, da ich Abends abreiſe.
Very well, I shall try to make it possible.	Sehr wohl, ich werde trachten es moglich zu machen.
I have 4 shirts, 6 collars, 4 pairs of cuffs, 10 handkerchiefs, 3 pairs of socks, and 3 pairs of pants. The shirts must not be starched.	Ich habe 4 Hemden, 6 Kragen, 4 Paar Manſchetten, 10 Taſchentucher, 3 Paar Socken und 3 Paar Unterbeinkleider. Die Hemden durfen nicht geſtärkt werden.
Everything shall be done as you wish.	Alles ſoll nach Wunſch beſorgt werden.
Can I rely on everything being delivered in time?	Kann ich mich darauf verlaſſen, daß Alles rechtzeitig geliefert wird?
Certainly, sir.	Gewiß, mein Herr.

VI. At the Telegraph Office

I want to send a wire to England.	Ich wunſche ein Telegramm nach England aufzugeben.
How much a word? Twenty pfennigs.	Was koſtet das Wort? 20 Pfennige.
Can I have a form?	Kann ich ein Formular haben?
How must I mark it for reply paid?	Welche Bezeichnung iſt fur bezahlte Ruckantwort erforderlich?
R. p., sir.	R. p., mein Herr (Réponse payée).
How many letters may a single word contain?	Wie viele Buchſtaben darf ein einfaches Wort enthalten?
Sixteen, sir; more letters in a single word are charged as two words.	Sechszehn, mein Herr; mehr Buchſtaben in einem Wort werden als zwei Worte gerechnet.
Is the handwriting legible?	Iſt die Schrift gut leſerlich?
Oh, yes; only this letter is not quite clear.	O ja, nur dieſer Buchſtabe iſt nicht ganz deutlich.
When does the telegram reach London?	Wann kann das Telegramm in London ſein?
In about three hours.	In ungefahr drei Stunden
Can I have telegrams forwarded?	Kann ich mir Telegramme nachſenden laſſen?
Certainly, if you let me know your new address and fill in this form.	Gewiß, wenn Sie mir Ihre neue Adreſſe mitteilen und dieſe Form ausfüllen.
How many words does the telegram contain?	Wie viel Worte enthalt das Telegramm?
Is the signature to be wired as well?	Soll die Unterſchrift auch telegraphiert werden?
No, only the surname.	Nein, nur der Familienname.

By Amalia de Alberti & H. S. Duncan

REGULAR VERBS

Spanish verbs have three conjugations. All verbs, regular or irregular, ending in *ar* belong to the first conjugation. Example: *Amar*, to love.

All those ending in *er* belong to the second conjugation. Example: *Comer*, to eat.

All those ending in *ir* belong to the third conjugation. Example: *Vivir*, to live.

Regular verbs are those in which the terminations conform to the model verb of their conjugation; these terminations are applied directly to the unchanged stem found by suppressing the infinitive ending. Examples:

am-*ar*; am-*amos*—to love; we love
com-*er*; com-*emos*—to eat; we eat
viv-*ir*; viv-*imos*—to live; we live

Those verbs which by changes in stem and termination differ from the model verb of their conjugation are called irregular.

This, however, does not apply in the case of orthographic changes in certain regular verbs, made for the sake of euphony only. These will be pointed out later.

First Conjugation

MODEL VERB: **Amar,** to love

INFINITIVE	GERUND
amar, to love	*amando*, loving

PAST PARTICIPLE
amado, loved

INDICATIVE MOOD

Simple Tenses

Present	*Imperfect*
amo, I love	*amába*, I was loving
amas, thou lovest	*amábas*, thou wast loving
ama, he loves	*amába*, he was loving
amamos, we love	*amábamos*, we were loving
amais, you love	*amábais*, you were loving
aman, they love	*amában*, they were loving

Past Definite	*Future*
amé, I loved	*amaré*, I shall love
amaste, thou lovedst	*amarás*, thou wilt love
amó, he loved	*amará*, he will love
amamos, we loved	*amarémos*, we shall love
amásteis, you loved	*amaréis*, you will love
amáron, they loved	*amarán*, they will love

CONDITIONAL MOOD

amaría, I should love
amarías, thou wouldst love
amaría, he would love
amaríamos, we should love
amaríais, you would love
amarían, they would love

IMPERATIVE MOOD

ama, love (thou)	*amémos*, let us love
ame, let him love	*amád*, love ye
	amen, let them love

SUBJUNCTIVE MOOD

Present	*Imperfect*
ame, I may love	*amára*, or *amáse*, I might love
ames, thou mayst love	*amáras*, or *amáses*, thou mightst love
ame, he may love	*amára*, or *amáse*, he might love
amémos, we may love	*amáramos*, or *amásemos*, we might love
améis, you may love	*amárais*, or *amáseis*, you might love
amen, they may love	*amáran*, or *amásen*, they might love

Future

cuando yo amáre, when I shall love
cuando tu amáres, when thou wilt love
cuando él amáre, when he will love
cuando nosotros amáremos, when we shall love
cuando vosotros amareis, when you will love
cuando ellos amáren, when they will love

COMPOUND TENSES

Infinitive Past

haber amado, to have loved
habiendo amado, having loved

INDICATIVE MOOD

Past Indefinite

hé amado, I have loved
has amado, thou hast loved
há amado, he has loved
hemos amado, we have loved
habeis amado, you have loved
han amado, they have loved

Pluperfect

había amado, I had loved
habías amado, thou hadst loved
había amado, he had loved
habíamos amado, we had loved
habíais amado, you had loved
habían amado, they had loved

Past Anterior

hube amado, (when) I had loved
hubiste amado, thou hadst loved
hubo amado, he had loved
hubimos amado, we had loved
hubísteis amado, you had loved
hubieron amado, they had loved

Future Perfect

habré amado, I shall have loved
habrás amado, thou wilt have loved
habrá amado, he will have loved
habrémos amado, we shall have loved
habréis amado, you will have loved
habrán amado, they will have loved

CONDITIONAL MOOD

habría amado, I should have loved
habrías amado, thou wouldst have loved
habría amado, he would have loved
habríamos amado, we should have loved
habrías amado, you would have loved
habrían amado, they would have loved

SUBJUNCTIVE MOOD

Past Indefinite

haya amado, I may have loved
hayas amado, thou mayst have loved
haya amado, he may have loved
hayamos amado, we may have loved
hayais amado, you may have loved
hayan amado, they may have loved

Pluperfect

hubiera, or *hubiese amado*, I might have loved
hubieras, or *hubieses amado*, thou mightst have loved
hubiera, or *hubiese amado*, he might have loved
hubiéramos, or *hubiesemos amado*, we might have loved
hubierais, or *hubieseis amado*, you might have loved
hubieran, or *hubiesen amado*, they might have loved

Future Perfect.

hubiere amado, (when) I shall have loved
hubieres amado, thou wilt have loved
hubiere amado, he will have loved
hubiéremos amado, we shall have loved
hubiéreis amado, you will have loved
hubieren amado, they will have loved

Second Conjugation

MODEL VERB: **Comer,** to eat

INFINITIVE	GERUND
comer, to eat	*comiendo*, eating

PAST PARTICIPLE

comido, eaten

INDICATIVE MOOD

Present	*Imperfect*
cómo, I eat	*comía*, I was eating
comes, thou eatest	*comías*, thou wast eating
come, he eats	*comía*, he was eating
comémos, we eat	*comíamos*, we were eating
coméis, you eat	*comíais*, you were eating
comen, they eat	*comían*, they were eating
Past Definite	***Future***
comí, I ate	*comeré*, I shall eat
comiste, thou atest	*comerás*, thou wilt eat
comió, he ate	*comerá*, he will eat
comimos, we ate	*comerémos*, we shall eat
comisteis, you ate	*comeréis*, you will eat
comiéron, they ate	*comerán*, they will eat

CONDITIONAL MOOD

comería, I should eat
comerías, thou wouldst eat
comería, he would eat
comeríamos, we should eat
comeríais, you would eat
comerían, they would eat

IMPERATIVE MOOD

come, eat (thou)	*comámos*, let us eat
coma, let him eat	*comed*, eat (ye)

coman, let them eat

SUBJUNCTIVE MOOD

Present

coma, I may eat	*comámos*, we may eat
comas, thou mayst eat	*comais*, you may eat
coma, he may eat	*coman*, they may eat

Imperfect

comiera, or *comiese*, I might eat
comieras, or *comieses*, thou mightst eat
comiera, or *comiese*, he might eat
comiéramos, or *comiésemos*, we might eat
comiérais, or *comiéseis*, you might eat
comieran, or *comiesen*, they might eat

Future

comiere, when I shall eat	*comiéremos*, when we shall eat
comieres, when thou wilt eat	*comiéreis*, when you will eat
comiere, when he will eat	*comieren*, when they will eat

REMARKS. In the first conjugation the accent distinguishes identical forms. Example: *Amo*, I love; *amó*, he loved. In the first case the stress is laid on *a*, in the second on *o*.

In the second conjugation, *cómo*, I eat, takes an accent to distinguish it from *como*, as.

The compound tenses are formed as in the case of *amar* with the verb *haber* and the past participle *comido*. Example: *He comido*, I have eaten, etc.

Vocabulary	Vocabulario
To buy	Comprar
To calculate	Calcular
To compare	Comparar
To devour	Devorar
To wish	Desear
To demonstrate	Demostrar
To remain	Quedarse
To eclipse	Eclipsar
To edify	Ynstruir
To embroil	Embrollar
To muffle	Embozar
To empower	Facultar
To give sentence (judicial)	Fallar
To fatigue	Fatigar
To congratulate	Felicitar
To run	Correr
To enter	Entrar
To deliver	Entregar
To give sparingly	Escatimar
The famine	El hambre
The skirt	La falda
A flounce	Un volante
The lantern, lighthouse	La linterna, el faro
The luggage	El equipaje
The watch-tower	La atalaya
The short-cut	El atajo
The main road	El camino real
The village	La aldea
Hasten	Prisa (darse)
The jail	La cárcel
The prisoner	El prisionero
A problem	Un problema
Prismatic	Prismático
Favourite	Favorito
A prophet	Un profeta
A ravine	Una barranca
Brittle	Quebrajoso
The complaint	La queja
Perhaps	Quizá
A parasol	Una sombrilla
The Bible	La Biblia
Biblical	Biblico
A parable	Una parábola
The Gospel	El Evangelio
The evangelist	El evangelista
To evangelise	Evangelizar
To excavate	Excavar

EXERCISE XII. (1)

Translate the following into Spanish:

1. I buy meat, eggs, and milk at the farm; the farmer is very honest. 2. I, too, shall buy them there, and we shall also, my daughter and I, buy fowls (there). 3. Do you eat many birds? 4. Yes, we are very fond of them. 5. I eat a great deal of game; we have bought partridges and pheasants. 6. I wish to demonstrate this problem to you. 7. The judge has given sentence in the lawsuit. 8. Shakespeare's fame has reached to the end of the world. 9. That woman friend of yours is capable of embroiling the most united family. 10. Driving along the main road the carriage upset, and the coachman and the horses were hurt. 11. They took the prisoner in haste to the prison. 12. Perhaps the doctor may come to see me; my son complains of headache. 13. Open your parasol; the sun is hot. 14. When they excavated in the ravine, they found a beautiful statue. 15. The lantern (of the lighthouse) of the port of Cadiz is seen very far off. 16. They have stolen my money from my pocket. 17. When was this? 18. When I went to buy the Bible for the children. 19. I wish you a happy New Year.

NOTE. Students should now attempt to translate the exercise with the aid of a good dictionary, such as the new edition of Velasquez' Spanish Dictionary (published by Hachette, King William Street, Strand. 10s. 6d. net).

EXERCISE XII. (2)

Translate the following into English:

1. Los huérfanos amaban á su padre. 2. Los estudiantes áman á su perro. 3. Amaré á mis hijos. 4. No dejes de amar á tu enemigo, así lo manda el Evangelio. 5. Coman con nosotros. 6. Comerémos con Vds con mucho gusto. 7. Un ciego no necesita ver para comer. 8. Es mejor reir que llorar. 9. Ganó su pleito, y dió una gran comida. 10 Los sordos mudos pueden hablar con los dedos. 11. El actor declamó muy bien. 12. Los canarios cantan, y los perros ladran. 13. Cuando vamos al huerto comemos fruta.

PROSE EXTRACT X.

From "El Buey Suelto" (The Unyoked Ox).

By José de Pereda.

Grant me, reader, if you have no objection, that when a man has been accustomed from his earliest years to have the ordinary and most pressing needs of life supplied as if by magic, he is well on the way to be an egoist. This does not prevent the man who has won the goods he enjoys in a fierce struggle with Fate from being an egoist also.	Concédame el lector, si mal no le parece, que cuando un hombre ha visto desde que empezó á serlo, satisfechas como por ensalmo las mas comunes y perentorias necesidades de la vida, tiene mucho adelantado para ser egoista. Lo cual no se opone á que también lo sea el que ha ganado el bien que disfruta en guerra encarnizada con la suerte.

Is that to say that egoists abound, that the species varies with every specimen? Agreed; but it will be well to draw a distinction between the cases as regards the subject of these reflections.

He who is selfish because he has been made so by the ill-usage of Fortune, he who devotes himself to his own enjoyment as a reward for bygone hardships, finds an excuse in this, and a perennial delight in comparing the smiling present with the anxious past. Thus, imagination does not beguile him, changes cannot bewilder him, neither is he "the slave of habit," according to the popular saying applied to those waverers who deplore imaginary evils from excess of good. His course lies clear before him and he follows it firmly, without any risk of stumbling into error from the very fact that he has no illusions to light the way.

The case of Gideon is very different; he is a type which includes all kinds of egoists who ought not to be so, even from selfish motives.

To these gentlemen I address my tale. I speak to you; to you, who, eager to avoid material annoyances, fly from the most legitimate joys of the spirit; to you, prodigal of your substance, when it is a case of pampering the body and niggards of it when your soul requires a halfpenny to purchase joy.

¿ Querrá decir esto que los egoistas abundan, y que sus especies varían en cada ejemplar ? Enhorabuena, pero conviene distinguir el caso para el objeto de estos apuntes.

El que es egoista porque así le hizo el desdén de la fortuna, el que se consagra al propio regalo como en recompensa de pasadas fatigas, tiene en éstas la disculpa, y perenne deleite en la comparación del presente ruiseño con el ayer angustioso. De este modo, ni la imaginación le seduce, ni las vacilaciones le marean, *ni el vicio le mata,* como el vulgo dice de los indecisos que lloran soñados males por exceso de bienes. Lleva su rumbo bien trazado, y camina con pié firme, sin el riesgo de tropezar en desengaños, por lo mismo que no se alumbra con ilusiones.

Otra cosa muy distinta es Gedeón, tipo en que se resumen todas las especies de egoistas que no debieran serlo, hasta por razones de egoismo.

A estos señores enderezo mi cuento; con vosotros hablo; con vosotros, los que afanados en evitarle desazones de la materia, huís de los más legítimos goces del espíritu; con vosotros los que, pródigos de la hacienda cuando se trata de regalar al cuerpo, sois avaros de ella si el alma os pide un óbolo para adquirir un regocijo.

José de Pereda (1834), a master of the provincial novel, renowned for his power of description and realistic pictures of peasant life in the mountains. The novel of which our extract is the opening is a satirical history of the miseries and misadventures of an old bachelor, partly intended as a reply to Balzac's novel "Petites Misères de la Vie Conjugale."

José de Pereda (1834), pasado maestro en las novelas provincialas, afamado por su poder descriptivo y pinturas realisticas de la vida aldeana en la montaña. La novela de la cual nuestro extracto es el principio, es una história satírica de las miserias y desventuras de un soltero viejo, en parte escrita como contestacion á la novela de Balzac. "Petites Misères de la Vie Conjugale."

KEY TO EXERCISE XI. (1)

1. El amor al dinero trae la avaricia. 2. El ser pródigo no es siempre tener caridad. 3. La actividad vence la apatía y la pereza. 4. El ser ilusivo es tener poca conciencia. 5. La incredulidad es una triste cosa. 6. La curiosidad demuestra una imaginación poco ocupada. 7. La desesperación no es cristiana. 8. Muchos hablan, pocos son elocuentes. 9. El entusiasmo hace el hombre heróico. 10. La erudición no es siempre sabiduria. 11. Los celos hacen la desgracia de los celosos. 12. El celo es una virtud. 13. La gratitud demuestra nobles sentimientos. 14. En el peligro la presencia de espíritu vale mucho. 15. El remordimiento no remedia el mal hecho. 16. La necedad es siempre orgullosa. 17. La vanidad es tonta. 18. La ociosidad es madre de todos los vicios. 19. El aseo es una gran cualidad. 20. El desaseo es desagradable. 21. El pensamiento es dado al hombre para guiarlo.

KEY TO EXERCISE XI. (2)

1. I am aged. I am an old woman. 2. We are hungry. Eat bread and meat. 3. They are not guilty; I am guilty of this crime. 4. I am ashamed to have spoken against my neighbour. I am ashamed! 5. They are right, I am reasonable. 6. I am thirsty. Drink water and wine. 7. Let us have patience. 8. Thou art a fool to talk thus. 9. She is a beautiful woman, and has money. 10. We are fortunate to have such a celebrated father. 11. They will be punished for their crimes. 12. He would be a man of talent if he were not so vain. 13. Thou wast amiable to sing. 14. He is a braggart and a liar. 15. Let us have courage. 16. Originality in a man of letters is a great quality. 17. Love of liberty is natural to man. 18. Insolence is unpardonable. 19. It is well to ascertain the truth. 20. Exaggeration sometimes amounts to falsehood. 21. It is well to count one's money before spending it.

METALS UNDER THE MICROSCOPE

The New Science of Metallography. Preparing Specimens Alloys and their Preparation. Characteristics and Composition of Alloys

Group 14
METALS
2

Continued from page 3810

By A. H. HIORNS

Metallography. The branch of metallurgical science termed *metallography* is, in the broadest sense of the word, the description of the structure of metals and alloys. It is not necessarily limited to the employment of the microscope or even to the hand glass, for the fractured surface of a metal often reveals valuable information when viewed with the naked eye. We form an opinion of the nature of metals also from their colour, their manner of solidifying in a mould, and the texture of their surfaces. But only very limited information as to the structure of metals can be obtained by simply using the unaided eye to examine the rough or unpolished surface. The structure of what may be termed the *internal architecture* of metals can be accurately ascertained only by the use of the microscope, generally on the polished and etched surface.

Microscopic Investigation. One of the great results of the microscopic investigation of metals has been the confirmation of their crystalline character, even in metals in which such a structure could not have been anticipated or proved by other means The appearance of the polished structure of a metal under the microscope seldom reveals definite and well-formed crystals—in fact, the conditions of solidification from the molten state and the mechanical treatment to which most metals are subjected militate against the formation and retention of the true external crystalline form The result is a compact mass of irregular-shaped bodies termed *crystal grains*, giving the surface the appearance of a mosaic with irregularly shaped stones.

Character of Crystal Grains. In the act of solidifying, crystals begin to form and gradually grow in size according to the time allowed for their development. The junction lines are the surfaces of the crystals, and appear as thin dark lines in the micro-structure. If impurities be present, the crystals of the pure metals in the act of crystallising reject such impurities, which collect at the crystal boundaries. The particles of the pure metal coalesce together so as to form little islands surrounded by the impurity, which thus forms the investing membrane, separating the crystals from each other.

Obviously, the mechanical and physical properties of an alloy will depend largely on the nature of the investing membrane, since the crystals themselves may be quite malleable and ductile, while the mass of the metal, with the including impurities, may be quite brittle. The main factor in the development of crystalline structure is the temperature. It is a well-recognised fact that the more slowly a metal is cooled from the freezing point, the larger will be the dimensions of the crystals, the more perfectly will they be formed, and the more symmetrically will they arrange themselves with regard to each other. On the other hand, if a metal be submitted to pressure, not only will the individual crystals be distorted, but the orderly arrangement of the whole mass will be disturbed. Messrs. Ewing and Rosenhaim have shown that when a piece of metal is strained in tension its crystal grains become elongated in the direction of the tension; but when the metal has been annealed all signs of the elongation disappear from the crystalline pattern revealed by the microscope, and the metal has assumed its original condition. On investigating the metal under strain, when the metal is stretched beyond its elastic limit it has also been found that sharp and fine black lines appear on the surface of the crystals, parallel to each other in each crystal but in different directions in different crystals. These lines are not cracks, but *slips* along the cleavage or guiding planes, and are termed *slip-bands*. Such bands are also produced by compression or tension, and it is in virtue of this action that plasticity in metals is possible.

Preparing Metals for the Microscope. For exact examination of the structure of metals it is absolutely necessary to have the surface polished free from scratches, as well as perfectly flat, if high powers are to be used, since scratches and other imperfections tend to mask the real structure and convey an erroneous impression regarding the character of the components. Polishing is an art requiring skill and patience, and while no exact rules can be given to cover all cases, the following will serve as a general guide. The section of metal should be about ½ in. square, and ⅛ in. thick. It may be mounted for final examination on a glass slide with Canada balsam, plasticine, wax, or other suitable adhesive materials, or soldered on to a flat piece of metal. The first process is to rub it smooth on a dead-smooth file, and afterwards to remove the scratches with emery and rouge Different grades of emery can be purchased, marked O, OO, OOO, and OOOO, respectively. Each grade should be mounted on a smooth block, and the specimen rubbed on each in turn, care being taken to rub at right angles to the former rubbing, so as to obliterate the previous marks completely. The final polishing may be done on a skin of chamois leather coated with the very finest rouge.

Etching the Specimens. Various etching liquids are used, varying with different metals. Those employed for steel are dilute nitric acid, tincture of iodine, infusion of liquorice, ammonium nitrate and picric acid; for copper and brass, dilute nitric acid, hydrochloric acid and ammonia; while for alloys with much zinc, potash is the best reagent. In fact, numerous etching liquids are available.

It is sometimes an advantage to polish in bas-relief. When a complex body is polished, its different constituents tend to wear away unequally, and it is possible, by placing it in convenient positions, to show the structure by the unequal relief. To do this, the section is polished on a bed elastic enough to bring out the finest details, such as parchment on soft wood, and moistened with wet rouge. Another method of polishing is known as *polish attack*. This consists of adding to the polishing pad some liquid which exerts a slight chemical action when assisted by the friction of the rubbing.

Heat Tinting. Etching polished metals with corrosive liquids is more or less liable to lead to the confusing of the constituents and crystalline structure. With feeble etching the component parts are, as a rule, revealed; with strong etching the granular, and often the crystalline structures, are developed. By heating polished sections at different temperatures the constituents become differently coloured by oxidation films, and may therefore be detected. This has the advantage over etching, that none of the metal is dissolved, and the surface remains flat.

The Microscope. A very simple form of microscope is all that is necessary for examining metals, but the lenses must be of good quality. The objectives must give a flat field, should be achromatic, and should possess clear definition. A bull's-eye condensor is required for condensing the light on to the object, or on to the vertical illuminator.

The most useful objectives are 1 in. and ¼ in., which give magnifications from 50 to 200 diameters. Two kinds of illuminators are in use, termed respectively *oblique* and *vertical* illuminators. In the former, the microscope is generally tilted at an angle, and the light thrown directly on the object, which reflects it to the eye. For vertical illumination a piece of glass is arranged at an angle of 45 degrees, so as to reflect a horizontal beam of light on the object, which then reflects the light vertically up the tube of the microscope to the eye. Instead of the plane glass reflector, a right-angled prism may be used. It is fixed in a brass mounting, and may be placed just above the objective, or just under the eye-piece.

Iron and Steel. *Wrought iron* is composed of three chief parts: the crystals of iron, termed *ferrite*, the carbide of iron, termed *cementite*, and the included slag which imparts to iron its fibrous structure. *Cast iron* is of two chief kinds—namely, grey cast iron, consisting chiefly of ferrite and graphite; and white cast iron, containing no free ferrite, but iron combined with carbon in a form which imparts to it a white crystalline structure and great hardness. *Steel* is composed of different components, according to the amount of carbon present. When the steel contains less than 0·9 per cent. of carbon, it consists of ferrite embedded in a matrix of what is termed *pearlite*, which is an intimate mixture of ferrite and cementite in alternate laminæ. When the steel contains just 0·9 per cent. of carbon, the whole mass is composed of pearlite, with no free crystals of ferrite. This is termed the *eutectic mixture*, and the iron is said to be saturated with carbon. When the steel contains over 0·9 per cent. of carbon, it consists of crystals or grains of pearlite, surrounded by a network of cementite, which hardens the steel according to the quantity present.

A section of pure iron, when polished and etched in dilute nitric acid, is seen to consist of irregular-shaped grains or crystals. Two disdinct types are generally observed: (1) smooth and bright areas consisting of pure iron (ferrite); and (2) greyish rough areas of a wavy or mottled appearance, being more readily attacked by nitric acid. When carbon is present the crystals of ferrite are surrounded by a matrix of pearlite, which encroaches more and more on the ferrite as the carbon is increased, as shown in the plates following pages 2936 [2 and 3]. The pearlite matrix is seen in the latter to have a characteristic banded structure. When the steel contains about 0·9 per cent. of carbon, the whole mass consists of pearlite. When the carbon is increased beyond 0·9 per cent., the ferrite crystals have entirely disappeared and have been replaced by pearlite; the excess of carbon over 0·9 per cent. then appears in combination with iron as free cementite, as seen in **4**. These three figures represent the steel in the normal state.

Effects of Annealing Steel. On annealing steel a change is produced in the physical properties, and this change is coincident with a change in structure. By *annealing* is meant heating to a certain elevated temperature and cooling slowly to the ordinary temperature. The effect on the micro-structure by annealing is seen in **5** and **6**. The changes which have been produced occurred mainly in the ferrite, but the pearlite has become more granular. The effect of annealing high carbon steel at 620° C., as seen in **7**, is chiefly to sharpen the outline of the cementite. The above remarks apply also to **8**, **9**, and **10**, but the effects are intensified by the long soaking or annealing for 12 hours, the cementite and pearlite being very well defined in **10**. In all the specimens which have been described the white parts represent ferrite and cementite respectively, and the darker parts the pearlite.

Malleable Iron. Malleable iron castings consist of white cast iron which has been subsequently annealed in iron boxes packed with hæmatite. The carbon in the castings before annealing is chiefly in the combined form, as cementite, and this undergoes a more or less complete change in the process of annealing. Some of the carbon is removed, but the greater part remains as graphite. On the outside of the casting the carbon is oxidised by the oxygen of the hæmatite, leaving ferrite. On the other hand, there is a store of carbon towards the centre of the bar in the form of amorphous graphite, which is continually re-

[illegible]

carburising the ferrite by solid diffusion. The structure of the outside, intermediate and centre of the casting, is seen in **11**, **12** and **13**.

Copper. The micro-structure of copper varies with the mode in which it has been produced. Electrolytic copper is confusedly crystalline. Pure copper consists of irregular-shaped crystal grains with very fine and sharp boundaries. These crystal grains increase in size according to the slowness of cooling Small secondary grains are often built up from the larger ones. Fig. **14** is the top of a button of copper. When copper is rolled or hammered, as in **15**, the secondary grains are elongated in the direction of the rolling, and finally may become so attenuated as to break down. Annealing tends to release the strain and allows the grains to rearrange themselves. Fig. **16** is copper foil, etched in nitric acid, and shows fine elongated grains.

Tin. When an ingot of pure tin is cast it shows a bright surface, but if impure, the surface shows a structure of dendritic crystals. If the surfaces of the ingots be etched, they are seen to be coarsely granular. Fig. **17** is from the base of a very thin sheet of tin cast on stone. Fig. **18** shows a piece of hammered tin, by oblique illumination, etched with dilute nitric acid. The original structure has disappeared, and a finer crystallisation has taken its place. Annealing causes a growth of the crystals. Fig. **19** shows the structure of tin after annealing.

Zinc. An ingot of zinc shows dendrites similar to those of lead and tin. Fig. **20** shows part of a dendrite on the surface of metal cast on stone. There are three main axes.

Aluminium. On the sides and base of a bar of aluminium, where it has cooled in contact with the mould, dendrites of a leaf-like form are seen, and in **21** are several of these dendrites which are the centres of crystallisation.

Lead. Cast lead exhibits a dendritic structure, and the dendrites are the skeletons of grains or primary crystals. In **22** the secondary crystals are seen. This surface was the last to solidify in an ingot cast in stone. Etching brings out the primary crystallisation very distinctly.

Platinum. Fig. **23** shows dendrites on the surface of a platinum button. They consist of two axes at right angles, and form skeletons of the crystals, as in the case of the metals mentioned above.

Silver. Fig. **24** shows the surface structure of an ingot of silver. Three or more primary crystals are seen to be built up of numerous secondaries, possessing distinct orientation.

Gold. Pure gold crystallises in hexagonal crystals, which are built up of secondary crystals. Fig. **25** shows some of the dendrites met with in a slowly-cooled gold button. Rolling breaks down the primary crystals, producing a finer structure.

Alloys. When two or more metals are made to unite permanently, the resulting body is termed an *alloy*. When mercury is the chief constituent the alloy is termed an *amalgam*. Comparatively few of the metals possess such properties as render them suitable to be used alone by the manufacturer, but most of them have important applications in the form of alloys.

The condition of an alloy in the liquid state may be (1) either a solution of one metal in another; (2) a chemical compound; (3) a mechanical mixture; (4) a solution or mixture of two or all of the above; and similar differences may obtain in the solid state. A solidified solution is illustrated in the alloys of lead and tin. Copper and tin produce a chemical compound ($SnCu_3$). Lead and zinc form an example of a mechanical mixture.

The general effect of alloying metals together is to increase the hardness, lower the melting point and conductivity, and otherwise to modify the properties of the separate metals. An illustration of the hardening power by alloying is seen in the case of standard gold and silver; of the lowering of the melting points, in the case of fusible alloy; and the class of alloys known as brass forms a good object-lesson in varying changes of colour produced by alloying.

Properties of Alloys. Metals may be perfectly alloyed together when in the liquid state, but when poured into a mould there is often a tendency for the constituents to separate, causing the mass to be non-homogeneous. The reason of this is that the addition of one metal to another produces an alloy, the solidifying point of which is often lower than it should be according to calculations based on the fusing points of the separate metals. One particular mixture has a lower fusing point than any other possible mixture of the metals employed, and this is termed the *eutectic alloy* of the series. Apart from true chemical compounds, a fluid mixture of two metals begins to deposit its less fusible constituent first, and as the temperature falls, more and more of this constituent will be deposited, the other elements remaining in the fluid portion until it has acquired the eutectic composition, when it will solidify as a whole in the spaces left between the already solidified particles.

The more slowly an alloy solidifies, the greater will be this tendency to separate into two or more portions. Separation in the early stages of cooling may be partially prevented by mechanical agitation, such as stirring with a rod and by pouring into a cold mould. In some cases the difference in the fusing points of the general alloy and the eutectic is so great that they may be largely separated from each other by pouring off the still liquid alloy after the other portion has solidified. An alloy of silver and lead may be separated from copper in this way.

Preparation of Alloys. The usual method of preparing alloys is to melt the metals together in a crucible or furnace, but they may in some cases be produced by strongly compressing the metals together in the form of powder. Certain alloys, such as gold and copper, or copper and zinc, may be made by electro-deposition. Large quantities of alloys, chiefly those of iron and the rarer metals, are made in the electric furnace. Aluminium alloys are also made in this way

By the thermal method it is usual to melt the metal of highest fusion point first, and then to add the other constituents. Brass, consisting of copper and zinc, may be taken as an example. The copper is melted first because it has a much higher melting point than zinc, and the latter is also very volatile.

Alloys generally have properties differing from their constituents, and some alloys have these differences very strongly marked. Thus, if a very small quantity of arsenic be added to tin, the resulting alloy will have a crystalline fracture closely resembling zinc. Sometimes metals combine with evolution of heat, and sometimes with an absorption of heat. The following metals evolve heat when they are united—aluminium and copper, platinum and tin, arsenic and antimony, bismuth and lead. On the other hand, lead and tin when they unite absorb heat. Metals are capable of diffusing into each other if one of them be kept melted and the other in the solid state. Thus, if molten lead be kept in contact with gold or platinum, some of the gold or platinum will pass into the lead, and some of the lead will pass into the gold or platinum. Similar results occur with tin or bismuth

Copper Alloys. Copper forms with other metals a numerous series of alloys, and is valuable on account of its red colour, high malleability, ductility, softness, tenacity, and toughness, which properties it imparts in a great measure to many of its alloys. Of these the most important is brass, which is an alloy of copper and zinc. These constituent metals may be united in all proportions, forming alloys of a red or yellow colour, and other properties, according to the amount of copper present The best varieties are exceedingly malleable and ductile, harder than copper, easily worked, and have a lower melting point and higher tenacity. The composition and properties are shown in the following table:

ALLOYS OF COPPER AND ZINC

		Copper			Tensile Strength Tons per sq in.	Centigrade
Gilding Metal	Red	94			13	1,060
Pinchbeck . .	Red Yellow	90	8	(Lead) 2	12	1,040
Oroide . .	„	90	10	—	12	1,050
Talmi Gold	Gold	91	8	(Gold) 1	12·5	1,055
Rich Sheet Brass	Yellow	84	16		14	1,015
Bath Metal		80	20		14	1,008
Dutch Metal		76	24		13	980
Bristol Brass		73	27		13	960
Wire Brass		70	30		13	940
Mosaic Gold	Full Yellow	67	33		13	918
Muntz Metal		60	40		20	890
Delta Metal		58	39	(Iron) 3	30	900
Sterro Metal	„	56	42	2	—	
Brass Solder	Light Yell.	50	50		9	
„ „	White	48	52		8·5	870
Lap Alloy	Grey	12	88		2	600

Brass or brazing solders are used for joining parts of brass articles together. The solder must have a lower melting point than the metal to be soldered, and the above table clearly indicates the different temperatures for fusion. Some varieties of brass contain iron which increases the strength, hardness, and tenacity, but diminishes the ductility.

Bronze. Bronze is an alloy of copper and tin, but lead, zinc, nickel, manganese, iron, or silicon, is often added to produce certain effects, or to reduce the cost. Zinc in small quantities makes bronze harder. Iron and manganese also harden it. Phosphorus and silicon are used as so-called *deoxidisers*, influencing the removal or solution of gases, thus making the alloy more sound and compact, and forming hard, dense, and tenacious alloys. Sulphur and antimony tend to make bronze brittle. Arsenic acts much in the same way as phosphorus.

The physical properties of bronze depend on the composition, mode of manufacture, mechanical treatment, and rate of cooling. Starting with pure tin, the hardness increases with the addition of copper up to 35 per cent., and from this up to 73 per cent. the alloys are exceedingly brittle; beyond this the hardness diminishes as the copper increases. The alloy with 62 per cent. of copper ($SnCu_3$) is distinguished from all the rest by several characters; it presents the same homogeneous composition after repeated fusion, is peculiar in colour, has the highest density, exhibits the greatest degree of contraction, and is so brittle that it can be powdered in a mortar.

Minor Alloys with Copper. *Gun-metal* contains 8 to 11 per cent. tin, and the rest copper, but it frequently contains zinc in addition. *Bell Metal* contains 76 to 80 per cent. copper and 20 to 24 per cent. tin. Small bells are also made of brass. *Speculum Metal* contains 68 to 70 per cent. copper, and 32 to 30 per cent. tin It is white, takes a beautiful polish, and was formerly used for mirrors.

Special bronzes are made with or without tin. *Phosphor-bronze* is gun-metal to which a little phosphorus has been added. Aluminium bronzes are alloys of copper and aluminium, of which the alloy with 10 per cent. aluminium is the strongest. It has a gold colour, takes a high polish, and is very hard, malleable, and tenacious. The addition of 2 to 3 per cent. of brass increases its tenacity and renders it less liable to oxidation. *Aluminium brass* contains 2 parts copper, 1 part zinc. and 2 per cent. aluminium.

Manganese Bronze is brass to which 2 to 3 per cent. of manganese is added. The manganese in ordinary bronze is added in the form of ferro-manganese. This necessarily adds to the alloy 15 lb. of iron for every 80 lb. of manganese introduced.

Silicon Bronze is ordinary bronze to which 1 to 2 per cent. of silicon is added.

Nickel Alloys. German silver is an alloy of copper, zinc, and nickel. It is used as a substitute for silver, and as the basis of electroplated wares. The properties which make

German silver so valuable are its white colour, lustre, hardness, tenacity, toughness, malleability, ductility, and power of resisting certain chemical influences. When carefully prepared, it works well under the hammer and stamp and between the rolls, but it is advisable that the metals used in alloying should be as pure as possible, since small quantities of impurities, such as antimony and bismuth, seriously injure its working properties. Cobalt is sometimes added to German silver to the amount of 2 to 3 per cent., and improves the colour of the alloy. The following proportions make good working alloys:

Copper ..	52	54	54	56	58	60	60
Nickel ..	20	18	16	14	12	10	8
Zinc ..	28	28	30	30	30	30	32

German silver is made in crucibles by melting the requisite amount of a 50 per cent. cupro-nickel alloy, and adding the requisite zinc in the form of brass containing equal parts of copper and zinc

German silver is largely used by electricians for standard electrical resistances because it has a low conductivity, and because the conductivity is not greatly affected by moderate differences in temperature Platinoid, the electrical resistance of which is singularly constant through considerable ranges of temperature, is a German silver containing 2 per cent. of tungsten

Cupro-nickel, containing 75 parts copper and 25 parts nickel, is used for small coins, and an alloy of 80 parts copper and 20 parts nickel is employed for making projectiles

Refractory Materials. When a material is capable of resisting high temperatures without melting, softening, or decomposing, it is said to be *refractory*. Such materials are essential in the construction of furnaces in which most metallurgical operations are conducted; at any rate, refractory bricks and materials are required for the interior, where a high temperature prevails and the scouring action of metallic oxides have to be resisted. Refractory materials are used in the natural state, such as quartz, sand, alumina, oxide of iron, lime, magnesia, and fire clay; or they undergo a preliminary preparation before use.

The degree to which a substance is refractory depends on the circumstances under which it is employed, and chiefly on the substances with which it is brought into contact. For instance, silica (sand) heated alone to a very high temperature does not even soften, but if brought in contact with a base, such as lime or oxide of iron, union takes place with the formation of a fusible silicate. Again, many substances are capable of resisting a very high temperature if gradually raised to it, but have not the power of resisting sudden changes of temperature, as, for instance, when a cold crucible is suddenly placed in a hot furnace.

Silica and Alumina. In the form of quartz, silica is able to resist all ordinary furnace temperatures, and coarse grained sandstones, such as millstone grit, are frequently advantageously used. White sand is very refractory, and is a valuable material for furnace lining, for the beds of reverberatory furnaces, or, mixed with refractory clay, to form silica bricks for the roofs. *Dinas Rock*, found in the Vale of Neath, contains about 97 per cent. of silica, and, when powdered and mixed with a little lime or clay to make it cohere, is pressed into bricks. These resist very high temperatures, and are especially useful for the arches of reverberatory furnaces, as they expand with heat, but they will not withstand the corrosive action of metallic oxides *Ganister* is another siliceous material, largely used for lining Bessemer converters, and found in the lower coal measures of Yorkshire. It differs from Dinas rock in having the power of binding together when mixed with water. Natural siliceous stones are occasionally used for the hearths of blast furnaces and similar purposes.

Alumina is as infusible as silica, but is rarely found in nature in a pure state. *Bauxite*, which occurs in several localities in France, consists chiefly of alumina and oxide of iron. It is highly refractory, owing to the aluminate of iron that forms at high temperatures being very infusible.

Lime and Magnesia. *Lime and Magnesia* are practically infusible bodies, and strongly basic in character, but readily form fusible compounds with silica. These oxides occur as *dolomite*, from which material the lining of basic furnaces is prepared *Dolomite* consists mainly of carbonate of lime and magnesia, unlike ordinary limestone or chalk, and after it has been very strongly calcined it can be reheated and cooled as often as required without crumbling The most successful method of utilising dolomite or magnesium limestone is to fire it strongly, and then to grind it fine and mix pitch with it. The bricks made from this mixture are then strongly fired. Such bricks shrink considerably during firing, which gives them a more or less curved form, and they have to be set with similar material, which is very difficult to fire satisfactorily. In consequence of this, the calcined dolomite and pitch are made into a "slurry," or liquid mass, and run into a mould of the required size and shape, then consolidated by heat.

Clay. *Fireclay* is essentially a hydrated silicate of alumina, with varying amounts of lime, magnesia, oxide of iron, alkalies, and some free silica. The plastic property which clays possess is due to the chemically combined water. All clays have been derived from the disintegration of felspars, which occur in igneous and some stratified rocks. The character of the clay mainly depends on the nature of the rocks from which it originated, and to the extent to which the felspar has been decomposed. The refractory power depends on its freedom from oxides of lime, magnesia, oxide of iron, and alkalies.

Pure clay may be said to consist of alumina, silica, and water, represented by the formula Al_2O_3, $2SiO_2 + 2H_2O$, or approximately 46 silica, 40 alumina, and 14 per cent. water. The best china clay has very nearly this composition. The composition of fireclay ranges from 50 to 55 per cent. silica, 20 to 32 per cent. alumina, 2 to 4 per cent. lime, magnesia, etc., and 10 to 15 per cent. water. If raw clay be moistened with water, it can be moulded to any desired shape, and preserve its form after drying and baking. If, however, the baked clay be crushed up and again moistened, the plastic property will be found to have disappeared, because the baking at a high temperature has effectually removed the chemically combined water.

Refractory Materials. Refractory materials may be classified as *acid*, such as quartz and Dinas rock; *neutral*, such as graphite and chrome iron ore; and *basic*, such as dolomite, lime, oxide of iron, etc. In furnace construction, a basic material has been found in many cases, especially in steel making, a great advantage for the bed or bottom of a furnace; but basic bricks, as already explained, would not be suitable for the roof arches, because of their contraction on being heated. Hence it is necessary to build the roof with acid bricks. If acid and basic bricks touch each other, a mutual combination is likely to occur at high temperatures, so they are generally separated by a course of neutral material, of which chrome iron ore has been found very effective.

Firebricks are mostly made of fireclay mixed with quartz or burnt clay. The mortar for setting firebricks is prepared from the same materials as the bricks themselves, or from good fireclay, because lime mortar would not be suitable.

Crucibles and Retorts. For certain metallurgical operations, such as the manufacture of cast steel, the extraction of zinc, antimony, arsenic, and mercury, special vessels are employed, in the form of retorts, crucibles, muffles, tubes, etc., and these require to be made for the most part of refractory materials. *Crucibles* are made of fireclay, with sand, burnt clay, or other infusible material, so as to counteract the tendency which raw clay possesses of shrinking when heated. A good crucible should be capable of resisting high temperatures, sudden changes of temperature, and the corrosive action of metallic oxides. It should not be brittle or tender when hot. Some crucibles are required to withstand the corrosive action of metallic oxides, and in such cases the clay should be as neutral as possible, and not contain free silica. In order to test a clay as to its suitability for resisting high temperatures, it should be crushed up fine, sifted, mixed with a proper proportion of burnt clay and water, and kneaded to the right consistency. A piece of the clay is then shaped into the form of a prism or pyramid, so as to form sharp edges, carefully dried, baked and exposed to a high temperature in a covered crucible for some time. If very refractory, the test piece will show no signs of fusion. If the edges have become somewhat rounded it indicates incipient fusion, and if melted, the clay is useless. A similar piece should be tested in a reducing atmosphere by packing it round with charcoal in the crucible. In order to test fireclay as to its resistance to corrosion, the crucible may be half filled with copper, which is then melted, and a little borax inserted, so as just to form a ring round the edge of the molten metal, and yet leave the centre free for oxidation. The borax will absorb the oxide and rapidly corrode the crucible unless it be of excellent quality. The behaviour of the crucible under the weight of the copper melted indicates the other qualities of the crucible.

Plumbago Crucibles. Plumbago crucibles are made of clay and graphite, in the proportion of 51 of the former to 49 of the latter. Only certain varieties of graphite are suitable, the texture being of great importance. The graphite is picked, ground, sifted, and mixed with fireclay, and left for some time to *mellow* after it has been kneaded damp. The crucibles are moulded, dried, then burnt in kilns. An oxidising atmosphere must be avoided to prevent the carbon burning off.

The following analyses show the approximate composition of British materials used in furnace construction:

THE MYSTERY OF THE N-RAYS

Do the N-rays Exist? The Mysterious Discovery of M. Blondlot. The Fallacy of Human Vision. The Doubtful Result of the Camera. Prof. Rontgen and the X-rays

By Dr. C. W. SALEEBY

The Unity of Ethereal Vibrations. Everything goes to show that the one ether is adequate, as Faraday expected, for the explanation of light and of electromagnetic phenomena. Says Clerk-Maxwell: "The properties of the electromagnetic medium are therefore, as far as we have gone, similar to those of the luminiferous medium, but the best way to compare them is to determine the velocity with which an electromagnetic disturbance would be propagated through the medium. If this should be equal to the velocity of light we should have strong reason to believe that the two media, occupying as they do the same space, are really identical." We now know that, as Hertz proved, the two velocities are equal. Again, Clerk-Maxwell goes on to recount a number of difficulties which lie in the way of the acceptance of "the undulatory theory, in the form which treats the phenomena of light as the motion of an elastic solid" We cannot do better than quote his own words:

"The first and most important of these (difficulties) is that the theory indicates the possibility of undulations consisting of vibrations normal to the surface of the wave. The only way of accounting for the fact that the optical phenomena which would arise from these waves do not take place is to assume that the ether is incompressible.

"The next is that, whereas the phenomena of reflection are best explained on the hypothesis that the vibrations are perpendicular to the plane of polarisation, those of double refraction require us to assume that the vibrations are in that plane.

"The third is that, in order to account for the fact that in a doubly refracting crystal the velocity of rays in any principal plane and polarised in that plane is the same, we must assume certain highly artificial relations among the coefficients of elasticity.

"*The electromagnetic theory of light satisfies all these requirements by the single hypothesis that the electric displacement is perpendicular to the plane of polarisation.*"

New Kinds of Radiation. We must now turn from this theory of light, which completes, perhaps, a magnificent train of optical discoveries made in this country from the time of Newton onwards, and must consider one or two kinds of radiation, the very existence of which was unsuspected until recent times. Of these, by far the most important are the Röntgen rays, which have proved themselves to be of such very great practical importance. But in the first place we may address ourselves to the so-called N-rays which are sometimes named after their discoverer, M. Blondlot, of the University of Nancy, in France.

Did M. Blondlot See the N-rays? Let us begin in the first place by noting that some measure of doubt still exists as to the objective actuality of these rays. M. Blondlot has a sound reputation as a physicist, and there is no suggestion of fraud in his assertions, but for some reason or other there has been very great difficulty on the part of other men of science in obtaining the results which M. Blondlot believes himself to have obtained M. Blondlot worked at the subject for three years before he made any announcement. A number of French physicists confirmed the discovery, and a continuous flood of papers on the subject poured into the Paris Academy of Sciences for some time. The N-rays were promptly hailed as proof of "telepathy," and it was hoped that, since they are said to be specially emitted by active nervous tissue, they might be utilised in medicine The Blondlot rays are said to pass through aluminium or black paper, and, according to these observers, can be focused by an aluminium lens just as rays of ordinary light can be focused by a glass lens They seem to be emitted by almost all kinds of matter —and ceaselessly so. Professor Charpentier, of the Chair of Physiology at Nancy, declares that these rays are given out in special degree by living muscle and nerve. According to him it is possible, by using means to identify these rays, to trace the course of relatively superficial nerves in the forearm, such as the median nerve; and it is found that the amount of radiation increases when the nerve is at work

"Spectral" Rays. It would evidently be hasty, however, to assume at once that the discovery of these rays establishes an epoch in the study of telepathy, because there is no essential distinction between these supposed Blondlot rays and the rays of radiant heat which are also emitted by nervous tissue. The N-rays are said to include at least four sets of rays of slightly different properties, just as the octave of visible light includes many different colours. They are definitely asserted to be spectral rays -- that is to say, to lie in the ethereal keyboard, and not to be, in reality, material like the so-called alpha rays of radium. It is asserted that they can be reflected, refracted and polarised just like ordinary light, and that their wave length is measurable.

It was next shown, according to the French observers, that under certain other conditions a closely allied set of rays could be discovered, and these are known as the N_1-rays. And it seems to have been shown that, in the first place, nervous structures exceed all other substances, organic or inorganic, in their emission of the N and the N_1-rays; and, secondly, that the application of anæsthetics arrests the production of both by nervous tissue. It was at this stage in the history of the subject that the Paris Academy of Sciences, a body comparable in dignity and knowledge to our own Royal Society, awarded to M. Blondlot the Le Comte prize of 50,000 francs for the most interesting work in physical science (July, 1904).

Are the N-rays a Myth? A few months later the editor of the "Revue Scientifique" instituted an inquiry into the subject. He addressed questions to all the leading physicists in France, including such men as Becquerel, Berthelot, Moissan, d'Arsonval, and Professor Curie, whose recent death is to be deplored by all students of science. Now, if there is anything quite certain it is that no scientific question nor any other matter of truth or falsehood can be settled by a counting of heads. But, nevertheless, the opinions of men such as these are worth noting. The inquiry was well timed, for the question had become acute. A well-known Anglo-Saxon physicist had visited the laboratory at Nancy and could see nothing. He wrote a letter to "Nature" saying so. Also the subject was discussed during an entire sitting of a section of the British Association in 1904, and the general opinion arrived at was that the N-rays are a myth.

The result of this notable inquiry was most interesting, and may be typified by the translation of parts of two consecutive answers. M. Poincaré said: "I have made researches which have not given me results"; and M. d'Arsonval said: "I have made some trials which have perfectly succeeded"

Can We Believe Our Own Eyes? Of course, such differences of opinion as these give the enemies of science occasion to blaspheme. They say that if scientific methods are worth what they are said to be worth they should be able to solve such a simple question as this; but, as the present writer has pointed out elsewhere, "no matter is simple that involves anything so infinitely complex as human vision." M. Poincaré, for instance, goes on to say that he has a spasm of accommodation (that he is unable to relax the internal muscles of the eye, so as to focus it for distant objects); and it is asserted that one cannot observe these phenomena unless the accommodation be relaxed. This argument will appear quite reasonable to anyone who has tried to look into the interior of an eye with the ophthalmoscope, when it is essential for success (by the direct method) that the accommodation be relaxed, as if one were gazing at the horizon, though one is really trying to see an object not two inches distant. Then, again, it is perfectly well known, in the case of the sense of hearing, that different people have different capacities. Some can hear the shrill cry of a bat, while others cannot. Without doubt, the same is true of the visual sense. There may be very few eyes that happen to be capable of seeing these phenomena.

Sources of Fallacy. But this is by no means all. It is notorious that when experiments are repeated under what purport to be the original conditions, but without producing the original result, it is often found that the conditions have not really been similar. If the one experiment has been made in a room whose temperature was 60° F., while the other was five degrees warmer, the discrepancy may be accounted for. Frequently the discovery that such minute conditions are potent has led to important results. Then, again, if we assume that the N-rays have no objective existence, but are simply due to peculiar happenings in the eyeball of the observer, we have not yet explained why some observers obtain the results and others do not. Does not this immediately show that eyes vary?—which is what those who believe in the rays very properly assert.

There remains bad faith, which can be excluded in this case, and the influence of what the psychologists call *suggestion*. It may be that, especially perhaps in people with a French temperament, those who see the rays are those who believe most strongly in M. Blondlot's ability, and conversely.

From just about the time that the "Revue Scientifique" published the result of its inquiry, the flow of papers on this subject to the Paris Academy of Sciences ceased; and for a very considerable time practically nothing whatever was heard of the N-rays.

Evidently it is the photographic camera that should settle this question, once and for all, as it has indeed settled the parallel question of the canals of Mars. And quite recently, when many had almost forgotten all about the N-rays, they "turned up again." Photographic evidence was brought forward. The N-rays do not directly affect a photographic plate, any more than they directly affect the eye. The question all along has been whether the production of these rays really affects other luminous bodies, altering their brightness in the fashion which, as M. Blondlot asserts, can be readily seen by the eye.

Have the Rays Been Photographed? It now appears that the observers at Nancy have succeeded in photographing the result of the production of N-rays under certain conditions. Nevertheless, this question seems to be still destined for the production of doubt, and highly competent observers are now to be heard saying that when they repeat in every particular —apparently—the Nancy conditions, they do not obtain the photographic results which were there obtained. Hence it is impossible even yet to say for certain whether or not the N-rays are a reality. On the whole, perhaps, recognising the superior value of well-attested positive evidence, as against equally well-attested negative evidence, and remembering also that there is no inherent improbability, but rather the utmost probability, in the asserted existence of these rays, we may tentatively incline to the view that their objective reality will shortly be demonstrated. It would surely seem incredible that the present gaps in the ethereal keyboard, as we know it, correspond to actual gaps in

Nature; nowhere will there be found a physicist to doubt that from the longest electric waves—perhaps half a mile in length—up to the Röntgen rays, the length of which must be measured in millionths of an inch, there is perfect continuity. The assertion of M. Blondlot is no more than that he has discovered the means of production, and has detected the consequences, of certain of the rays, as to the necessity of the existence of which we all agree.

The Interpretation of Nature. "Man," said Bacon, "is the servant and interpreter of Nature," and Science, properly so-called, is not observation or experiment or calculation, but interpretation. The greatest of the names which have been mentioned hitherto in this course, and the greatest names in all the sciences, are not, after all, necessarily the names of the greatest observers or the most ingenious and patient experimenters; they are the names of the interpreters. The main principles on which we act, according to Bacon, in attempting the interpretation of Nature, are discussed in another course. But this present controversy about the N-rays affords a particularly instructive instance of the actual difficulties that may beset us.

In interpreting the facts, or alleged facts before us, we may be tempted in this case, as we are tempted, indeed, at all times, to assume that the explanation must be either A or B, or perhaps A or B or C. We then proceed to exclude each of these factors in turn until, having successfully excluded A and B, perhaps we can rest content in the belief that C is the true explanation. Now, the process of exclusion is an absolutely valid and efficient one if our assumptions are sound, but it leads to the most unfortunate consequences if they are unsound. The commonest defect of such assumptions is the omission of possibilities. For instance, if there be a fourth possibility, D, which we ignore, our inference from the exclusion of A and B—*viz.*, the inference that C is the correct explanation—plainly ceases to be valid.

The Possible Explanation of the Mystery. Now let us apply this to the present case. The more we think about it, the greater is the number of possibilities which we discover. It has been the particular endeavour of the writer to enumerate as many possibilities as he can, but he has no doubt whatever that there may be others—perhaps many others—which he has not recognised. Either (1) the phenomena asserted to have been seen by M. Blondlot have an objective existence; or (2) they have not. First, considering the latter possibility, we find a number of possible explanations of M. Blondlot's assertions: (1) That he is self-deceived; (2) that he is consciously dishonest; (3) that he and his fellow-workers are the victims of mutual suggestion; (4) that the eyes of M. Blondlot and those who have seen these phenomena differ in some specific way from the eyes of those who have failed to see them.

On the other hand, various possibilities may be assigned on the assumption that the N-rays have an objective existence: (1) That those who have denied their existence are dishonest; (2) that they are self-deceived; (3) that, in various attempts to confirm M. Blondlot's results, all the conditions have not been reproduced, even though all that he himself names have been reproduced. There may be other conditions which he himself has not recognised, but which are present in his experiments, are necessary for the production of the N-rays, and, as it happens, are not present when proof of the existence of these rays is sought for elsewhere than at Nancy.

We would appear to have completely exhausted, or more than exhausted, all the possibilities which have to be reckoned with if this problem is to be solved by the "method of exclusion" Yet there actually remains a possibility, which many will have forgotten, and which is not included in either of the two simple propositions with which we began. Perhaps it is quite possible that the N-rays have not an objective existence in the sense in which we have used the words, and yet that they have an objective existence. Nothing could appear fairer or more final than the simple alternative with which we started, and yet it was false, for it totally omitted to recognise the possibility that the so-called N-rays may be none other than the manner in which certain persons under certain conditions can appreciate some internal phenomenon of the retina Is such a phenomenon objective or subjective? The student of psychology cannot fail to answer that it is really objective, but then he has looked rather more deeply than most of us into the proper meaning and use of those adjectives. Such vision is now known as *entoptic vision*—that is, vision of what is *within the eye*.

Professor Röntgen and the Rontgen Rays. The remarkable Röntgen rays which we are about to study are very frequently known as X-rays, this being the name which was given them by their discoverer, obviously with the intention of indicating their unknown character. But in the last decade physical science has moved by tremendous strides, and the nature of these rays is no longer unknown There are sufficient phenomena in Nature indeed to which the term X may well be applied, and it is surely a pity that we should not now always use the name of the discoverer to indicate these remarkable manifestations of energy.

Professor Conrad Wilhelm Röntgen made his great, if somewhat fortunate, discovery on November 8th, 1895. The date is really a memorable one because of the amazing impetus which this discovery imparted to the progress of physics. Professor Röntgen still flourishes, and was the subject of a celebration held in Berlin last year in honour of the completion of a decade since his first observation. He was undoubtedly fortunate in not being anticipated by Sir William Crookes, after whom the Crookes or vacuum tube is named, for these tubes had actually been in general use, mainly for purposes of demonstration, for considerably more than twenty years before 1895. Dr. Hertz also, to whom we have already referred, had all but completed the observation of these new rays.

THE ART OF NORTHERN EUROPE

Renaissance Architecture and Sculpture outside Italy. Elizabethan Architecture. Wren. Painting in Flanders and Holland. The Van Eycks. Rubens and Rembrandt

By P. G. KONODY

Renaissance Blending with Gothic. Just as the Gothic style, born in the North, found the Italians reluctant to accept its tenets. so Renaissance architecture could only slowly force itself upon the Northern nations. In France and in Germany the new forms made their appearance comparatively late in the sixteenth century, and to a great extent lost their original purity through combination with Gothic motifs. The church of St. Eustache (A.D. 1532), in Paris. illustrates the blending of the two styles, and such French private buildings as the castles of Chenonceau and Chambord show the picturesque combination of Renaissance motifs with Gothic turrets and slanting roofs. One of the most graceful structures of the Renaissance in France is the famous winding staircase at Blois, which a recent critic has tried to prove to be designed by Lionardo da Vinci [see pages 3244-5] The Louvre. the Luxembourg. the Panthéon, and the Dome des Invalides in Paris, are notable examples of the French Renaissance. In Germany the castle of Heidelberg (A.D. 1545) is a remarkable instance of the blending of Classic decoration with Gothic sentiment. But in both countries the new style did not achieve complete victory before the seventeenth century, when its severe beauty had given way to the flamboyancy of the Baroque.

In England, the introduction of the Renaissance style is due to Italians, such as Torrigiano, the designer of Henry VII.'s tomb in Westminster Abbey, John of Padua, Giovanni da Majano, and Rovezzano.

Elizabethan Work. The Elizabethan style, "an attempt on the part of the English to translate Italian ideas into their own vernacular," was chiefly employed for richly-decorated private mansions and dwellings, of which we need only mention Longford Castle, built by John Thorpe; Knole, Kirby, and Penshurst. In the Jacobean period the Renaissance character became more pronounced, especially in the use of columns and entablatures. Holland House and Hatfield House may be quoted as notable examples. But Elizabethan and Jacobean buildings on the whole only form a transition from the Gothic to the pure Renaissance style, which appeared, with Inigo Jones, in the seventeenth century. This master's great buildings, such as the Banqueting Hall, Whitehall, and the Duke of Devonshire's villa at Chiswick, prove him a student and follower of Palladio. Inigo Jones was followed by Sir Christopher Wren, the builder of St. Paul's and several other beautiful churches. He died in 1723.

Northern Renaissance Sculpture. The progress of sculpture in Northern Europe cannot be followed as easily as in Italy. for in spite of the colossal output of artistic work in France, Germany, and the Netherlands there is a lack of brilliant individualities which stand forth as landmarks of the progressive

stages of development. Local schools there were in vast numbers, and throughout these countries the same tendency is to be noted; but few, indeed, are the men whose names have been handed down through the ages as creators of masterpieces. Love of carefully-studied detail, clear rendering of facial expression, close adherence to nature, and delight in rendering the various textures are the chief characteristics of Northern Renaissance sculpture, which could never rival the triumphs of Italy, partly owing to the lack of classic examples, partly to the absence of the suitable material — the marble of which the Italians had an abundant supply.

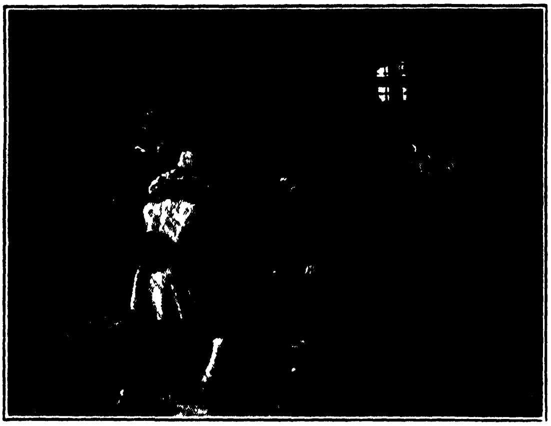
Wood-carving in Germany. During the fifteenth century the art of wood-carving reached an extraordinary degree of perfection in Germany. The tendency of the carved wood statues and altars with many figures in high relief, was distinctly pictorial, especially in the restless arrangement of the draperies; and painting and gilding were frequently resorted to to enhance the effect. Nuremberg at that time became the chief centre of German arts and crafts. It is almost essential to visit this quaint old-world city to form an adequate idea of the art of this period, for it harbours the chief works of such masters as Veit Stoss, the wood-carver; Adam Krafft, the stone-sculptor; and Peter Vischer, the bronze-worker, who is the author of the famous figure of King Arthur in the "Hofkirche" at Innsbruck.

Sculpture in France and England. In France the chief works of sculpture produced between the Gothic period and the triumph of the Italian influence of the masters summoned by Francis I. to Fontainebleau, are to be found among the monumental tombs at Dijon, Amiens, Rouen, St. Denis, and Bourges. Then Primaticcio and Rosso started the Italianising school of Fontainebleau which produced sculptors like Jean Goujon and Germain Pilon. The naive realism of the earlier sculptors had now given way to an elegant and sometimes mannered style, the chief aim of which was decorative effect. The reliefs of the Fontaine des Innocents, at the Louvre, in Paris, represent Goujon at his best; whilst Pilon's Three Graces, likewise at the Louvre, illustrate this master's exaggerated elegance. What little indigenous style there was in English sculpture was stifled by Torrigiano, Benedetto da Rovezzano, and other Italians called to England in Tudor days.

The rise of pictorial art in the North coincides with the invention of oil as a medium for painting by the brothers Jan and Hubert Van Eyck, at the end of the seventeenth century. And curiously enough, Flemish painting, at its very beginning, appears at a stage of development which Italy had only reached by slow and gradual steps. The Van Eycks are great masters, not only by comparison with those that went before, but even if measured by those that followed them. We have already seen how the conditions imposed by the Gothic architectural system limited the painter's activity to small panel pictures, so that his attention was fixed on the elaboration of minute detail, instead of monumental massing of line of form, and on soulful expression instead of stateliness of pose.

Oil Painting in Flanders. The new school arose in Flanders—the Belgium of to-day—which was then one of the chief commercial and industrial centres of the world. The brilliant pageants of the Flemish cities with their constant coming and going of wealthy traders from every part of the world, must have been a powerful stimulant to the local painters, who had ample opportunities of feasting their eyes on colour, and studying the types and costumes of the seething international crowds that filled the streets and markets.

The Van Eycks. Hubert Van Eyck was born about A.D. 1366, and worked principally at Bruges and Ghent. The subject matter and symbolism of his paintings are still quite mediæval, but the actual incidents, costumes and types, architecture and landscape, are lovingly and faithfully copied from the scenes which he had daily before his eyes, and set down with painstaking precision, which was only surpassed in minuteness by the work of his brother Jan. The "Adoration of the Lamb" [77] is their chief work. Rogier van der Weyden, born in A.D. 1400, was a little less literal in his transcripts of nature, and more emotional in expression. Hans Memlinc, a Bruges painter of German origin, born about 1430, is the most lovable painter of a school which too frequently delighted in the realistic representation of scenes of tortures and other horrors. In him the realistic tendency of the school finds expression in the wonderful rendering of landscape and accessories, but he was an artist full of tender feeling and poetry, with a rare sense of feminine purity and innocent grace. Gerard David, who was born about 20 years later and worked at Bruges at the end of the century, was much influenced by Memlinc, and is distinguished by a glowing sense of colour and beautiful line. Quentin Matsys, born 1460, practised portraiture and genre, besides religious art, and marks a decided advance in expressive modelling. With Mabuse, who died in 1532, and even more with his contemporary, Raphael's pupil, Bernard van Orley, the Italian influence begins to filter through the local tradition, and in the case of the latter is to be detected in a more ample sense of design and a departure from the severe exactitude of the earlier masters. But what had been the result, in Italy, of centuries of slow development, could not be transplanted in its mature form to foreign soil, and became mere mannerism with the later Flemings, until a new era of superb artistry dawned with the advent of the great Rubens.



79. "THE DELIVERANCE OF ST. PETER," BY TENIERS THE YOUNGER
(From the Wallace Collection, London)

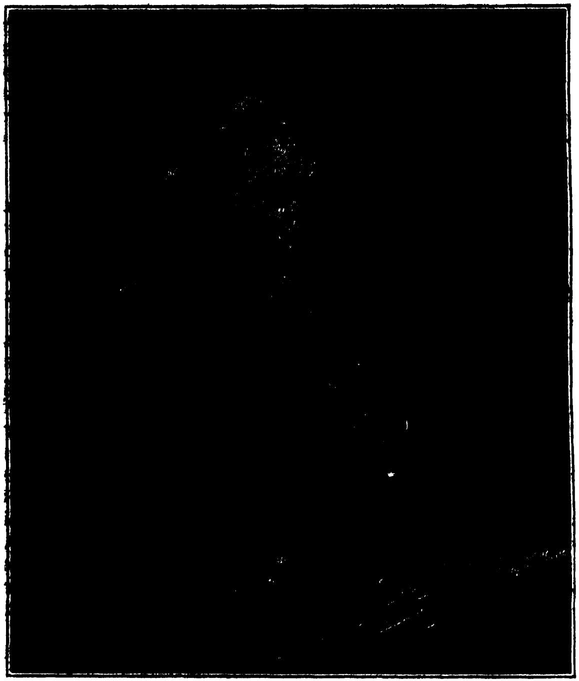
Rubens. Rubens (A.D. 1577-1640), too, had drunk at the same source of Italian art, and his early work in particular evinces his love of Venetian colour, but he brought into his painting a strong, virile, and altogether personal temperament that could never have been content with mannered imitation. A colourist of tremendous power, Rubens excelled above all in the painting of flesh, in which he stands unrivalled to this day. One may be repelled by the coarse, fleshy type of his women, but the mastery with which he expressed with bold, sweeping strokes of luminous paint the roundness of form, the texture of the skin, and the very blood coursing under the skin, irresistibly compels one's admiration. The passionate movement, the vigour and verve of his work, seem to exclude the possibility of a deliberately calculated design, and yet the noble disposition of his figures, the effective massing of light and shade are as "scientific" as the movement and sensuous colour are instinctive. Rubens was the most worldly of all painters, yet he could treat a religious subject with a reverent spirit [78]. He was equally great in portraiture, in genre, in landscape, and in animal painting But it should be remembered that in accordance with the custom of the period, he had a horde of assistants working under him, and many of the inferior pictures that pass under his name owe to him merely their conception, while the execution is entirely due to his pupils.

Van Dyck. Much the same remark applies to the greatest of his pupils, Van Dyck (A.D. 1599-1641), who, as Court painter to Charles I., exercised so potent an influence on English art that he may rightly be considered the real founder of the great English school of portraiture. Indeed, many of the paintings turned out from his studio at Blackfriars during his English period are the work of his numerous assistants, save for the first sketch and the finishing touches. Van Dyck, too, studied for some years in Italy, where, like his master, Rubens, he fell under the spell of the Venetians. An accomplished courtier and man of the world, he became the favourite of society in his native country, as in Genoa and in England His pictures are a perfect mirror of the English aristocracy of his day, reflecting their taste and distinction and effeminate elegance. As a colourist, he was more subtle and refined, if less vigorous, than Rubens.

The coarser side of Rubens's art attracted Jacob Jordaens, whose lack of refinement is scarcely atoned for by his great technical skill and good humour. Franz Snyders (A.D 1579-1657) was a brilliant animal painter, whilst Jan Fyt and Jan Weenix excelled in still life, generally of dead game. Melchior Hondekoeter devoted himself almost exclusively to the bird life of the farmyard. All these masters were great colourists, and stand supreme, each in the narrow range he imposed on his art.

Growing Popularity of Art. The earliest Dutch painters, among whom Dierick Bouts and Lucas van Leyden are the most prominent, were almost completely dominated by the genius of the Van Eycks and the other early Flemings. In fact, in their early stages, the two schools can scarcely be considered separately. Then came the Reformation and the War of Independence, which resulted, in 1648, in the final shaking off of the Spanish yoke. The long period of warfare and bloodshed was not favourable to extensive art production, but when Protestant Holland issued victorious, a great period of art commenced—of art led into new channels, since Protestantism looked askance at religious painting, and preferred bare, white-washed walls in the churches to an imagery of glowing colour. On the other hand, a demand for art arose in the civic community. The well-to-do citizens enlisted art for the adornment of their living rooms, and the subjects favoured were no longer, as may well be imagined, flagellations and crucifixions, and images of the Virgin and saints, but portraits, landscapes, genre scenes depicting the daily life of the burghers and peasants, and, for the guild halls and other official buildings, large portrait groups of prominent burghers.

Pictures in the Dutch Home. Of idealism and ideology, there is little or nothing in Dutch art which is entirely based on love of nature and on the keen appreciation of the value of pigment. The rich quality of the paint, the subtlety with which the play of light and shade on objects and textures is observed—these were the chief points that appealed to the Dutchmen. These little genre scenes—interiors of burghers' houses, with ladies before a mirror, or occupied with books or musical instruments; or tavern scenes depicting the life of the humbler classes—are never of anecdotal or literary character; they are just glimpses of real life stated in terms of ornamental craftsmanship. Of this nature are the precious gemlike pieces of Terburg, Vermeer van Deft, Metzu, Jan Steen, Mieris, Gerard Dow, and, in Flanders, of the Teniers, who had more in common with the Dutch "small masters," than with the Flemings. Fig. 79 is an example by the younger Teniers.



80. "ST. MATTHEW," BY REMBRANDT Mansell
(The Louvre, Paris)

Frans Hals. But the seventeenth century small masters were preceded by a few men who must rank among the very giants in the realm of painting. Rembrandt is one, and by no means the least brilliant, of the great triple constellation that stands out from the firmament of art, the compeer of Velasquez and Titian. Before him, Frans Hals (A.D. 1584-1666) had achieved the greatest triumphs in bold, daring portrait painting. For sheer bravura and dashing brushwork and brilliant characterisation, Hals has probably never been equalled, and his large "Doelen" groups at Haarlem are an inexhaustible source of delight to all who can appreciate masterly brushwork. Then, Van der Helst (A.D. 1613-1670) may be taken as the most capable of the numerous serious portrait painters who recorded with faultless conscientiousness in a somewhat tight manner the features of civic dignitaries and their buxom housewives.

Rembrandt the Revealer. But with Rembrandt (A.D. 1606-1669), all hardness, one might almost say all linear design, was abandoned, and everything that the artist's eye could see, or his brain conceive, expressed in terms of soft lights and shadows and golden, liquid half-shadows. Everything is given plastic form through the play of light on the surfaces which are seen through the surrounding atmosphere [80] In his golden illumination and forced contrasts, Rembrandt is, perhaps, not always strictly true to nature, but he has the power to make us feel that, if such conditions of light were possible, faces and objects would appear just as he has set them down [see "The Night Watch," reproduced on page 724]. Rembrandt is the antithesis to the Italians of the Renaissance, who were ever striving for beauty. With him character is everything, but the mastery of his brush and his sympathetic insight into the very soul of his sitters give beauty even to subjects repellent in themselves. Apart from his paintings, Rembrandt's etchings alone would entitle him to one of the most exalted positions among the world's great artists. As a master of the burin he has never been approached.

HARMONIUM & AMERICAN ORGAN

Character and Mechanism. The Stops. Practice and Exercises. Keyboard Study. Fingering

By J. CUTHBERT HADDEN

THE harmonium, in common with several other instruments, traces its origin to the invention —speaking more correctly, to the revival—of the free reed. The free reed is so ancient that they say it was employed for musical purposes in the time of Confucius. At any rate, its revival in Europe dates only from the beginning of the nineteenth century; and the harmonium was the instrument in which it was most effectively revived. The sounds of the instrument are produced entirely by these reeds —thin tongues of metal set in motion by currents of air from the wind-chest: called reeds because they correspond in principle with the shepherd's pipe; *free* reeds, because the tongue moves freely in the orifice of the frame, thus differing from those of the organ, which strike against the frame at each pulsation, and are termed *beating reeds.*

The Youngest Keyboard Instrument. If we except the American organ, the harmonium is the youngest of all keyboard instruments. Though it had several tentative predecessors, it may be fairly said to have been invented and first brought out by M. Alexander Debain, of Paris, whose patent was dated August 1840. Since then it has been successfully improved by various makers, mostly French, until, in the best specimens of its class, we have now an instrument of the utmost possible perfection. Its capabilities are considerable. For accompanying voices, for church and domestic purposes, for solo work, for duet playing with other instruments, such as the piano, it is invaluable. The variety of beautiful effects and the delicate shades of tone-colour which may be produced on a good and fairly large instrument not even the organ itself can excel.

By the use of the *Expression* stop, for example, the harmoniumist gains a power of increase and decrease of sound almost equal to that which the violoncello player secures by means of his bow. The harmonium is often regarded as a long-suffering, unpopular instrument. This is really because there are so few who are capable of handling it to advantage. The pianist is supposed to be able to play it without any special study; the organist, too, as a matter of course. Here is the cardinal mistake. The harmonium must be studied by and for itself.

The American Organ. It will be seen that we have bracketed the American organ with it. Rightly so, for the keyboards of both instruments are practically identical, and the method of playing both is entirely identical. It is only in their internal construction and in the quality of tone produced that the two instruments differ. In the harmonium the wind is forced *through* the reeds, while in the American organ it is *drawn in.* It is this that accounts for the more delicate tone of the American organ as compared with that of the harmonium; which instrument, however, has more character and greater distinctiveness, besides being more quickly responsive to the finger of the player. For solo purposes the American organ is of great use, the stops in the right hand being well suited for giving prominence to a melody, while in good instruments the left-hand side always furnishes one or more soft stops for accompaniment. About the tone, as a whole, there is a more general approximation to that of the church organ than in the case of the harmonium. It is therefore more peculiarly adapted for sacred music, and perhaps also for chamber or domestic use.

But the harmonium has much more "carrying" power, and is thus specially suitable for conditions to which the American organ cannot be so well applied. As one of its advocates has put it: "Where a large number of voices are to be accompanied, or where power and marked delivery are called for, in church, concert, or school work, the harmonium, not to speak of its superior hardiness, possesses immense advantages over the American organ." It is, then, the harmonium that we deal with specially in these lessons, which, however, so far as playing is concerned, are equally applicable to both instruments. When points of difference arise as regards the treatment of the individual instruments, they will be carefully explained.

Buying an Instrument. Perhaps, before going further, a word or two should be said about the purchase of an instrument. Small harmoniums and American organs can be had for £5. Many (not all) of these are quite good enough for the learner's purpose. Larger-priced instruments simply mean more stops; which, again, mean on'y more variety of tone. To the learner, variety of tone is not essential—he does not know how to use it to advantage—and, if money is a consideration, he need not hesitate to buy an instrument at the price just named, provided it is by a maker of some standing. Naturally, we cannot advertise names here. We can only advise the student to go to a firm with a reputation for honourable dealing, state the price he is prepared to pay, and make his own selection from the instruments submitted to him. Beware of "bargain" instruments advertised to be sold "at a sacrifice." Large firms have always a number of second-hand instruments for sale—instruments that have been out on hire or taken in exchange—and a capital instrument, a genuine "bargain," may often be got in this way for a comparatively small sum. Be sure, at any rate, that you secure an instrument with a tone that pleases you. A harsh, unmusical chest of reeds will soon disgust you, besides having a deteriorating effect on your ear. Thus, on every ground, it is advisable to put yourself in the hands of a trustworthy expert with a reputation to sustain.

The Mechanism. Now we are ready to give our attention to such of the mechanism of the harmonium as it is expedient for the student to be acquainted with before beginning actual work at the keyboard. We have spoken of the reeds, termed now more generally *vibrators*. Well, to every digital on the keyboard there is a separate vibrator, and a harmonium must always have at least one full row of vibrators. Instruments with six and seven sets of vibrators are common ; those with eight or more often have two keyboards. We shall learn further about this when we come to deal with the stops.

The external mechanism may be said to be represented by the foot-pedals for blowing. By these the bellows are fed ; they force the air through the wind-trunk into the wind-chest, from whence (if the Expression stop is not drawn) it proceeds to the reservoir in an equal and continuous stream. When the Expression stop is drawn, all communication between the wind-chest and the reservoir is cut off, so that the air goes straight to the reeds. It is thus directly under the control of the player, whose least change of pressure upon the foot-pedals produces a like change in the strength of the sounds. It is important that the student should note this, for the Expression stop (more will be said about it) is the most difficult piece of mechanism to manage in the harmonium, and an ill-regulated use of it may easily damage the instrument.

The Stops. Under the head of mechanism we may fairly consider the various stops. We will take the harmonium alone here, for in this matter of stops the American organ differs. Makers, unfortunately, do not agree as to the nomenclature of every stop placed in their harmoniums. In most instruments, however, the first four stops on each side will be found to correspond. They are as follow:

LEFT-HAND SIDE	RIGHT-HAND SIDE
① Cor Anglais	① Flute
② Bourdon	② Clarinette or Clarionet
③ Clarion	③ Fifre or Fife
④ Bassoon	④ Hautbois or Oboe

The numbers, you observe, are repeated on both sides. Why ? Because each stop goes only half way. Thus, if you draw a stop on the right-hand side without drawing anything on the left-hand side, you will get no sound below F at the middle of the keyboard. In reality, therefore, though you have on your instrument the eight stops enumerated above, you have only four separate kinds of sound.

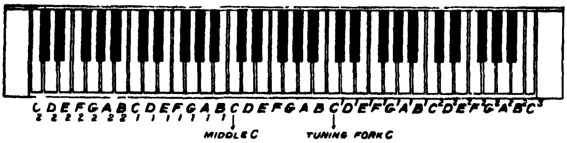
Division Stops. It may be asked why one stop should not be made complete—to run from end to end of the keyboard ? The reason is that it is not always necessary or desirable to have the same kind of tone in both treble and bass. For instance, a melody may be played on the *Hautbois*, and accompanied with the left hand on the *Cor Anglais* ; or a tune may be " brought out " in the bass on the *Bassoon*, with a light right hand accompaniment on the *Flute*. This will be better understood when we come to speak of the combination and individual tone qualities of the stops.

In addition to the sounding stops enumerated above—and others found in large instruments—there are usually six stops of a purely mechanical nature. One is the *Expression* stop, already mentioned. Another is the *Grand Jeu*, which brings out the full power of the instrument at once—in fact, all the stops. Then there is the *Sourdine*, assigned to the bass part of the *Flute* stop. It regulates a contrivance whereby a smaller quantity of wind is supplied to the reeds, thus modifying the strength of the tone. The *Tremolo*, again, alternately opens and closes the wind-chest, thus producing the effect from which it takes its name. Finally, there are the two *Fortes*—one for each side of the instrument—which simply increase the volume of sound by the opening of a sliding or revolving wooden shutter above the reed. Thus provided with mechanical stops, our original instrument, as above, mounts up to the imposing total of fourteen " knobs."

American Organ Stops. In the American organ one or two of the harmonium stop names are repeated, but the names are, as a rule, peculiar to the instrument itself. In the harmonium the arrangement and naming of the stops are—as regards the first four on each side, at least—practically stereotyped. In the American organ, on the other hand, you can never be sure of what you have on any particular instrument till you examine it. The diversity is indeed so great, different makers using a nomenclature according to their own fancy, that any attempt at an ordered list of stops would be futile Generally speaking, however, the *Melodia* and the *Diapason* correspond to the *Flute* and the *Cor Anglais* of the harmonium ; the *Flute* and the *Viola* to the *Fife* and *Clarion*. That is to say, the first two give the standard pitch, making therefore the " foundation " tone, while the second two produce sounds an octave higher than the written notes. A stop called *Sub-bass*, providing reeds of 16 ft. tone—an octave lower than the written note—to the lowest octave of the instrument is frequently met with. Take care in using it that all the notes of the bass are confined within its range.

With mechanical stops and accessories all good American organs are well supplied. Among the former are the two *Fortes* of the harmonium, but their use is restricted—the one on the right to the *Diapason* and *Melodia* stops ; that on the left to the *Viola* and *Flute*. The octave coupler couples every key with the reed an octave above or below ; in some instruments only above, in others only below. The *Vox Humana*, a leading feature of the instrument, controls a fan behind the soundboard ; the fan, being made to revolve rapidly by the pressure of wind, meets the waves of sound, and gives to them a pleasing vibrating quality much more delicate than that produced by the *Tremolo* stop in the harmonium. Large instruments have, in addition, a *Tremulant.* Every instrument has at least one *Knee Swell;* most instruments have two. That at the right of the player opens the swell when pressed towards the right; that at the left is usually a full organ "stop," so that by pressing it to the left as far as it will go, all the speaking stops of the instrument, except the *Voix Celeste,* are made to sound. Both swells return, when allowed, by the force of a spring.

Study of Keyboard. Now, after all this preliminary, we are ready to sit down at the instrument. As we do so, let us look at the keyboard, so that we may know where to find any note as we may want it.

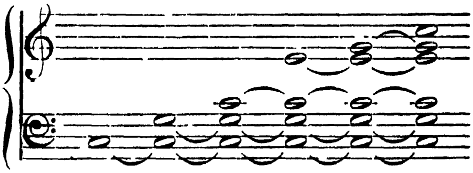


C D E F G A B C D E F G A B C D E F G A B C D E F G A B C D E F G A B C
MIDDLE C
TUNING FORK C

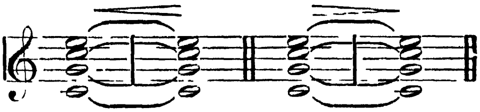
In the case of the American organ, the keyboard compass is also five octaves, but the instrument usually begins and ends with F. Instruments are, however, made with what is called the "C compass." In any case, the order of the notes is, of course, the same, the "blacks" being in groups of twos and threes alternately, with the "whites" between. If the student does not already know the names of the keys, and cannot readily pick out any given note, he had better master that point at once.

Position. All this time we have been sitting at the instrument. But something must be said about that very process. It seems a simple enough matter to get seated in front of a harmonium, but it really is not. Nothing is more important to the harmoniumist than efficient blowing; and in order to secure it—to secure control over the bellows—a good position at the instrument is essential. If the chair is too high, the blow-pedals cannot be depressed the whole way, and the player will run, besides, the risk of sliding off the seat. Again, if the chair is too low, the entire underpart of the feet will be thrown on the pedals, with the toes pointing up towards the knees. In this case you will find it difficult to exert any downward force upon the footboards, and will be gradually pushing your seat back. The chair, then, should be of a suitable height, and placed exactly in front of the middle of the keyboard. Keep the knees about an inch from the front of the case; see that only the toes and ball of the foot are placed on the pedals—the heels being left free—and think of the act of pressing as forwards rather than downwards.

The Blowing. Blowing is supposed to be quite an easy performance. It is by no means easy—that is, to blow so that a steady, continuous tone shall be produced. The student ought certainly to learn to blow first, before taking up keyboard work; and if he follows this advice he may as well learn to blow at once with the Expression stop, and thus overcome two difficulties at the same time. Let him draw, then, the Expression stop and the stops marked (1) on each side. Press down one of the digitals near the middle of the keyboard, say F, and begin blowing with the right foot only. When the pedal has reached its limit, the sound will cease. A similar result will follow the use of the left pedal. Obviously, if a continuous sound is to be produced, one pedal must be depressed while the other is rising. Here the learner will find his chief difficulty. His primary efforts will almost certainly result in a series of jerky, spasmodic sounds; and there is nothing for it but to go on practising until the sound becomes even. Get the one sound (the F) even first; then add the third above—namely, A—and be sure that you have the same good, steady tone. Add next the fourth below the original F—namely, C—and listen carefully again. Finally, strike in with the octave below the starting note; and if, with all four notes sounding together, you are able to command an even tone, you may go on to practise the following more elaborate exercise in blowing:



Here the keys are, of course, to be pressed down in the order of the notes, the previous note always being retained when the other is added. Another chord, such as this, might be taken for the practice of crescendo and diminuendo:



When these exercises can be done satisfactorily the student may assure himself that he has learnt to blow. One word of caution—beware of falling into the habit of blowing in time with the music. This is a serious, as well as a quite inexcusable, habit, for when the *tempo* is rapid the reeds will run the risk of being damaged by overblowing. Lastly in this connection, avoid all kinds of mannerisms at the keyboard. Try also to keep the body perfectly steady, without any swaying from side to side or backward and forward.

Practice. In proceeding now to direct the practical studies of the pupil, it is necessary to mention at once certain books of exercises for his use. It is, of course, assumed that no pupil starts without knowing something of the theory of music, and without being able to "read" with fair facility from the stave. More than that we do not ask. Nevertheless, the writer of these lessons must recognise the fact that many who can already play the piano want to take up the study of the harmonium or American organ.

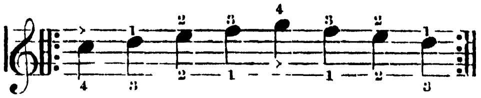
Obviously, for such students, the course must be somewhat different from that to be laid down for the pupil who cannot play any keyboard instrument at all. The one will have to learn everything from the beginning; the other will only have to learn to blow, to practise a new style of fingering, perhaps to exercise himself a little more in reading four-part harmony, and generally to adapt himself to the peculiar conditions of the harmonium as an instrument of sustained sounds.

For the student who can already play the piano, we recommend Mr. King Hall's "The Harmonium," in Novello's series of music primers. For the student beginning from the beginning—and he will receive, of course, our chief attention—especially the student who aims at the practice and rendering of church music, there is no better book than "The Harmony Player for the Harmonium," edited by John Curwen. [See note *re* exercises on page 3860.] This work is also easily adaptable to the American organ, but if the student of that instrument can play a little already, he will probably prefer Dr. Stainer's "Tutor for the American Organ," published by Messrs. Metzler. Direct reference to all these works will be made in the course of our lessons. Let it be added that each in some way supplements the other, so that the individual student, beginner or not, will find the interest of his work greatly increased by having all three at hand.

Phrase Fingering. We will imagine, then, the beginner sitting down to a practical study of the "Harmony Player." He must first understand something of the plan of the book. It has two essential features: (1) a new art of fingering (new so far as reducing it to a system is concerned); and (2) a study of the chords more commonly met with concurrently with their production by the fingers. Of late years an improved fingering has come into use in which the player looks forward and studies the range and other peculiarities of the harmonic phrase before him, and adapts his fingering to its needs. Experience shows that this plan is much superior to the elaborate system of scale fingering once so much in vogue; a system which, as a matter of fact, is totally foreign to the character of the music generally played by the harmoniumist. "Phrase fingering," then, as it has been appropriately termed, is the first essential feature of the "Harmony Player."

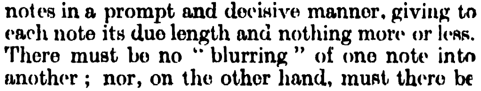
The second feature touches the fringes of theory in such a way as to make practice both easier and more interesting. An intelligent knowledge of chords and chord progressions which have to be played helps the fingers in a way which those who are entirely ignorant of harmony would scarcely believe. It helps the eye, too, in reading the notation, for certain harmonic combinations are so fixed in their progressions that the player can often dispense with a visual following out of the individual parts on the staves.

Finger Exercise. We now want to get the hands a little into shape, and for that purpose select the following five-finger exercise. It looks absurdly simple, but remember that it is the "carriage" of the hand and the correct placing of the fingers upon the keys with which we are concerned just now. It will be understood that the upper line of fingering is for the right hand, the lower for the left, and that the × signifies the thumb. The left hand will, of course, be played an octave lower than written.



Let us take the right hand first. Look at the plates in the "Harmony Player," and copy the positions there shown. The thumb being placed above C, notice that all the fingers are exactly above the keys which they are to depress. When not actually in use, there is a tendency to let the thumb hang off the finger-board. It should be kept persistently to its place, about half an inch on the digitals, otherwise, when it has to be used, there will be an awkward shifting forward of the whole hand. At the moment of striking the note D, the thumb must be raised and the second finger held in readiness for the note E. Each finger will thus, in turn, come to be used when we reach G, and the exercise should be repeated again and again, until the hand has assumed its proper position and the player feels that position to be natural and easy. Be careful to get an exact "touch"—that is, to strike the notes in a prompt and decisive manner, giving to each note its due length and nothing more or less. There must be no "blurring" of one note into another; nor, on the other hand, must there be the least perceptible break between the sound of one note and another. Practise the two hands separately, and when each has gained its own facility, let them be combined. Continue this exercise till the fingers move like automatons. Then transpose it into the key of G, and repeat the process. You may also try the keys of D and F, remembering that the third note of the former will be F♯, and the fourth note of the latter B♭. There may be at first a slight difficulty in placing the fingers evenly and firmly on the black digitals; but that, too, is a thing to be mastered by persistent practice.

When you have so far exhausted this preliminary exercise, take the following five-finger exercise, practising first the right hand, then the left, and finally both hands together. Never attempt to combine the two hands until each can do its own part easily.



Strengthening the Fingers. This exercise will be found valuable for strengthening the fingers. Some hands will require to practise it more than others. It all depends upon what one's hands have had to do in the business of life. But do not get disheartened if the muscles are stiff. It is only a question of time and practice. This second exercise may, if persevered in, cause at first a little pain, but that must be borne. Do not persist, however, in giving the hands more than they can do at any one time; rather allow them rest, and resume after a certain interval. Finger exercises are of the utmost value, and cannot be dispensed with by anyone who desires to become even a tolerable player. Merely practising the difficult passages which occur in classical compositions is not of itself sufficient; and, indeed, without a previous course of finger-training such passages will often be found impossible of execution. When you have practised the above exercise for some time in the key of C, as written, transpose it into the keys of G, D, A, E and F, still preserving the same fingering as in the example. This will assist further in the "handling" of the black keys.

Playing Separate Parts. You will have now gained a certain independent action of the hands, and will be ready to play separate parts in each. For this purpose, turn to the "Harmony Player," and look at Ex. 8. You will see that the left hand has here a part of its own, consisting of the notes C and G, used alternately. Observe that in the second, fourth, tenth, and twelfth bars, two notes are played in the left hand while one is held on in the right. The fingering is not marked beyond the first bar, but, of course, as the compass is only C to G (five notes), in both hands, the five fingers occupy their original places. Ex. 10 is of a similar nature in key G. The left-hand part is, in fact, exactly the same as in Ex. 8, and the right-hand part has been given already in Ex. 9, which should be played over several times previously. Ex. 12 is a further development of the separate action of the hands, a peculiar feature being four notes in the left hand against one note in the right. Notice that toward the end the left-hand part rises diatonically from C to G, while the right-hand part also moves. This is the first example of the kind, and will require careful practice. Do not leave this exercise until you can play it with freedom without looking at your hands. Then take the exercises as they follow in order, noting that in Ex. 16 the bass again rises a fifth by diatonic progression.

Exercises 17 and 18 will require careful study in the separate parts before combination is attempted. The difficulty arises from the hands being kept at a greater distance than they have been accustomed to in the previous exercises. In Ex. 19 note that the right hand has two beats of a rest while the left plays B and A. Be careful to lift the first finger of the right hand at the moment the A has received its due portion of time. In Ex. 20 the same rest occurs in the treble part, which latter moves in a form known as sequence—that is, one phrase following the other on a definite plan at a higher or lower degree. Exercises 21 and 22 should be well practised; they are for strengthening the third finger, which, being the least used in ordinary life, and also for a physical reason, is the weakest of the fingers. Schumann invented a little machine for "bringing it right," as he vainly supposed, and many players used to have its stiffening tendon cut. Better to get even with it by ordinary finger exercise, persistently and systematically pursued.

New Keys. We are now supposed to have carefully worked through the first step of the "Harmony Player." In this step the exercises have been *written* in only two keys—C and G, and there have never been more than two parts. The second step brings forward the keys of F, D, and B♭, and the exercises are in three parts. The first two (25 and 26) present the new difficulty in the most elementary way—that is, with a considerable use of holding notes. Notice that at the end of the first section of Ex. 25 the right hand has a rest of two beats, while the left completes the bar. Be careful to have the second finger exactly above the E which begins the moving tenor at the beginning of the second section. Ex. 26 calls for no remark, unless to warn the player against leaving the G in the tenor part at the end of the first section. Hold it down firmly while the bass plays F, E, D, C, being ready at the moment the latter comes in with the E in the treble part.

The next exercise is entirely for strengthening the fingers and adapting them to the neat execution of passages running in thirds in the same hand. It will show the learner more than anything he has yet tried how weak and stiff is the left hand compared with the right. That is only natural, of course, since in everyday life we give the left hand so little to do. To the player, however, both hands are of equal importance, and no trouble ought to be spared to make the left as supple and obedient as the right. This exercise will do something towards that end. Practise with the right hand first, being careful to press down both notes exactly at the same time. This even production of the two sounds and ultimate facility of execution at a rapid pace are the chief ends to be kept in view in working up the exercise. When the right hand begins to feel uneasy, take the left, transposing the exercise an octave lower. Presently the hands may be combined, and the exercise should be returned to daily for a considerable time. Do not over-fatigue the hands; stop immediately the slightest pain begins to be felt. If the student has a piano at hand he will find material benefit by alternating this exercise between the two keyboards.

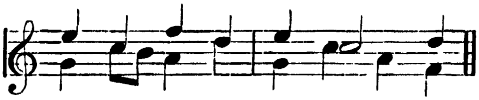
Fingering. Now look at Ex. 28. We have here a real "tune," a well-known single chant of Tallis. Glancing at the right-hand parts, you will see at once that the compass is a fourth—from F♯ to B—and can therefore be covered by the four fingers. Always remember that if a passage does not extend beyond five notes, the five fingers, or as many as may be required, should be used in their natural position, one for each note. Placing, then, the fourth finger on the highest note, the first finger will fall upon F♯, and there will be no use for the thumb. From this exercise we deduce a rule which should be kept constantly in mind—*Never use the thumb on a black digital unnecessarily.* If we had placed the third finger on the B in the melody, the thumb would have been thrown on the F♯, which would have caused an awkward shifting forward of the hand not justified by the necessity.

Ex. 29 is so simple as to call for no remark. Exercises 30 and 31 present the first examples in the key of D. In the case of the first, the second finger of the right hand is placed on D to avoid having the thumb on C♯. Be particular to restrike the D in the second bar, otherwise it will sound as being the alto note in the former bar held on. In Ex. 31 a little discomfort may at first be felt from the hands being brought so near each other, and by the left having two moving parts of its own. After good practice with the hands separately, the discomfort will vanish. Ex. 32 is in six-pulse measure, and is played properly by counting two in the bar. In consideration of this novelty, the technical side of the exercise has been kept simple. The following exercise introduces the key of B♭, in which two black digitals have again to be dealt with. Keeping in mind the rule about the unnecessary use of the thumb on a black key, the player will place the first finger on B♭, the fourth finger will take E♭, and the thumb the A. The left-hand part being only a fifth in compass, will be played by the hand in its natural position. Keep the right hand well forward on the keyboard, otherwise when you come to use the short fourth finger on the E♭ an uncomfortable forward movement of the hand will be necessitated.

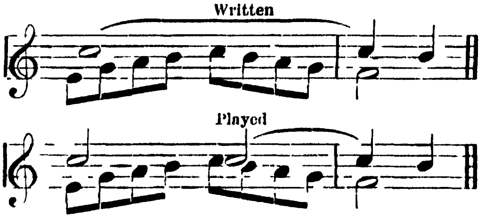
Ex. 34 has two parts in the left hand against one in the right. The compass of the latter, you will observe, is a fifth—C to G—and is covered, therefore, as before, by the fingers in original position. In the left hand see that the tenor moves neatly and exactly with the treble in the third bar. The upward progression of the left-hand part here, while the melody is stationary, has a pleasing effect, and should be artistically done Ex. 35 will be found very valuable for further strengthening the intractable third finger of the right hand, which is held firmly on the key while the first and second fingers move. One would think it very easy to keep a finger pressed down on a certain key while the other fingers shift about, but learners often find that the finger has left its key and wandered some way out of its place. The moving part of the left hand in Ex. 35 is given to the right hand in Ex. 36 and an under part added. There is no particular difficulty here, though some hands find F♯ and C in the lower part a little awkward at first. Finally, to end this step, we have the moving parts of Exercises 35 and 36 "varied," first in the left hand and then in the right.

Four-part Score. We are now face to face with a harmony of four parts, the player having been led so far, first by a course of exercises in two parts, and then by a course in three parts. This reading in parts admittedly proves a difficulty with learners, and before going further it will be well to give some advice with regard to it, and reading at sight generally.

To avoid the inconvenience which would be experienced in reading from vocal score, only two staves are used, on the upper of which are written the treble and alto parts, on the lower the tenor and bass. For the sake of distinction the stems of the notes of the higher part on both staves are turned upwards, those of the lower part downwards. When two parts come into unison—that is, have the same note—the fact is expressed by writing the note with a single head and two stems; or if the note as used in the one part is of longer duration than the note as it occurs in the other, and if the difference between the two lengths is one which cannot be expressed by the stems only, the note is written twice, once for each part, and the two notes, which are placed beside each other, are written as one. This will be seen in the second bar of the following example, where a single head with two stems would not have sufficed, as it would then have been impossible to tell whether a crotchet or a minim were intended:

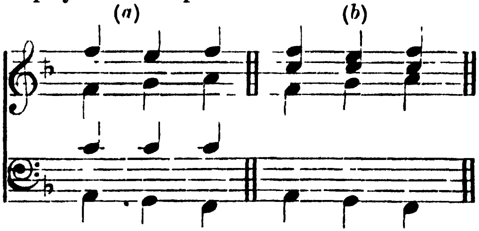


Occasionally a note which is sustained in one part is required to be used a second time as a note of the other part before it has properly come to an end. In that case the key must be pressed down again where required in the second part, and this repeated note is then held for the remainder of the value of the original sustained note.



The correct rendering of many hymn tunes and pieces often requires an inner part to be divided between the two hands, and it will frequently be found that neither of the hands is able to reach some note in the tenor or alto part as written.

In the latter case it will do no harm to transpose the inaccessible note to the octave above or below, provided always that when so transposed it does not become higher than the melody or lower than the bass. For instance, at (*a*) of the following illustration it would be impossible to play the tenor part as written:



But when it has been raised an octave, as at (*b*), the fingers meet with no inconvenience, and the chord is then made complete. Theoretically, this method of bridging over the difficulty is incorrect, but it is the only one available.

THE INTEREST IN A WORM

The Various Groups of Worms. Their Characteristics and Structure. How the Earthworm helps the Farmer. Worms and Pearls. An Industry Saved by Science

By Professor J. R. AINSWORTH DAVIS

SEVERAL groups of the lower animals are collectively known as Worms (*Vermes*), a word which has a certain convenience, but is decidedly unscientific, for most of these groups are but remotely related. The more important of them are: (1) Ringed Worms (*Annelids*); (2) Wheel-animalcules (*Rotifers*); (3) Siphon-worms (*Gephyrea*); (4) Moss-polypes (*Polyzoa*); (5) Lamp-shells (*Brachiopoda*); (6) Round-worms (*Nemathelmia*); (7) Flat-worms (*Platyhelmia*); (8) Nemertine Worms (*Nemertea*).

Ringed worms are elongated creatures in which the body is made up of a considerable number of rings or segments, most of which are, on the whole, much alike. There is often a well-marked head, but no distinct thorax and abdomen, as in an insect or crayfish. Two subdivisions are recognised: (*a*) Bristle-worms (*Chaetopods*), and (*b*) Leeches (*Discophora*).

Worms of the Sea. Bristle-worms include a host of marine worms, together with some that live in fresh water, and also the earthworms. Their average characters are best understood by examining one of the commonest shore-worms, known as the sea centipede (*Nereis*) [**520**]. Here the segments are very clearly seen, and almost every one of them bears a pair of unjointed conical *foot-stumps*, used for crawling. The remote ancestors of the jointed-limbed animals were no doubt somewhat similar, but in the course of ages their segments have become fewer in number and more specialised, while the foot-stumps have evolved into jointed limbs.

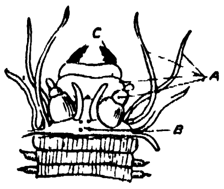
Imbedded in the foot-stumps of the sea centipede are bundles of strong bristles, which give a hold on the underlying surface, and prevent slipping. The head region is fairly distinct [**516**], and bears a number of feelers of various kinds as well as four simple eyes. Sea centipedes and many of their allies are highly carnivorous, and seize their prey by means of a pair of horny jaws, which can be protruded at will [**516** C]. When this is done the muscular first part of the digestive tube (*pharynx*) is pushed out through the mouth.

517. LUG-WORMS
(Photo by Prof. B. H. Bentley)

Some of the shore-worms have become broad and flattened to enable them to live conveniently under stones and in similar cramped places, as in the so-called sea-mice [**518**]. Here it will be seen that many of the bristles are long and sharp, serving as an excellent means of defence. In one kind of sea-mouse (*Aphrodite*) they are beautifully iridescent. On the upper side of the body are a series of scales [**518**] which serve for breathing purposes.

Some of the marine bristle-worms have taken to a swimming life, and in these the foot-stumps have been broadened out into serviceable paddles. Their bodies are transparent.

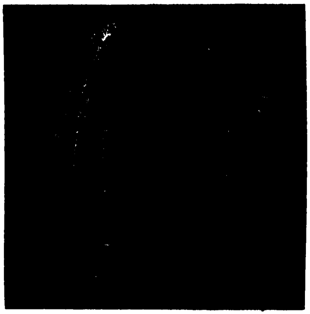
A Worm that Lives in a Tube. The bristle-worms so far mentioned move actively about, but some have taken to a comparatively sluggish burrowing life, as in the case of the lug-worm (*Arenicola*) [**517**], greatly esteemed as bait, which swallows sand or mud for the sake of the nutritious matter contained therein. Foot-stumps and feelers are reduced, for they would only be in the way, but beautiful feathery gills have been developed. One of the specimens figured is abnormal, for another individual is growing out of it, like the branch of a tree.



516. HEAD OF A SEA CENTIPEDE
a. Feelers *b.* Eyes *c.* Jaws

A sticky fluid oozes from the skin of a lug-worm and glues the surrounding mud or sand together into a sort of ill-defined temporary tube. Many bristle-worms, however, have taken to a purely fixed or sedentary habit, and these construct firm tubes of various kinds and shapes. They may be of horny texture, built of sand-grains and the like, or else calcareous. A worm which lives in a limy tube is figured here [**521**] extracted from its dwelling. The foot-stumps are greatly reduced, but some of the head-feelers have been converted into elegant branching plumes. These are beset with microscopic threads of living matter (*cilia*), which by their constant movement set up currents of water. The plumes themselves serve as breathing organs, and the currents they originate bring all sorts of small organisms and nutritious particles to the mouth of the worm. Below the plumes is a sort of collar, which is concerned with the making of the tube.

The sinuous calcareous homes of one of our commonest native tube-worms (*Serpula*) are often to be seen upon stones and shells [**522**]. When fully extended the single head-plume is a most beautiful object on account of its elegant shape and bright colour. On the least alarm the worm retreats into its home in the twinkling of an eye, the opening of the tube being closed by a conical stopper, formed by modification of a head-feeler. The little spiral dwelling of another common type (*Spirorbis*) is especially abundant on brown seaweed, and here the conical front-door is hollowed out to serve as a brood-pouch, within which the eggs pass through the early stages of their development.



518. SEA-MOUSE

a. Lower side
b. Upper side

The Farmer's Friends. Earthworms [**519**] are profoundly modified in adaptation to the burrowing habit. The pointed head-end (one can scarcely speak of a head) is devoid of feelers and eyes, and the foot-stumps are only represented by rows of bristles, which can be felt if the finger be passed along the body from back to front. There are no jaws, but the muscular first part of the digestive tube (*pharynx*) acts as a kind of pump for taking in food. This consists of fragments of plants or even of animals, but mostly of earth. The worm possesses a strong gizzard, containing small stones as in a bird, and making up for the absence of jaws.

As Darwin long since demonstrated, the earthworm is one of the farmer's best friends. Its burrows drain and aerate the soil; while the earth which has passed through its body is finely divided, and constantly being brought to the surface from lower levels.

519. EARTHWORM

a. Lower side
b Upper side

520. SEA CENTIPEDE

521. TUBE-WORM AND TUBE

Not far from the front end of an earthworm a thickening will be seen [**519**], often erroneously supposed to be the result of injury. From it exudes a fluid which hardens into the egg-cases.

Leeches. Leeches live in the sea, fresh water, or even in damp tropical forests. Their characters will be understood by examining a medicinal leech [**523**], which is one of the freshwater types. The flattened body is transversely divided by grooves into a number of narrow parts, several of which go to make up a segment. Foot-stumps and bristles are entirely absent, and progression is effected by means of suckers, one at each end. They effect a looping movement, but the animal can also swim by undulations of its body. This particular leech is a blood-sucking parasite. The mouth is situated in the middle of the front sucker, which serves to fix the animal to its victim. Three saw-edged jaws are then brought into play, a three-rayed cut being made, and a fluid poured out which prevents the blood from clotting. Digestion is slow, and the food is stored in a large crop, drawn out into numerous pairs of pouches. The head possesses eye-spots, but no feelers.

522. TUBES OF SERPULA ON MUSSEL SHELL

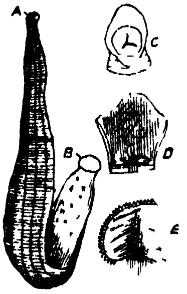
(Photographs by Prof. B. H. Bentley)

"Wheel-animals." The minute transparent creatures known as *wheel-animalcules* abound everywhere, provided there is a little moisture for them to swim about in. They may be kept in a dried condition for years, resuming their vitality when placed in water. Some of their leading characters may be gathered from the illustration given of a common freshwater type [**525**]. The body is not divided into segments, though the external membrane (*cuticle*) is transversely grooved, especially in the mobile "foot," which is provided with a pair of pincers at its end, and serves as a creeping organ.

At the front end of the body is a ciliated disc, or "wheel organ," the latter name being derived from the fact that the cilia move in regular succession, and give the impression of a rotating wheel. This is, of course, only an optical illusion. These movements enable the animal to swim, and also set up currents which bring food particles (minute organisms, etc.) to the mouth. These are ground up in a sort of gizzard, into which tooth-like structures project.

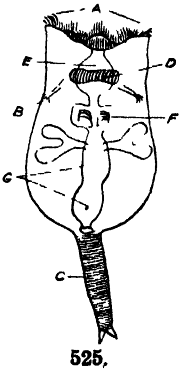
Some of the wheel-animalcules are sedentary, and construct tubular dwellings. In one remarkable case (*Melicerta*) these are made of pellets of mud, or other foreign matter, cemented together [**524**]. Each pellet is moulded into shape within a little cup, and there is a special cement-gland.

Siphon-worms in the Sand. Siphon-worms are distantly related to bristle-worms, but distinct segments are not to be made out, and there are no foot-stumps, though a few bristles are sometimes present. The common siphon-worm, Sipunculus [527 A], burrows in sand, which it swallows, after the fashion of an earthworm. A more remarkable form is Bonellia, of which the female is figured [527 B]; the male is minute and degenerate. The animal lurks with its rounded body securely ensconced in some rock cranny, while its long forked proboscis is extended to a relatively enormous distance in search of food. This is conducted along a groove to the mouth.



523. LEECH
a. Front, and *b.* back suckers *c.* Front sucker, with mouth *d.* The same, cut open to show the three jaws *e.* Jaw with toothed edge

Many Bodies in One. Moss-polypes are the first example we have met of *colonial* animals, in which a number of individuals (*polypes*) are aggregated together, their bodies being actually continuous. There is a horny (or sometimes calcareous) external skeleton, with a series of little cups for the reception of the polypes. The colony is formed by the budding of an original individual, and a more or less plant-like appearance is typical. A common freshwater type (*Plumatella*) is figured [528], from which it will be seen that each polype possesses a crown of feelers. These are ciliated, and serve as breathing organs, also setting up currents of water which bring food.



525. WHEEL-ANIMALCULE
a. Ciliated disc *b.* Feeler *c.* Foot *d.* Brain *e.* Cavity of mouth *f.* Gizzard *g.* Rest of digestive tube

One of the best known marine kinds is the sea-mat (*Flustra*) [533], which looks very much like a flat seaweed. Upon this particular specimen tufts of another species are growing.

Lamp-shells. These worms are often mistaken for molluscs, as they possess a bivalve shell, the valves of which, however, are *upper* and *lower*, not right and left, as in a mussel or cockle. In the tongue-shell (*Lingula*) [526], the shell is horny, and the animal lives in a burrow in the sand. Between the two halves of the shell a fleshy stalk passes out, and this can be contracted [526 C] so as to draw the animal down out of danger. Projecting from the sides of the mouth are two ciliated fringed "arms," which play the same part as the crown of feelers in a moss-polype. In lamp-shells [529-530], the valves are transparent, and calcareous. The lower one is much larger than the other, and is pierced by a hole through which the short stalk projects. This serves to fix the lamp-shell to some firm object.

Round-worms: A Danger in Food.

These are unsegmented worms of cylindrical shape, pointed at either end. Most of them are internal parasites, which give rise to serious or even fatal disease. An example of one of the larger forms (*Ascaris*) is figured [532], the sharply bent tail showing it to be a male specimen. Well-known species of the genus infest the horse and human beings. Another obnoxious round-worm (*Dochmius*) attacks the lining of the small intestine in man, and causes "miner's anæmia."

The female of the Guinea-worm (*Filaria medinensis*) lives under the human skin in tropical Africa, setting up abscesses. Its slender body is two feet in length or even more. A minute related species swarms in the blood of human beings in tropical regions, but is only to be found there at night. The round-worm, however, which is most dangerous to man is a form known as *Trichina*, which is under one-twelfth of an inch long. It infests the rat, and if this should be eaten by the pig, as it often is, the young worms bore into the walls of the stomach, and are carried in the blood to the muscles, where they pass into a quiescent or encysted condition. Should a human being eat insufficiently-cooked pork containing the young worms, they become mature in the stomach, producing countless eggs (as many as 1,000 per female), the embryos hatched from which make their way into the muscles, and become encysted. Serious illness, and not infrequently death, result from the disturbance thus set up, for though the parasites are very small, as many as 40,000,000 may be present in the same victim.

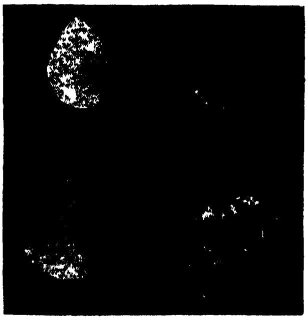
Flat-worms. These are unsegmented forms in which the body is generally flattened from above downwards. Very many of them are parasites with a complicated life-history. There are three groups of these creatures, (1) Planarian Worms (*Turbellaria*), (2) Flukes (*Trematoda*), (3) Tapeworms (*Cestoda*). Planarian worms abound both in salt and fresh water, and some of them are even found upon damp earth. Their skin is soft, and closely beset with cilia, by means of which they are able to glide along in a characteristic way. Planarians are highly carnivorous in habit and possess a long muscular pharynx, which can be protruded from the mouth in search of prey [535].

529. LAMP SHELLS

A Sheep Parasite. The *fluke* group is closely allied to the last one, but the animals included in it have become greatly specialised in relation to the parasitic habit. The covering of cilia has been lost, while suckers and other organs of attachment have been developed

We may conveniently take as an example the liver fluke (*Distoma hepaticum*), the cause of the disease known as "liver-rot" in sheep. [See AGRICULTURE, page 2625.]

The adult parasite, which attacks the liver of the sheep, is leaf-shaped [537], and an inch, or rather more, in length. The mouth is in the middle of a sucker, and situated on the end of a conical projection. A second sucker is present on the under-side of the body, far forward. The food consists of blood, and disintegrated liver-substance, taken in by the action of a pharynx that serves as a suction pump, and passed on into the numerous branches of the forked intestine. Very large numbers of eggs are produced, as will be realised from the fact that the gall bladder of a sheep infested by about 200 flukes contained something like 7,400,000. Parasites of all kinds are notoriously fertile, especially when their life-history is complex. The chances of survival in a given case are so small that if it were not so they would soon become extinct.



530. LAMP SHELLS

531. TAPEWORM

532. MALE ROUND-WORM
(Sex is shown by the curly tail)

533. SEA-MAT
(Photographs by Prof. B. H. Bentley)

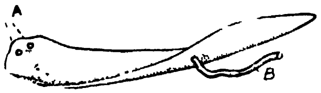
The eggs of the fluke ultimately pass out of the body of the sheep, and if this take place on damp ground in the vicinity of water, they have a chance of developing further. Low-lying pastures liable to be flooded offer particularly favourable conditions. A minute ciliated embryo hatches out from the eggs [537 B] and swims actively about in search of a small species of water snail (*Limnæus truncatulus*), soon perishing if unsuccessful.

The ciliated embryo bores into the lung chamber of the snail and becomes an irregular germ-bag [537 D]. Within this the next stage or *redia* is developed, which makes its way to the snail's liver and feeds upon it. During the summer several generations of rediæ arise, one within the other, by a process of internal budding. Later on in the season the next stage (*cercaria*) is similarly formed within the bodies of the last generation of rediæ. It resembles a minute tadpole in shape [537 F], and makes its way out of the snail, swimming to the stem of some water-plant, losing its tail, and passing into a quiescent or encysted stage, in which it is surrounded by a limy covering. If a sheep crops some herbage to which the cysts are attached, their limy coats will dissolve in the stomach, and the young flukes thus liberated pass on into the intestine and make their way up the bile duct to the liver.

Tapeworms. All the tapeworms are internal parasites, and the characters of some of the more simple among them show that these creatures have descended from fluke-like ancestors by still further modification. Digestive organs, in the ordinary sense, are entirely absent, for these creatures live surrounded by nutritious food in the liquid form, consisting either of the digested food or the blood, etc., of their hosts. This is absorbed through the soft covering of the body.

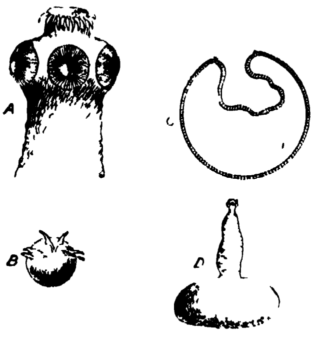
One of the best-known members of the group is the common tapeworm (*Tænia solium*), which lives, when adult, in the intestine of human beings [**531** and **536**]. At the front end is a minute "head" which holds on by hooks and suckers to the lining of the intestine. Behind this are very numerous flattened joints (*proglottids*), of which the ripest are those furthest from the head. Each joint gives rise to a large number of eggs, and since new joints are constantly being formed during the life of the worm, there is little likelihood of the parasite becoming extinct.

534. NEMERTINE WORM



535. PLANARIAN WORM

a. Eyes *b.* Extended pharynx



536. TAPEWORM

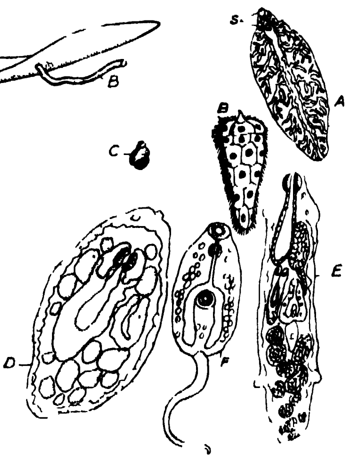
a Head, with hooks and suckers *b.* Six-hooked embryo *c.* Young bladder-worm (section) *d.* Full-grown bladder-worm

The ripe tapeworm joints pass out of the body of the host, and if any of their eggs chance to be swallowed by a suitable warm-blooded quadruped, especially the pig, they develop further [**536**]. A minute spherical embryo hatches out, and by means of six little hooks it possesses bores into the blood-vessels and is carried to the muscles. Here it passes into the quiescent bladder-worm (*cysticercus*) stage, in which it may remain indefinitely, for no further development can take place in the body of the pig. Pork infested by bladder-worms is said to be "measly," for the encysted parasites give it a spotty appearance.

The bladder-worm is a hollow sphere, the wall of which is pushed in at one spot. This in-pushing is gradually converted into a tapeworm head, hollow, and outside in. Should a human being eat some measly pork which has been insufficiently cooked, the tapeworm head of the bladder-worm turns inside out, and becomes solid, while the bladder itself is absorbed. The head attaches itself to the lining of the small intestine, the chain of joints develops, and the adult stage is reached.

How Science Saved a Pearl Industry. The finest "orient" pearls of Ceylon are merely the tombs of dead tapeworm embryos. In this case there are *three* hosts, and their life-history is as follows:

1. Ciliated embryos which hatch out from the eggs enter the bodies of pearl oysters, and pass into the bladder-worm stage. Some of these die and get surrounded by layers of limy matter; hence pearls.
2. The file-fish (*Ballistes*) feeds upon the pearl oysters, and some of the bladder-worms taken in develop a stage further.
3. A large ray (*Trygon*) preys upon the file-fishes, and within its intestine the tapeworm attains its full development. Tapeworm eggs pass out of the body of the ray, and the embryos which hatch from these attack the pearl oyster.



537. LIVER FLUKE

a. Adult fluke, with branched intestine and two suckers (*s*) *b.* Ciliated embryo *c.* Water snail *d.* Germ bag *e.* Redia *f.* Cercaria

The pearl tapeworm affords a good example of the value of scientific research to industry. A few years ago the Ceylon pearl fisheries became greatly depreciated in value, and to discover the reason became an urgent matter. First came the so-called "practical" man, who, reasoning by the "light of Nature," suggested that file-fishes should be ruthlessly exterminated, since they devour pearl oysters. Fortunately the aid of scientific investigation was next invoked, and the life-history given above was made out, proving conclusively that extermination of the file-fish would do away with the formation of orient pearls altogether.

A Rare Sight by the Sea. Nemertine worms, unsegmented and usually cylindrical, are a numerous marine race, though practically unknown to other than professional zoologists. Some of them are much elongated [**534**], and may be found coiled up in odd corners between tide-marks. One of our commonest British species is jet black in colour and several yards long. Helpless though these creatures appear, they are eminently carnivorous, and devour tube-worms. At the front end of the body, immediately above the mouth, which is on the under-side, a small hole may be seen. Through this a long tubular proboscis can be shot out, and this is the means by which prey is secured. In some nemertines its tip is armed with sharp stylets, at the bases of which poison-glands open. Nemertine worms have a considerable theoretical interest, because in some respects their structure foreshadows the peculiarities of backboned animals, which possibly have taken origin from creatures of the kind.

WORKSHOP PRACTICE
continued from page 3880

By JOSEPH G. HORNER

TESTING, as done in the engineers' shops, is the work of the firm in the first place, preliminary to that of inspectors, who are appointed by the purchasers. Hence there are often two separate testings made, one for the satisfaction of the firm before calling in the inspector, the other which is done by the latter. Often, however, in big contracts, the inspector remains on the premises, observing the work in its progress as well as noting the quality of the materials being used.

Inspectors. An inspector, to be fully qualified, should possess an intimate practical knowledge of materials and operations, such as can be gathered only during a considerable period spent in the shops. With this must be combined a good training on the technical side. Too often inspectors fail in the first, to the intense irritation of manufacturing engineers. Work is condemned without just reason because the inspector is not qualified to judge between the essential and the non-essential. The strict letter of a specification is insisted on, to the condemnation of really excellent work. The same kind of mistake is often made on the part of consulting engineers, who draw up specifications with unnecessary increase in cost and without increased efficiency.

The character of the tests made vary with every class of mechanism. Generally they commence with the rough castings, or forgings, or other articles. That section which relates to the taking of test pieces, having been treated in Materials, need not be repeated. But the following points lie outside the mere laboratory work.

Test Pieces. Test pieces must be taken from the actual material used in given iron or steel castings, in steel plates, or sections, or forgings. If in castings, they must be run on the castings, to be cut off in the presence of the inspector, or else poured from the same ladle in the presence of the inspector, and stamped by him. Steel plates and angles must have sufficient additional length or width to permit of one or more test pieces being shorn, or sawn off, one or more from a batch of the same quality, also in the presence of the inspector, and stamped.

Testing Machine. The test bars for castings are usually 3 ft. 5 in. long, by 1 in. wide, by 2 in. deep. They are laid on supports 3 ft. apart, with the 2 in. dimension depthwise, and loaded until fracture occurs. This takes place at from 28 cwt. to 36 cwt., with a deflection of three-eighths of an inch. Plenty of machines are used in foundries in which actual loads are applied directly to a sling hung from the bar. But the lever machine is far neater and better. Fig. 352 illustrates one of the best designs, by Messrs. W. & T. Avery, Ltd., of Birmingham. It has a capacity of 40 cwt. It takes cast-iron bars of 2 in. by 1 in. section, or less, and up to 36 in. between the supports, or dogs, CC. The bed-plate D is of cast iron, machined, and the dogs have hardened edges where they come into contact with the specimen. They are adjustable to suit different lengths of bars, and the base-plate is graduated so that the specimens may be accurately located for spans of 12 in., 24 in., or 36 in. between supports. A cast-iron standard, E, is machined and bolted to the bed-plate, and is fitted with hardened steel bearing-blocks, upon which the fulcrum knife-edge of the steelyard F rests. Brass caps are fitted over the main fulcrum knife-edge to protect it from dust. The steelyard is made of wrought iron, machined and polished bright, and fitted with hardened steel knife-edges, and graduated up to the full capacity of the machine, thus dispensing entirely with the use of loose weights.

The Testing Machine at Work. The steelyard is provided with a sliding poise, G, by means of which it is kept in equilibrium, and the strain indicated. To ensure the strain being steadily and evenly applied, and the most accurate results attained, a small hand-wheel, H, is fitted to the poise for propelling the latter. A buffer spring is fitted in the carrier J to minimise the shock on the steelyard due to the breaking of the specimen. The hand-wheel is keyed to a spindle passing through the poise, and to this is also fastened a hardened steel roller having a milled edge. The rotation of the hand-wheel causes the milled roller to grip the top face of the steelyard, thus giving motion to the poise. To facilitate the movement of the latter, a trailing roller is provided with a turned edge; this also runs upon the top face of the steelyard, and relieves the milled roller of the greater part of the weight of the poise. A graduated scale and pointer is attached to the machine for ascertaining the deflection of the specimens being tested. The strain is applied by actuating a hand-wheel, K, with a screw working in a stirrup, L. The point of the screw is hardened, and bears in a hardened steel bearing-block on the edge of the steelyard.

Limitations of the Test Bar. But this method of test in any hands but that of an experienced man is apt to be misleading. It would not do to apply the results rigidly to castings made from the same bars. But it does, nevertheless, indicate the quality of the iron in a valuable way, and provided the castings are also tested to detect any unsoundness or faulty portion, the test bar will not be misleading. But if a casting is accepted as sound and strong only because the test bar is sound and strong, trouble will in many cases follow. By the aspect of the fractured surfaces—their dull or lustrous appearance—the experienced inspector is able to form an approximate estimate of the character of the iron, whether poor or good, hard or soft. Uniformity must never be looked for either in test bars or in castings run from the same ladle of metal. Variations of 10 or 20 per cent. occur in bars, and twice as much in castings of variable sections. This is one reason why a large margin of safety must be allowed. Hence test bars alone are not relied on in a rigid system of inspection, but a small percentage of castings is broken. These are taken at random, and are therefore reliable samples of the whole.

There is one aspect of the test bar that has only been taken account of in late years—namely, shrinkage. Here we touch the fringe of a wide subject, known to foundrymen as *Keep's tests.* Though ultimately based on the chemistry of the iron—namely, on the proportion of silicon present in relation to other elements, carbon chiefly—and to the mass of a casting, the shrinkage of the bar is used as a test to reveal the physical characteristics of the metal. Where Mr. Keep's testing appliances are installed, very precise tests can be made with little risk of error in judgment.

Castings. The test pieces from a casting or a steel plate may fulfil the terms of the specification as to strength and ductility, etc; but that does not guarantee a sound casting or plate, which must be the object of a careful inspection.

Castings offer by far the greater difficulty, plates being generally homogeneous and reliable. Castings are often not homogeneous, besides which they are subject to faults developed in pouring and cooling, faults in the mould, or due to bad proportioning. Many of these are hidden, though their existence may be suspected by an experienced man. They may often reduce the strength of a casting by as much as 50 per cent., so that the test piece alone becomes illusive.

Faults. The worst faults in castings are draws, blowholes, and general sponginess. A rough skin should not condemn a sound casting, but the faults just named should, if they exist in vital parts, condemn a smooth casting. By vital parts are meant those which are subject to severe stresses of a tensile or cross bending character. Faults may occur in parts which are subject to little stress, or to one of a purely crushing character. They may occur in the neutral axis of a body or in the centres of masses surrounded with metal far in excess of that required for mere strength, as in some portions of machine framings, or bed-plates. Hence the inspector must judiciously make a distinction between the vital and the non-essential.

Draws. Draws, or open spaces, are as often as not invisible from without. If due to the shrinking of metal away from central portions, there is no indication of their presence. But wherever thin and thick portions tie one another, draws may be suspected. Hammer taps will then indicate a tense condition. Draws need not occur in a properly designed casting. But the moulder can do much to avoid the errors of the draughtsman by judicious local cooling off, or, in steel, by filling in fillets in weak places.

Blowholes. Blowholes and general sponginess are due to insufficiency of vents. A clean surface may conceal sponginess. The hammer test may detect it, or small holes on the upper surface may indicate the presence of extensive blowholes which may be probed by a wire. Blowholes are most liable to occur on the upper faces of castings.

Scabs. Scabs are visible on the outside and if the fettler has trimmed them off, the smooth surface indicates what he has done. Then holes are present somewhere in the casting, because the scab is simply metal taking the place of sand that has been flaked off and washed away at the time of pouring, and lies somewhere in the mould. Such a casting, if subjected to much stress, must be regarded with suspicion, and may have to be condemned.

Plates, sheets, and angles are liable to pitting, and to seams or laminations, but far less so in steel than wrought iron. Steel is practically homogeneous; poor iron is not. But if sponginess is present in a steel ingot, it will show in the rolled plates. These faults can be detected only by ocular examination, and by hammer blows in the case of laminations, which, if present, do not emit a clear, ringing sound like a solid plate does.

Impact Tests. These are used for railway rails, tyres, and axles, because the stresses which these have to sustain are of the nature of shocks or hammer blows. Tensile tests are usually taken also, but the rails, tyres, or axles must pass the drop tests before they are accepted. These vary in different countries. In England engine axles are tested by the falling of a 1-ton weight through a distance of from 25 ft. to 30 ft. The number of blows varies, ranging from five to sixteen. The axles are laid in bearings 3 ft. 6 in. apart, and are reversed after each blow, or each alternate blow, so that the result is a number of bendings, ranging from 2½ in. to 3 in., and straightenings, which the axle must endure without sign of crack or fracture. Then, having withstood these, the axle is broken, and specimens cut from it for tensile and bending tests in a machine. Rails are tested in a similarly severe manner, with considerable variations in different countries. Tyres are also subjected to a drop test, being stood edgewise, and receiving successive blows from a 1-ton weight dropped from an increasing range of heights, extending from 10 ft. to 30 ft., until it is bent through a distance of one-sixth or one-eighth of its external diameter without cracking.

Finished Mechanisms. These, speaking generally, are tested by the agencies by which they are stressed in practice, as steam, water, imposed loads, etc. The tests may have for their object the strength of the mechanisms, or their rigidity, or stability, or

TESTING APPLIANCES

352. Transverse testing machine **353.** Test indicator **354.** Indicator testing running of spindle **355.** Testing alignment of lathe spindle **356.** Special face-plate for testing cross-slide of lathe **357.** Testing parallelism of cross rail with planer table **358.** Indicator diagram the tightness of joints and seams. In another class of test, speeds, discharge, capacity, power, etc., are ascertained.

Steam-pressure Tests. Testing by steam pressure to be sure of the strength of a vessel is practised to but a limited extent, and then, as a rule, following hydraulic tests. Even in steam boilers, with the exception of the locomotive, it is not generally practised. Many hold that it is of no value, while it is certainly risky to test a boiler at much higher pressure than that at which it has to be worked. The hydraulic test fulfils the required conditions equally well, and involves no risk whatever. On the other hand, testing by steam is done under working conditions of expansion due to heat, and these will often find out weak and leaky seams that a higher hydraulic pressure had failed to detect.

The Hydraulic Test. This is by far the most valuable and most extensively employed. It can be regulated within any range with absolute precision, from a few pounds to two thousand pounds or more to the square inch. It tests the strength of pipes in iron, steel, copper, and copper alloys; the tightness of welded and riveted joints, of caulked, of flanged, and other joints. If a joint fails, there is just a fizz of escaping water, or a mere *weeping* only, and the pressure is relieved at once, and therefore there is no danger as there is with the highly elastic steam. Pressure water finds out spongy metal, and weeps through it, hence cast pipes are tested thus. It will find its way through bad welds, through boiler seams imperfectly riveted and caulked. It will force its way between the leathers and rams of hydraulic cylinders if the leather and the fitting are poor. The test pressure pump is used, fitted with a gauge which indicates the rising pressure accurately.

Deflection. The amount of deflection of a beam or structure under a dead or a live load is very important, and specifications are generally stringent on this point. The maximum load on a structure must not stress it beyond the elastic limit, and the structure must therefore possess sufficient rigidity or resistance to enable it to return to its original form on being relieved from its maximum load. This original form need not be that at which it leaves the manufacturer, but that which it takes after it has acquired a *permanent set*. But specifications as to amounts of deflection permissible guard these contingencies, and the inspectors have to see that they are fulfilled. Sometimes firms have had to substitute new girders for others that would not stand the deflection test.

Alignment. This signifies the centres or axes of shafts, spindles, bearings, etc., being in one plane, or in line. It is most important in lengths of shafting, in machine tools, and engine rods. It is tested in some cases by the same methods as those used in erection, namely, by straining lines, and by parallel straightedges and spirit levels, or by plumb lines. But for fine machine construction this would not be accurate enough. Centres may be brought together, but that is not sufficient in some cases. Fine alignment is checked with an indicator, the point of which is brought to the centres, or axes, and any departure from accuracy is magnified at the other end by a pointer moving over an index. There is also a practical testing commonly done in lathes, which will be noted immediately. Alignment in moving pistons and rods, and crossheads, or slippers in their bores, glands, and guides is often tested after erection by moving them along, and judging of the fitting by the ease or stiffness with which they work.

Stability. This is one of the essentials in structures which are subjected to stresses tending to disturb their equilibrium. It has its applications in locomotives and rolling stock, and in balanced jib cranes of all kinds, but specially in the travelling types. The higher the centre of gravity, the smaller, other conditions being equal, is the stability. Hence, weight is, when possible, massed low down to lower the centre of gravity; and the base, whether wheel base, or foundation plates, or beds, is made as broad as practicable.

Horse-power. This is estimated as the number of pounds, 33,000, lifted one foot high per minute. It is ascertained by calculation, or by brake, or other dynamometer, or by the indicator.

Speeds. These are reckoned by observation if slow and not extended over a long time, as the speeds of shafts, revolutions of some engines, and machine tools. But under opposite conditions a revolution or speed-counter is used, which records automatically the number of revolutions.

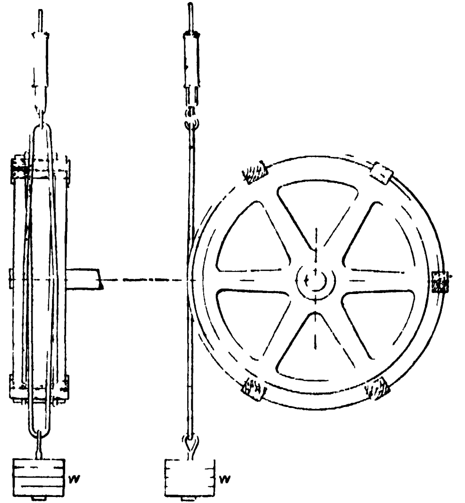
Modulus of a Machine. In plain words this means the efficiency of a machine, or the relation or percentage of the work which it is capable of doing to that which is put into it. It is always a fractional part, since no machine can possibly give out all the energy it receives unless it were absolutely frictionless. Calculations based on theoretical figures are of little value here because there are so many sources of loss which go to make up the total. The only practicable and reliable way is to test the machine as a whole, and when the work which is applied to it and absorbed by it is known, then the percentage between that and the work done represents the modulus, or efficiency. But this holds true only under identical conditions. The efficiency will not be the same under different loads because, in general, frictional resistances remain constant under greater or lesser loads, due to the surfaces in contact. Thus a planing machine absorbs nearly as much power while running idly as when cutting metal, due to the inertia of the heavy table. The power of an engine varies directly as the steam pressure and velocity, so that it is easy to double the power of a given engine without affecting the friction much. In hydraulic rams and pumps, and in machinery running at very high speeds, friction and ill-balanced parts complicate matters, but in average machines the remarks just made hold good. If therefore, as the result of test, the modulus of a machine working under given conditions is known, that of machines of different powers can be ascertained. The gross horse-power, or foot-pounds of work absorbed are multiplied by the modulus.

Testing Machine Tools. Machine tools are subjected to tests for accuracy and for capability to perform the work demanded. The latter is chiefly a question of driving power and strength of parts, combined with close fitting, to prevent slackness, except as regards the capacity for speed, which is governed in many cases, such as in automatic screw machines, by the skilful setting of cams, etc.

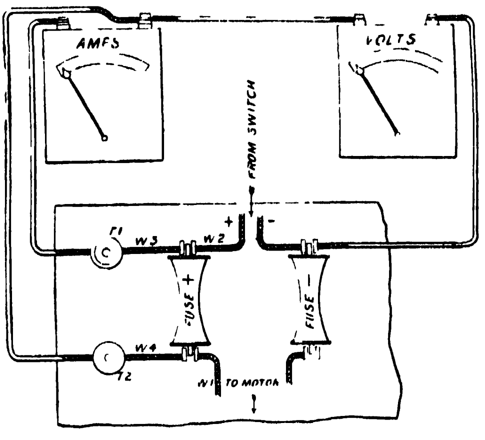
Machine tools are used for the production of true surfaces on work, so that questions of alignment, parallelism, and squareness of spindles and slides in relation to each other are of paramount importance, whereas in an engine, pump, etc., so long as the parts work correctly and freely, it may be passed. But a machine tool may look and operate apparently to perfection, and yet be very inaccurate in its product. In good work it is usual to test relations after the fitter and erector have done their part, and see that the permissible limits of error are not exceeded, absolute accuracy of course not being attempted. The principal forms of tests relate to: *Lathes*: Alignment of the headstock and poppet axes in regard to each other and to the bed, and squareness of the rest setting, so that turning, boring, and facing shall be effected parallel, and at right angles. *Planers*: Square relation of the uprights with the tables, and parallelism of the cross rail therewith. *Shapers*: Parallelism, and squareness of the ram movement in regard to the table. *Slotters*: Perpendicular movement of the ram to the table slides, including rectangular relation of the latter in regard to each other. *Millers*: Parallelism, and squareness of the spindle in relation to the table, and truth to the latter at right angles. *Drillers* and *borers*: Perpendicular relations, and parallelism of the spindle to the table or base. *Grinders*: Alignment of spindles to beds and tables, and squareness of cross movements.

Indicators. In those machines which have rotating spindles care has to be observed that they run truly, since a very slight amount of eccentricity will spoil results, especially in lathes, milling machines and grinders, while in drilling machines the "running out" of the drill causes much annoyance and risk of untrue work. In testing such spindles, a plug, ground truly and parallel, is inserted in the centre of the mandrel hole, and the spindle is revolved. An indicator is then made use of [353], a delicate instrument comprising a system of levers which magnify the movement of a stud or feeler, A, screwed into a pivoted block, B, which moves levers C and D, the last having its end travelling across graduations on the top of the casing. The levers C and D enormously magnify the movement, so that a motion of 1,000th in. of A shows as $\frac{1}{8}$th or $\frac{1}{12}$th in. on the end of D, according whether A is screwed into an upper or a lower hole in the block B. The spring E tends to keep the parts at normal positions. The shank F is for holding the instrument in place on machines, etc., the case being pivoted so that if too much movement is applied to the feeler the levers will not be damaged but the case will tilt back. A cover is screwed to the face by the holes seen, to protect the parts. The feeler G is for testing inside holes, while other forms are made for special work.

Lathe Testing. Another kind of indicator [354] comprises a pointer which is so pivoted that any movement is greatly magnified, and indicated on a divided scale. If the plug, therefore, held in the lathe or other spindle should happen to run eccentrically, the needle B of the indicator will move in sympathy, while if no inaccuracy is present the needle remains stationary. All circular revolving parts may



359. DYNAMOMETER



360. ARRANGEMENT FOR ELECTRICAL TESTING therefore be tested in a more delicate and easy manner than by setting the machine to work. The alignment of the spindle with the bed is tested by using a longer plug [355] and guiding the indicator base along the vees, or ways of the bed, so that any want of parallelism between plug and bed is shown. Or a short mandrel may be placed in the spindle and a couple of collars turned up on each end with a light cut travelling the rest from one to the other; these should be identical in diameter when measured by a micrometer caliper. If one is larger, then the spindle is not in alignment with the bed. The indicator in 355 is a type where the pressure on the feeler moves a needle over a circular dial in the case.

The alignment of the loose poppet is secured if an indicator held in the rest bears equally when brought to either end of a ground parallel shaft mounted between the heads. The barrel itself may also be tested by the use of a plug inserted as in the case of the headstock.

Squareness of movement of the cross slide is shown by its capacity for facing a plate flat, since if the tool leaves the surface either concave or convex, this shows that the slide does not move at right angles to the spindle. A neat method of testing is to make a special plate [356], projecting out into two rings, one at the periphery, the other encircling the screw hole. After a cut right over these rings, a straightedge laid against it should grip pieces of tissue paper between the four narrow faces, *a*, *a*, *a*, *a*. Should the facing be concave or convex, the paper will fall from the inner or the outer rings respectively.

Linear motions of slides or rams in relation to tables and beds are tested with the indicator. By clamping the stem in the tool-box of a planer, for instance, and moving the box along the cross rail, the want of parallelism of the latter to the table is detected by the needle moving if the feeler presses the table harder on one side than the other [357, A and B]. Shapers may be tested by holding the indicator in the tool-box and moving the ram to and fro, and the table also transversely, any divergencies in the extreme positions showing themselves. Parallelism of spindles to tables, as in milling, drilling, and boring machines is found by sliding the indicator along either the spindle or the table, the feeler making contact evenly all along unless the spindle lies out of parallel. These examples are sufficient to show how testing is carried out, being representative of the work in general. It may be noted that in many shops the inspector has to furnish a report of the test, giving as far as possible the amounts of inaccuracy present in the main parts. As mentioned previously, these inaccuracies must not exceed a predetermined amount, which varies, of course, as the machines are of common or of high class construction.

Crane Testing. Cranes are tested for stability, lifting capacity, and power consumption. The stability of a jib crane is measured in reference to the gauge of rails upon which it runs or to the length of support afforded by the blocking girders. In the case of a fixed crane, the foundation is proved by the test load. The test load imposed is usually in excess of the working load; for ordinary cranes, 20 per cent. overload is usual, but this rises to 50 per cent., and even 100 per cent., for special cranes. The load is applied gradually, half or two-thirds loads being successively lifted, and the behaviour of the crane carefully noted. A common device is to apply a long lever under the crane tail from time to time during the test, to ascertain what margin of safety exists.

Cranes are also tried for backward stability with the load off and the tail at right angles to the track. Many railway breakdown cranes are not stable in this position, except when the blocking-up girders are in use; such cranes are usually fitted with movable ballast weights. The overload test also proves the capacity of the crane to perform its various movements properly.

With overhead travellers and goliaths, the test load is also used to ascertain the deflection of the main beams; this may vary from ⅜ in to 1¼ in., according to span and construction of girder. This deflection is apart from permanent set, which must be noted by measuring the level of the beam before any load is imposed and measuring again after the test load has been lifted and set down. Permanent set depends largely on the workmanship of the joints, and may be equal to the deflection in amount.

Speeds are measured by noting the time taken to carry out a certain operation and then reducing it to feet per minute. Locomotive cranes are tested for travelling speed and for shunting power, also for steaming power. A locomotive crane boiler should maintain steam at or about the working pressure easily throughout the period of testing. Coal and water consumption is easily noted during a test, or for a complete day's work. Electric cranes are also tested for current used over given periods, and the results are reduced to tons per kilowatt hour, or, alternatively, to cost of current per ton handled.

Cranes are subjected to trials for efficiency in a similar manner to that to be described immediately for electrical machinery. Crane-building establishments record all their tests, and use the comparative results as a guidance in the design and manufacture of subsequent cranes. They are thus eminently qualified to act as advisers when specifications are being framed for prospective lifting appliances.

Engine Testing. Steam engines are tested to ascertain their indicated and brake horse-power, also for steam consumption and general efficiency. The indicated horse-power of an engine, or I.H.P., as it is termed, is obtained by means of an indicator, which records the actual steam pressure in the cylinder at the various periods of the stroke of the piston. The indicator is attached to the cylinder by small steam-pipes, and is driven by the engine crosshead by means of levers. It produces a diagram as in 358. The area of the boot-shaped figure represents the work done by the piston; its length is the stroke of the piston, whilst vertical dimensions give the varying pressure as the steam is cut off, and then expands. The mean height is the average pressure, and this, multiplied by the piston area in square inches and by the piston speed in feet per minute and divided by 33,000, gives the indicated horse-power.

In the diagram [358] *a* represents the point at which steam is admitted to the cylinder. From *a* to *b* the steam rises, making, in a good diagram, a vertical line. The paper on the indicator cylinder rotating, the line *b c* should be straight. At *c* the steam begins to be cut off, and the line drops to *d*, the point at which it is fully cut off. From *d* to *e* the steam is working expansively. At *e* the exhaust is opened and remains open from *f* to *g*. At *g* the exhaust is closed, and cushioning takes place to *a*, where steam is again admitted for the next cycle. This is the diagram for a high-pressure engine, in which *f g* is the atmospheric line. In a condensing engine, *f g* would represent the vacuum line, and the atmospheric line would be higher up. The 10 vertical full lines are ordinates. To get the total area, the spaces between these are divided midway, as indicated by the dotted lines, their lengths are measured, and added, and the sum divided by 10. The result is the mean pressure on the piston per square inch. Thus :

$$\frac{\text{Area of piston} \times \text{mean pressure} \times \text{speed of piston in feet}}{33{,}000} = \text{H.P.}$$

The indicator diagram is an open book, which shows as clearly what is going on within the cylinder as the stethoscope reveals the condition of the lungs. Abnormal cards show whether the exhaust opens too soon or too late, or closes too soon or too late, and much more.

The brake horse-power, or B.H.P. is measured with a dynamometer, as in **359** ; this particular form is known as a rope brake, and is applied to the flywheel of the engine. The weight W is adjusted to suit the load, and the B.H.P. is found by multiplying the weight by the circumference of the rope circle, and by the speed of the wheel in revolutions per minute, and dividing by 33,000. The difference between the I.H.P. and B.H.P. represents the friction losses in the engine, the relation

$$\frac{\text{B.H.P.} \times 100}{\text{I.H.P.}}$$

gives the efficiency per cent., which may vary from 75 per cent. to 95 per cent., according to the class of engine and accuracy of construction.

Engines are tested for steam consumption in connection with steam boilers. Water is measured into the boilers before and during test, and the residue measured afterwards. From these figures the amount of steam used over a prescribed time may be easily obtained, and reduced to pounds per I.H.P. per hour; the usual result is 18 lb. to 22 lb. for compound and triple-expansion engines, 25 lb. to 30 lb. for condensing engines, and 35 lb. to 40 lb. for ordinary non-condensing engines. Better figures are frequently obtained, but the above represents good average practice. Gas and oil engines are tested in a similar manner to steam engines for indicated and brake horse-power, the efficiency being about 85 per cent. Gas consumption is stated in cubic feet per I.H.P., and can easily be measured on the meter for any given period ; 15 cubic ft. to 25 cubic ft. of town gas is usual. Oil consumption for oil engines is reckoned in pounds per I.H.P., the ordinary results being from ½ lb. to 1 lb. per I.H.P., according to size of engine and class of oil. Suction gas engines are tested also for fuel consumption, as they are part of a complete gas plant; the I.H.P. is taken at intervals, and the fuel consumption noted for a given time. An average result with a good plant is 1 lb. of coal per horse-power hour.

361. STEAM ENGINE TESTING SHOP

Testing of Electrical Machinery. Tests to determine the power required by electrically-driven machinery are made by measuring with an ammeter and a voltmeter the electrical horse-power rate of working. If these instruments are not permanently fitted to each motor, the arrangement shown in **360** for inserting portable instruments at the motor switchboard may be provided. W1 W2 are the cables entering and leaving the terminals of the + main fuse F. Terminals, with milled nuts, T1, T2, are connected by wires W3, W4. When a reading is required, the terminals of a portable moving-coil type ammeter are connected across T1, T2.

When this connection has been made, the fuse F is removed, and the ammeter will then read the current passing to the motor. When the reading has been obtained the fuse is replaced, and the instrument may then be taken out, care being, of course, observed to use insulated tools, to prevent the risk of shock to the operator. The voltmeter is also connected as shown, being attached to both + and − cables. It is thus unnecessary to stop the motor to insert or remove the ammeter. An "efficiency curve" should always be supplied by the makers of the motor, showing its efficiency at various loads. The B.H.P. being delivered to the machine can then be calculated.

Thus, supposing the motor *input* to be 32·5 amperes at 230 volts, and that to be the full load rating of the motor:

$$\frac{32{\cdot}5 \times 230}{746} = 10 \text{ E.H.P.} = \text{input to motor.}$$

The efficiency curve showing 86 per cent. at full load, we deduct 14 per cent. inefficiency loss, and get:

$$10 \text{ E.H.P.} - 1{\cdot}4 = 8{\cdot}6 \text{ B.H.P.,}$$

output to the driving of the machinery.

We also get the approximate mechanical efficiency of the machinery driven. The machine is first run unloaded, and a reading obtained, say, 4 E.H.P., then:

Efficiency of motor at 4 h.-p. = say, 75 per cent., then B.H.P. = 3.

Full load of machine takes 8·6 B.H.P. Then

$$8{\cdot}6 - 3 = 5{\cdot}6 = \frac{5{\cdot}6 \times 100}{8{\cdot}6}$$

= 65 per cent. mechanical efficiency.

Horse-power & Rating of Motors. The horse-power that can be obtained from a motor depends upon its speed and the current which it takes. As the load upon it is increased, the current rises and the speed of the motor falls slightly in a shunt or compound, or more markedly in a series-wound motor. The limit of safe load depends chiefly on the heating up of the field and armature coils in a series motor, or the armature windings in a shunt motor, which must not be so great as to overheat the wires and damage their insulation. Thus, for motors running continuously a run of six hours at full load, or of 12 hours under variable load, should not raise the temperature of their windings more than 60° F. Motors for intermittent work, however, where the load is in regular alternations of light and heavy value, as in rolling mills, shears, etc., may be worked at higher rates; while for such work as that of cranes, hoisting machinery, capstans, etc., where load is followed by rest periods, a temperature rise of 75° F. after six hours full load test, or 90° F. after six hours under working conditions, may be allowed. These tests are taken immediately the motor is stopped, by laying thermometers, covered over by dry cotton-waste, upon the field and armature windings, and noting how far the mercury rises, having previously noted the temperature of surrounding air.

Cost of Power. In the absence of an "energy meter," an idea of the cost of running the motor may be obtained. Take a number of readings, say every 15 minutes for an hour or two when the motor is doing a normal load, by the ammeter and voltmeter. Then take the mean of each and reduce to watts. Thus, supposing the mean reading over two hours to be 32·5 amperes, 230 volts. Then

$$32{\cdot}5 \times 230 = 7475 \text{ watts or } 7{\cdot}475 \text{ kw.}$$

Kw. × time × price per unit = cost of power.

Thus, with power, say 1·5d. per unit, in above:

$$7{\cdot}475 \times 2 \times 1{\cdot}5 = 22{\cdot}425\text{d.,}$$

or 11·2d. per hour, at the average load of motor.

Insulation. A rough and ready insulation test for a motor is made by connecting a voltmeter momentarily first from the + brush to earth, and then from the − brush to earth while the motor is running. If the insulation is good there should be no reading. If there is a reading, either + or − side exceeding 3 per cent. of the working voltage, the motor should be carefully examined, and it and the circuits tested with proper instruments until the faulty spot is located and repairs effected. Faults in the insulation do not simply mean small leakages and waste of current. The chief danger is that once started they rapidly develop until complete breakdown occurs, and the motor has to stop, also because sparking and arcing take place at the point of failure and may result in fires or other damage, and persons handling the machinery may receive electric shocks.

Testing-rooms. In a modern works the testing-house is completely equipped with appliances for ensuring accuracy, and is a great advance on the testing done in the workshops. A brief notice of the testing-room [**361**] of Messrs. Belliss & Morcom, Ltd., makers of high-speed engines, will give an idea of what the equipment involves. It is a large building, served by several electric travelling cranes. Massive cast-iron slabs are let into the floor on which engines to be tested are bolted. Steam and exhaust pipes are laid down from which connections are made. They are arranged with shut-off valves at intervals, so that an engine can be connected and disconnected without interfering with any other engine under test. Four Babcock and Wilcox boilers supply steam at 250 lb. pressure per square inch. There are several condensing plants. A system of tanks is provided for measuring or weighing the water used by the engines. A number of Crosby indicators are employed. Electrical instruments form a large portion of the equipment. Switches and instruments with wire frame and water resistances enable currents and voltages to be measured up to 1,000 electrical horse-power, for both continuous and alternating currents. The men who make the tests do nothing else, becoming specialists in this work.

CLERKSHIP
from page 1920

By R. LAING

THE commodities in which it is the business of a bank to deal—money and credit—form the subject of a most important section in political economy, and, before discussing the functions and practice of a banker, a brief survey of their origin and development will not be out of place.

Barter. Barter is the direct result of division of labour. In a community in which each individual wholly supplies his own needs no exchange of commodities is necessary; but if A devotes his sole attention to the manufacture of shoes, he will, in a very short time, completely satisfy his own want of footgear, and be possessed of a stock which is (to him) without value, while at the same time he is aware of a painful lack of the other necessities of existence. However, B, the hatter, C, the shirtmaker, D, the grower of corn, and their fellows, are in a like condition, and, after a certain amount of bargaining, each rids himself of that which was to him superfluous and valueless, gaining in exchange that which is to him necessary and of, perhaps, great value.

The operation of barter creates values in exchange, or prices, which are solely dependent on the current supply and demand. These two factors are, however, subject to several influences. For instance, they must be effective. The tramp may greatly desire the motor car of the millionaire which passes him on a country road, but he cannot make his demand effective; while the millionaire may strongly wish to be possessed of the tramp's digestion, which, however, the latter cannot effectively supply. Prices, again, do not depend on utility, and vary greatly in differing circumstances. The most extravagant amounts may be given for old curios, which, shipped to Greenland, would command little more than the price of inferior firewood.

Defects of Barter. Barter is at best but a clumsy method of exchange, in consequence of:

1. The need of double coincidence—that A should desire shirts for shoes, and C shoes for shirts;

2. Exact settlement being almost impossible—if one shirt is worth two pairs of shoes and C has only need of one pair, no exchange is possible;

3. The ratios of value being practically innumerable, causing immense difficulty in the settlement of each transaction.

As a result, in every State whose commerce has obtained any measure of importance, a common medium of exchange has been adopted.

This medium is termed money, or currency, and the functions it performs are three in number: (1) It is a measure of values; (2) it is a medium of exchange; and (3) it is a standard for deferred payments.

As 1 it reduces the ratios of value to the number of commodities for sale, less one—itself. As 2 it disposes entirely of the necessity for double coincidence and of the difficulty of settlement, while as 3 it enables the payment in the future of debts now incurred to be carried out with justice to both parties. Supposing a 5 per cent. loan to be made for a year in the form of 100 hats, but that during the year hats become very much less difficult of manufacture. The labour embodied in one hat has been reduced to, say, half of that formerly represented by it, while that necessary for the manufacture of other commodities has remained stationary. In consequence, one hat only exchanges for one-half of the commodities it was worth before, and the lender will not be satisfied with the return of 105 hats at the end of the year, but will ask for 210. The commodity chosen as money requires at all times to possess as far as possible an equal purchasing power.

Upon the greater or lesser degree in which the commodity chosen as money possesses the following essentials depends the efficiency of its performance of the foregoing functions:

(*a*) Utility and intrinsic value.
(*b*) Convenience in size and weight.
(*c*) Indestructibility.
(*d*) Equal sizes and weights to possess always the same value.
(*e*) Divisibility without loss of values.
(*f*) Stability of value.
(*g*) Ease in recognition by all.

It has been found that the metals, more especially gold and silver, possess in the greatest measure the essentials mentioned above, while the State, in accordance with almost universal custom, gives to the public by a system of coinage a guarantee of weight, fineness, and value. In doing so three courses are open to it: all metal may be coined free of charge; a slight charge equal to expenses may be made; or a large profit may be obtained by the issue of a debased or a token coinage.

Standard and Token Money. In every coinage what is termed a standard coin, or coins, will be found—that is, the unit or its divisions, by which all values are reckoned, the standard coins of this country being the sovereign and half-sovereign. These two coins are *Legal Tender* for any amount—*i.e.*, they must be accepted in payment of debt, however large the sum in question may be. Retail transactions require, however, coins of smaller value, and, as further division would result in inconveniently small gold coins, recourse is had (in this country) to the issue of silver and bronze tokens, which are not regarded as divisions of the standard unit, but act as it were as counters in place of these, occupying very much the same position to the standard coin that the beans of card-players, desirous of obtaining the excitement of playing for seemingly large sums, do to the pence for which, perhaps, a score of them afterwards exchange. Both silver and bronze coins issued by the Mint come within the third class, and both are only legal tender to a limited extent—£2 and 1s. respectively.

In the establishment of a system of coinage it is by no means necessary that the State should confine its standard coins to one metal, but may enact that coins of different substances may circulate side by side, either at a fixed or at a varying ratio, and be equally available as legal tender. The double standard has been brought prominently before the public by the advocates of bimetallism.

Credit. Credit may be briefly described as a commercial lubricator, its absence having the same effect on commerce as the omission to apply the oil-can has on the powers of an express locomotive. It is not material wealth, but rather a transfer of it—*e.g.*, the existing mass of material wealth is not increased when a merchant hands over certain goods to another in exchange for a promise to pay at a future date. Credit allows material wealth to be employed to better advantage, and may release for the actual production of commodities that which was formerly engaged solely in their exchange. The advent of commerce having established in turn barter and coined money, its progress creates a growth of credit, and credit substitutes for coined money, until, as in this country, the transactions which are carried through by their agency far exceed in amount those in which the older medium is still used.

With their introduction, a new factor came into being. A seller who receives in settlement so many sovereigns will be quite assured that he can at any time exchange these for whatever he may desire, but he who takes in payment a paper promising to pay three months hence knows that ere that time comes the paper may be valueless, and, consequently, before taking it, he satisfies himself as to the stability and reputation of his debtor.

Credit Movements. In the course of business each merchant will usually become liable for a large sum, for the payment of which (although his assets may greatly exceed his liabilities) he is dependent on the due settlement of similar accounts owing to himself by other traders. The banks will also be due enormous amounts to their depositors, most of which has been lent out at interest. In the ordinary course of events all will go well; but from time to time a suspicion may arise, either rightly or wrongly, regarding one or more merchants, who, in combating it, will be called upon to prove their solvency by the payment of their liabilities. They may be able to do so by drawing upon their bank balances, or by arranging fresh loans; but, on the other hand, the matter may go further. Suspicion continues to spread, failures occur, universal distrust arises, and each one, fearful lest he may be the next called upon to establish his stability, takes precautions and endeavours to raise from his banker the amounts he deems requisite. The latter, however, is just then seeing his deposits diminishing, his reserves of coin disappearing (to make up the increased amount of money required for use), and finding that his securities are unsaleable and the debts due to him unrealisable. In short, unless confidence is restored, or a remedy found, a financial panic is imminent. The remedy for this country is dealt with later in connection with the Bank of England Discount Rate.

Credit Cycles. The recurrence of such crises as the above occur at well-marked intervals. The bank reserves of a country may be high, universal confidence is felt, interest is low, loans can be obtained without difficulty—"money is easy." An element of speculation creeps in —encouraged, perhaps, by the anxiety of banks to lend their surplus funds—and rapidly spreads, until one day some speculators cannot meet their engagements; suspicion soon becomes rampant, and a panic results.

We have now to consider the various forms of *Credit Documents.* The substitutes for coined money divide themselves into five classes: (1) Note Issues; (2) Cheques, drafts, etc., payable on demand; (3) Currency Bills; (4) Book credit; (5) Clearing Houses.

Note Issues. Notes fulfil in a greater measure than any of the other substitutes the functions of money, being in a manner a convenient form of large token money. The methods of issue are many and varied: they may be either convertible or inconvertible, issued by the State or by certain privileged institutions, with or without restrictions.

What are known as *Convertible Notes* take the form of a promise to pay the bearer on demand a certain sum in standard coin, and against such issues an amount in coined money is held as a reserve. If the issue is unrestricted this amount will not equal the total issue, but will only represent that proportion which experience shows is necessary to meet possible demands in the ordinary course of business.

Inconvertible Notes are simply circulating I O U's with a safety margin, no obligation being imposed on the amount mentioned on each note. They may be quite unobjectionable if certain precautions are observed, but in every case they possess a dangerous tendency to over-issue. They are invariably the result and sign of Governmental financial difficulty, the odium of fresh taxation being avoided by the receipt of the forced loan obtained through their issue. The results of inconvertible notes issued to excess are dealt with in a succeeding paragraph.

Regulations as to Note Issues. The regulations imposed by the State on the issuers of convertible notes may remain unaltered even although the notes are made inconvertible, the only difference being that the obligation to pay in standard money on demand is deleted. The issue of each class may be limited to a certain amount, a minimum reserve may be stipulated for, or a reserve varying with the issue may be required. The reserve may be partly composed of securities, while the limit of issue, if any, may perhaps be exceeded on payment of a certain penalty.

If through certain circumstances there exists in any country a good and a bad currency side by side, in the course of time the former will disappear and the latter become the sole money in use. The explanation is not a difficult one if it is borne in mind that the coins of one country when exported are only worth what they will fetch as bullion. No one would, for instance, export our silver token coinage to France so long as twenty shillings (which, when coined, can be exchanged for one sovereign) are only worth about half-a-sovereign when melted down. The coins chosen for export are those of the fullest weight and of the greatest value; the inferior ones being again issued, to circulate by force of law at a rate above their intrinsic value.

If the convertible issues of any country are beyond what are essential, they will be cancelled by being returned for payment to the issuing banks by the other institutions into whose hands they come. No such cancellation is possible in the case of inconvertible notes, which continue to circulate until they can be used by some debtor of the issuer in payment of his debt.

Provided they can be readily exchanged for their face value in gold, no great harm can be said to be done, and if a large issue is made without this exchange becoming impossible, it follows that the currency was formerly insufficient for requirements. An increase of inconvertible notes, without depreciation, results in a rise in prices, and as the notes are readily exchangeable for their face value in gold, encourages imports from foreign countries. At the same time exports will be discouraged—goods which, owing to the rise in raw materials, are now more costly of manufacture commanding abroad but the same price as before. This encouragement of imports and handicap to exports (which will also be brought about by an excess of purely metallic currency) results in an unfavourable exchange and a probable export of bullion. We shall refer to this later under Gold Points.

Additional Effect of Over-issue. If the inconvertible notes are, however, issued to excess, they will become depreciated in value and will no longer exchange for their face value in metal. Almost every country furnishes examples of paper documents, which, while actively circulating, would exchange for only a fraction—sometimes a most insignificant one—of the coin they were supposed to represent. By force of law, however, such paper is legal tender in payment of any debt, and consequently no one is so foolish as to pay any sum in coin while he has so cheap a medium to his hand. As a result the whole of the transactions of the country are settled in paper, which becomes the sole currency, the standard coins in circulation no longer fulfilling their function, being bought and sold with paper money as a commodity with a varying price.

The amount of this credit money current at any time varies with the sum of the transactions which it is called upon to settle, while the cash reserves which act as a basis are quite insignificant when compared to the transactions which they support. A large increase or decrease in these can be settled by means of this *elastic* currency without variation in the general range of prices.

Bills of Exchange. The characteristics of bills of exchange place them in a class midway between note issues and demand documents. Issued in a similar manner to the latter, they may pass through many hands before they become due—a practice that is referred to under the heading of the Continental Demand for London Paper.

The form of credit known as *book credit* will be best explained by the example of two merchants—one in this country shipping British goods to an American correspondent, the latter in return sending him American articles. The entries in the books balance each other, and obviate the use of currency in payment, limiting it at most to the settlement of a periodical difference.

The Clearing House system is specially adapted to the settlement of bargains in wholesale markets, Stock Exchanges, between railway companies, or by any body of traders whose number is small but whose transactions are many and large. The example which mostly concerns banking is that of the London Bankers' Clearing House, and an explanation of its operation will sufficiently explain the effects of the whole system.

The London Clearing House, originated by some private bankers, now includes nearly every important London bank, although even now some very large institutions (notably the Scotch banks) are still without the pale of its operations, and consequently clear through the agency of some other bank. The work of the Clearing House is divided into two sections—the country and the town clearing.

Country Clearing. To trace the actual course of a document passing through this clearing will most readily show its working. A, a Bristol merchant, posts to B, a trader in York, a cheque on Bristol which B hands to C, his banker, for collection on, say, Monday. The same evening C posts the cheque to his London clearing agent D, and on the following day it is handed to E, the London clearing agent of the Bristol bank (whose name appears on the cheque), by D at the Clearing House, and forwarded the same evening to Bristol, where it is received on Wednesday. If the document had been received on Tuesday by the Bristol banker (F), *direct* from the York banker (C), with value, and, as further division would result in inconveniently small gold coins, recourse is had (in this country) to the issue of silver and bronze tokens, which are not regarded as divisions of the standard unit, but act as it were as counters in place of these, occupying very much the same position to the standard coin that the beans of card-players, desirous of obtaining the excitement of playing for seemingly large sums, do to the pence for which, perhaps, a score of them afterwards exchange. Both silver and bronze coins issued by the Mint come within the third class, and both are only legal tender to a limited extent—£2 and 1s. respectively.

In the establishment of a system of coinage it is by no means necessary that the State should confine its standard coins to one metal, but may enact that coins of different substances may circulate side by side, either at a fixed or at a varying ratio, and be equally available as legal tender. The double standard has been brought prominently before the public by the advocates of bimetallism.

Credit. Credit may be briefly described as a commercial lubricator, its absence having the same effect on commerce as the omission to apply the oil-can has on the powers of an express locomotive. It is not material wealth, but rather a transfer of it—*e.g.*, the existing mass of material wealth is not increased when a merchant hands over certain goods to another in exchange for a promise to pay at a future date. Credit allows material wealth to be employed to better advantage, and may release for the actual production of commodities that which was formerly engaged solely in their exchange. The advent of commerce having established in turn barter and coined money, its progress creates a growth of credit, and credit substitutes for coined money, until, as in this country, the transactions which are carried through by their agency far exceed in amount those in which the older medium is still used.

With their introduction, a new factor came into being. A seller who receives in settlement so many sovereigns will be quite assured that he can at any time exchange these for whatever he may desire, but he who takes in payment a paper promising to pay three months hence knows that ere that time comes the paper may be valueless, and, consequently, before taking it, he satisfies himself as to the stability and reputation of his debtor.

Credit Movements. In the course of business each merchant will usually become liable for a large sum, for the payment of which (although his assets may greatly exceed his liabilities) he is dependent on the due settlement of similar accounts owing to himself by other traders. The banks will also be due enormous amounts to their depositors, most of which has been lent out at interest. In the ordinary course of events all will go well; but from time to time a suspicion may arise, either rightly or wrongly, regarding one or more merchants, who, in combating it, will be called upon to prove their solvency by the payment of their liabilities. They may be able to do so by drawing upon their bank balances, or by arranging fresh loans; but, on the other hand, the matter may go further. Suspicion continues to spread, failures occur, universal distrust arises, and each one, fearful lest he may be the next called upon to establish his stability, takes precautions and endeavours to raise from his banker the amounts he deems requisite. The latter, however, is just then seeing his deposits diminishing, his reserves of coin disappearing (to make up the increased amount of money required for use), and finding that his securities are unsaleable and the debts due to him unrealisable. In short, unless confidence is restored, or a remedy found, a financial panic is imminent. The remedy for this country is dealt with later in connection with the Bank of England Discount Rate.

Credit Cycles. The recurrence of such crises as the above occur at well-marked intervals. The bank reserves of a country may be high, universal confidence is felt, interest is low, loans can be obtained without difficulty—"money is easy." An element of speculation creeps in—encouraged, perhaps, by the anxiety of banks to lend their surplus funds—and rapidly spreads, until one day some speculators cannot meet their engagements; suspicion soon becomes rampant, and a panic results.

We have now to consider the various forms of *Credit Documents.* The substitutes for coined money divide themselves into five classes: (1) Note Issues; (2) Cheques, drafts, etc., payable on demand; (3) Currency Bills; (4) Book credit; (5) Clearing Houses.

Note Issues. Notes fulfil in a greater measure than any of the other substitutes the functions of money, being in a manner a convenient form of large token money. The methods of issue are many and varied: they may be either convertible or inconvertible, issued by the State or by certain privileged institutions, with or without restrictions.

What are known as *Convertible Notes* take the form of a promise to pay the bearer on demand a certain sum in standard coin, and against such issues an amount in coined money is held as a reserve. If the issue is unrestricted this amount will not equal the total issue, but will only represent that proportion which experience shows is necessary to meet possible demands in the ordinary course of business.

Inconvertible Notes are simply circulating I O U's with a safety margin, no obligation being imposed on the amount mentioned on each note. They may be quite unobjectionable if certain precautions are observed, but in every case they possess a dangerous tendency to over-issue. They are invariably the result and sign of Governmental financial difficulty, the odium of fresh taxation being avoided by the receipt of the forced loan obtained through their issue. The results of inconvertible notes issued to excess are dealt with in a succeeding paragraph.

Regulations as to Note Issues. The regulations imposed by the State on the issuers of convertible notes may remain unaltered even although the notes are made inconvertible, the only difference being that the obligation to pay in standard money on demand is deleted. The issue of each class may be limited to a certain amount, a minimum reserve may be stipulated for, or a reserve varying with the issue may be required. The reserve may be partly composed of securities, while the limit of issue, if any, may perhaps be exceeded on payment of a certain penalty.

If through certain circumstances there exists in any country a good and a bad currency side by side, in the course of time the former will disappear and the latter become the sole money in use. The explanation is not a difficult one if it is borne in mind that the coins of one country when exported are only worth what they will fetch as bullion. No one would, for instance, export our silver token coinage to France so long as twenty shillings (which, when coined, can be exchanged for one sovereign) are only worth about half-a-sovereign when melted down. The coins chosen for export are those of the fullest weight and of the greatest value; the inferior ones being again issued, to circulate by force of law at a rate above their intrinsic value.

If the convertible issues of any country are beyond what are essential, they will be cancelled by being returned for payment to the issuing banks by the other institutions into whose hands they come. No such cancellation is possible in the case of inconvertible notes, which continue to circulate until they can be used by some debtor of the issuer in payment of his debt.

Provided they can be readily exchanged for their face value in gold, no great harm can be said to be done, and if a large issue is made without this exchange becoming impossible, it follows that the currency was formerly insufficient for requirements. An increase of inconvertible notes, without depreciation, results in a rise in prices, and as the notes are readily exchangeable for their face value in gold, encourages imports from foreign countries. At the same time exports will be discouraged--goods which, owing to the rise in raw materials, are now more costly of manufacture commanding abroad but the same price as before. This encouragement of imports and handicap to exports (which will also be brought about by an excess of purely metallic currency) results in an unfavourable exchange and a probable export of bullion. We shall refer to this later under Gold Points.

Additional Effect of Over-issue. If the inconvertible notes are, however, issued to excess, they will become depreciated in value and will no longer exchange for their face value in metal. Almost every country furnishes examples of paper documents, which, while actively circulating, would exchange for only a fraction—sometimes a most insignificant one—of the coin they were supposed to represent. By force of law, however, such paper is legal tender in payment of any debt, and consequently no one is so foolish as to pay any sum in coin while he has so cheap a medium to his hand. As a result the whole of the transactions of the country are settled in paper, which becomes the sole currency, the standard coins in circulation no longer fulfilling their function, being bought and sold with paper money as a commodity with a varying price.

The amount of this credit money current at any time varies with the sum of the transactions which it is called upon to settle, while the cash reserves which act as a basis are quite insignificant when compared to the transactions which they support. A large increase or decrease in these can be settled by means of this *elastic* currency without variation in the general range of prices.

Bills of Exchange. The characteristics of bills of exchange place them in a class midway between note issues and demand documents. Issued in a similar manner to the latter, they may pass through many hands before they become due—a practice that is referred to under the heading of the Continental Demand for London Paper.

The form of credit known as *book credit* will be best explained by the example of two merchants—one in this country shipping British goods to an American correspondent, the latter in return sending him American articles. The entries in the books balance each other, and obviate the use of currency in payment, limiting it at most to the settlement of a periodical difference.

The Clearing House system is specially adapted to the settlement of bargains in wholesale markets, Stock Exchanges, between railway companies, or by any body of traders whose number is small but whose transactions are many and large. The example which mostly concerns banking is that of the London Bankers' Clearing House, and an explanation of its operation will sufficiently explain the effects of the whole system.

The London Clearing House, originated by some private bankers, now includes nearly every important London bank, although even now some very large institutions (notably the Scotch banks) are still without the pale of its operations, and consequently clear through the agency of some other bank. The work of the Clearing House is divided into two sections—the country and the town clearing.

Country Clearing. To trace the actual course of a document passing through this clearing will most readily show its working. A, a Bristol merchant, posts to B, a trader in York, a cheque on Bristol which B hands to C, his banker, for collection on, say, Monday. The same evening C posts the cheque to his London clearing agent D, and on the following day it is handed to E, the London clearing agent of the Bristol bank (whose name appears on the cheque), by D at the Clearing House, and forwarded the same evening to Bristol, where it is received on Wednesday. If the document had been received on Tuesday by the Bristol banker (F), *direct* from the York banker (C), with instructions to remit the amount, he would possess at law the option of holding over the cheque until the following day, Wednesday. In order that a cheque passed through the London Clearing House may be placed on an equality, this option is, by the clearing rules, not permissible with cheques passed through the clearing. If unpaid on Wednesday, F returns the cheque direct to C, and sends concurrently to E an advice of non-payment. If on Thursday morning this is not received by E, the cheque is assumed to be paid, and the amount is paid by being carried into the town clearing of that day, the operations and settlement of which are dealt with in the next paragraph. The necessary entries are passed by the banks concerned through their agency accounts, and the transaction is settled without the intervention of a single coin.

Town Clearing. To deal with the clearing a separate department is formed in each clearing bank, and to this department is handed all documents which can be passed through the Clearing House. These they enter under the headings of the other clearing banks, the total received during the day being afterwards agreed with the other departments. After being thus entered, the documents are forwarded by messenger to the Clearing House in Post Office Court, and there handed to the representative of the bank on whom they are drawn, and by him entered in a similar manner. At the close of the day the books written up at the offices of the delivering banks are compared with those made up at the Clearing House by the representatives of the receiving banks.

When the various balances have been agreed and any returned documents from head offices accounted for, the representative of each bank enters on a form provided the balances due to or by his bank to each of the others, bringing out the final balance either due to or by it. The final balances thus arrived at must liquidate each other. Each clearing bank keeps an account at the Bank of England, and a settlement is accomplished by the debtor banks paying into a special settlement account at the bank from their own accounts the amounts due by them, and from this account the sums due to the creditor banks are taken and credited to their accounts by the bank. In this way the settlement of transactions to the extent of £12,287,935,000 was in 1905 effected without the agency of a solitary penny piece. The offices, cheques drawn on which are included in the town clearing, comprise the head offices, the City branches, and most of the suburban ones.

Internal Trade. The natural advance of commerce in any country results in the territorial division of labour, some counties, by reason of natural resources, devoting themselves to those industries in which the expenditure of a large capital is necessary, while that required for those peculiar to other parts may be comparatively small. Assuming an equal rate of profit in either case, it will be found that while in the second class the resulting surplus cannot be employed in the place of origin, the first class, so far from being in this position, can actually utilise the surplus of the second. In addition to the consequent constant flow of capital from one part of the country to another the actual trading business may, in certain instances, have a somewhat similar effect. For example, a manufacturing town (whose productions are exported to foreign countries) purchasing the raw materials required in some other part of the country, will be constantly in debt to that locality from which it draws its raw materials. The methods by which the necessary transfers are made will be treated when dealing with the Branch System.

International Exchange. The factors in the trade between any two countries, and the methods of settlement, present a greater complexity than those relative to internal trade. At the outset we find that in nearly every case the currencies employed are dissimilar, and that between two countries possessing the same standard there exists what is termed a *Mint Par.*

This is a figure which represents the ratio between the amount or weight of fine metal contained in the standard coins of the two countries in question, the mint par between this country and France is 25·2215—simply meaning that in 25·2215 francs in French gold coinage there is contained the same amount of fine gold as in an English sovereign. A mint par is mechanical and fixed, and can only exist between countries possessing the same standard.

There are four individuals in each exchange transaction. The truth of this phrase will be apparent from the following example. If A in Paris owes X in London £100, while Z in London owes B in Paris an equal amount, the double indebtedness will be cancelled by B drawing a bill on Z, which he sells to A for a certain number of francs, and which, after being remitted by the latter to X in payment of his debt, is paid on presentation by Z, who thus satisfies his debt to B through the medium of A and X. This is, in substance, the working principle of every foreign exchange transaction, the only possible difference being the increase of the parties intervening between Z and B.

Gold Points. Assuming the indebtedness of the countries to be equal, the resulting equality of supply of, and demand for, bills will cause the sight rate to be quoted at the mint par. If, however, it occurs that in Paris there are more debtors than creditors of this country, the demand for bills will exceed the supply. Those indebted to London have two methods of payment open to them—they may either remit bills purchased in Paris, or they may ship sufficient bullion to liquidate the debt. The latter course will entail a certain expense, say of 10-12 centimes per £; so that to put down in London 25·2215 francs in French gold coinage, equivalent to one sovereign, the merchant in Paris will expend 25·3215 or 25·3415 francs.

He will certainly not do this if he can purchase a bill on London for £1 at a better rate, and accordingly the matter resolves itself into a struggle between buyers and sellers, in which the price of a bill for £1 on London (expressed in French francs) continues to rise until it reaches that point at which it is as profitable to ship bullion, unless in the rise a sufficient number of buyers drop out, hoping for a more seasonable opportunity, or a number of dealers in arbitrage [see later] enter the market as sellers. An excess of creditors of London in Paris would, of course, influence the exchange in the opposite direction.

Gold Points not Fixed. The two gold points between two gold standard countries can only be determined approximately, the cost of shipping and insurance varying, while other influencing factors may exist. The point at which gold leaves France and Germany for this country is, owing to certain restraints exercised by them, less easily reached than that at which gold leaves us for them.

If the rate of the French exchange should be quoted in the money column of the newspapers as approaching the point at which gold will leave this country for France, the City editor will no doubt remark upon its *unfavourable* aspect; while, if the rate is given as 25·25, he will refer to it as being in *our favour*. These terms owe their origin to an exploded theory in political economy, but their present meaning and significance is wholly wrapped up in the fact that, when there is no danger of gold leaving this country reserves will be high, interest low, and trade encouraged; while, if an export of bullion is threatened, an entirely opposite state of affairs will exist. The subject is further treated in dealing with the Bank of England Discount Rate.

The main elements in "International Indebtedness" are the imports and exports between the countries concerned, but in the case of nations such as ourselves, possessing a large amount of shipping, freights earned by such shipping affect very greatly the balance of trade. A British vessel transporting a cargo of machinery to Hamburg will, if the transaction is to be completely settled, require on the return voyage to carry a quantity of, say, grain, that will, when realised, liquidate the claim of the British engineer and the shipowner's charges for the *double* voyage. The vast sum of money invested abroad by this country possesses also a great influence on the exchanges.

Effect of Loans on Exchanges. The lending country may remit to the borrowing country the amount of a loan in one or all of three ways—either by the export of some products or bullion, or by the extinction of an already existing floating indebtedness. The effect on the exchange in each case will be exactly similar—it will become more favourable to the borrowing country; but, on the other hand, when the first instalment of interest is due, and on each subsequent payment, the exchange will be influenced in favour of the lender.

Other influencing factors comprise subsidies, indemnities, expenses of foreign travel, the cost of fleets and garrisons in foreign stations, and the purchase and sale of foreign securities. In addition, one important factor remains—namely, the operations of arbitrage. If some dealers in exchange in Paris are of opinion that in the future the London sight rate will fall greatly, they will, by arrangement with their London correspondents, sell largely bills drawn on the latter, hoping to be able to extinguish the overdrafts thus created by purchases at a cheaper rate. If an arbitrage firm are able to sell a bill for £1 on London for 25·27 francs, and next week buy a bill for the same amount (to recoup their London friends) for 25·20 francs, they will have gained a profit of 7 centimes per £1, less interest, etc. In doing so, they will, in the first place, reduce the high rate by selling, and, secondly, raise the low rate by buying.

Position of the Banker in Commerce. The functions of the banker in commerce are very much akin to those of the mortar employed in the construction of a large building, without which somewhat insignificant-looking agent the gigantic fabric would be non-existent, for in like manner the bank officials in this country, in the performance of what is largely commonplace routine, cement together the trading communities of the whole world. So great is the dependence of present-day commerce upon the facilities and conveniences afforded by banking institutions that even the total destruction of our railways would not equal the effect produced by the complete cessation of banking business. Banking may be considered, according to the inclination of the individual, either a trade or a profession, but in reality the former term is more correct, for, although not actually dealing with the products of commerce, the banker trades in the commodities on which commerce is dependent—money and credit.

Functions of a Banker. The most widely spread of banking functions is the practice of note issue. In all new countries —even though they be possessed of unrivalled natural resources—there is usually felt a lack of circulating medium. The expenditure of a large amount of their available capital in the establishment of a system of metallic currency does not meet with any favour in their eyes, while at the same time the opening of branch banks in a sparsely-populated country is rendered impossible on account of expense. To all such countries a good note issue, more especially a carefully-managed unrestricted one, is of the highest value, combining in itself at one and the same time an economical currency, a convenient form of internal remittance, and a factor in production which, although in itself valueless, may be the means of laying the basis of a far-reaching commercial greatness. [See Scotch Banking.]

The system in vogue in France at the present day partakes of this form to a great extent, while that function which is most in evidence in banking in this country (that of deposit) is comparatively neglected, the issues of the Bank of France taking the place occupied in this country by the cheques of private individuals.

FIRST STEPS IN JOURNALISM

Fitness for Journalism. How the Candidate may Test Himself. Opportunities on the Local Papers. Helpful Exercise. Preparing the Way for a Successful Career

By ARTHUR MEE

THERE are many gates through which the candidate for journalism may enter the profession. So simple is the passing through them that the ways and means of doing so need only brief mention. They will be apparent to the young man destined for journalism, the young man of more than average capacity, and it is entirely with him that we have to deal.

The First Thing to do. For journalism has no room for men whose mind and character are not above the average; no room, at any rate, at the top.

We have nothing to do here with the young man who wants to muddle through. The SELF-EDUCATOR is conceived and edited and written for the young man who believes that whatever he does is worth doing successfully, that if he is not doing it successfully he had better leave it alone and succeed at something else; and this course of journalism is written for the young man who would be a journalist in earnest, who wishes to be somebody worth being, and to do something worth doing.

To this young man, as he looks round on leaving school and makes up his mind to be a journalist, the course will be clear. He should get at once into touch with the nearest editor.

The very obviousness of this is one of the most wonderful things about the career upon which he is entering. If he had made up his mind to be a doctor, or a lawyer, or an architect, and the SELF-EDUCATOR had not come into existence to help him, he might have been bewildered by the difficulty of obtaining the simplest information, the expense of examinations, and the long period of waiting.

But it is safe to say that there is not a young man in England with the possibility of becoming a journalist into whose home there does not come at least once every week the very vehicle through which he may set out for his goal. We have discussed the democracy of journalism, and there is no more remarkable thing about this fascinating career than this, that we can train ourselves for it in our own homes, in every day that we live; that wherever we are we may equip ourselves for it, without any conscious effort, by ordering our lives naturally and reasonably and well. No course at a college is necessary, no costly period of apprenticeship. The training of him who would be a journalist is in his own hands.

The Study of Local Life. What, then, is the first thing that he should do? He should study the local papers and familiarise himself with the things with which they deal. He should make it his business to understand the village or town in which he lives, to let nothing happen in it of which he does not know; to interest himself in all its social and industrial developments; to be in touch, somehow, with all its active movements. He should lose no opportunity of discussing any subject of local interest. He should learn to understand the various points of view, the ideas that lie below things, to know the interesting personalities in local affairs, and what they stand for. The life of the town is the best training-ground he could possibly have, and by taking full advantage of the opportunities it affords, he will be living naturally and preparing himself at the same time for his career.

There are, of course, various definite preparations that he should make. He will naturally have learned shorthand. Any boy of average intelligence can learn shorthand from the SELF-EDUCATOR in six months. He will have thoroughly grounded himself in grammar at school, have mastered the art of punctuation, have learned to write plainly and without flourishes. He will read books as well as papers, and will not waste the time he should spend in study in watching men kick a ball about. He will not turn to the sporting page the moment he takes up a paper, but will have a sense of the real value of things, and know that a consuming passion for sport is his enemy.

What to Read and Learn. Such things as these must be obvious from the very beginning, and it will help him greatly to study the scientific and literary sections of the SELF-EDUCATOR. He cannot, indeed, be too strongly advised to study this book closely, with special attention to the following subjects:

BIOLOGY
PSYCHOLOGY
SOCIOLOGY
LOGIC
PHILOSOPHY
RELIGION
CHEMISTRY
GEOGRAPHY
HISTORY
APPLIED EDUCATION
IDEAS
LITERATURE
PHYSICS
PHYSIOLOGY
TRAVEL

It need not be said that a sound knowledge of his own language is essential, and he will do well, even if he possesses this, to study the course on English in the EDUCATOR. If he can learn French and German, too, he will add greatly to his opportunities; at any rate he should learn French. The value of a knowledge of languages is so apparent that it is not necessary to emphasise it; but it is strange that editors should feel more and more the necessity for emphasising the importance of a knowledge of our own language. It is an amazing thing that the number of people who can write a sensible and interesting letter is only a small proportion of those who would be hurt not to be called educated; and an editor's experience compels him to believe that the average man finds it exceedingly difficult to express himself clearly in writing. It is a commonplace that men whose conversation is packed with interest are often unreadably dull when writing, and the young journalist cannot regard this subject too seriously. It is the very essence of successful journalism that a man shall be intensely interested in things, and shall be able to make other people as interested in what he knows as he is himself.

The Art of Expression. The question of "style" in writing can be left to settle itself. If a man does not write plainly he will soon discover the fact by finding that journalism does not want him; and if he, a round man, insists upon trying to fit himself into a square hole he will be entirely to blame for the consequences. We shall have to discuss this question later; it need only be touched upon here to explain how the journalist may help himself to master the art of literary expression.

He will find the best opportunities for doing so in the local papers themselves. He is almost sure to find, wherever he is, one paper that gives long accounts and another paper that gives short accounts, and he will find it a very profitable exercise to take the long account of a ceremony, or the long report of a speech, from the one paper, and condense it to the length of the short report in the other paper. Let him take a column and condense it to a paragraph, without losing any vital point of argument, and with as little sacrifice of interest as possible. He should learn, also, to summarise a speech in longhand, writing it as it is delivered, and for exercise of this kind he will find a knowledge of the abbreviations used in journalism of great service. We come to them in the next few pages.

The question of personal fitness for newspaper work will decide itself quickly for the young man who is sensible enough to realise his own capacities or honest enough to recognise his limitations. But it will save a great deal of disappointment if the candidate for journalism tests himself in some main points before seeking to enter the profession. There are some specific tests we may quite easily apply to ourselves.

Object Lessons. We may make a newspaper an object-lesson—may ask ourselves if, had we edited the paper, we would have passed this or sanctioned that? We may compare the length of two articles, and form our own opinion of their comparative values. We may consider the appropriateness of the headings, and ask ourselves if we could improve upon them. We may compare papers, and note where one succeeds and the other fails; we may study them closely and discover for ourselves the reason why people buy one and not another. Best of all, we may prepare our own map of the life of the town on any given day or in any given week, and compare it with the corresponding daily or weekly paper. It is possible to obtain quite an intimate knowledge of the way in which newspapers deal with events by constant exercise of this kind.

The regular practice of shorthand is essential, and no better method of practice can be devised than constant attendance at public gatherings of all kinds. The young journalist should never fail to take advantage of an opportunity of making notes. His notebook and pencil should be as essential a part of his outdoor equipment as his hat. He should take down speeches and sermons, and it will be better still for him if he has opportunities of making notes of conversations. If he has friends who are interested in his progress, they could, perhaps, do him no better service than to let him interview them on some topic in which he and they are interested.

Early "Copy." Another experience the young journalist may give himself will be very useful to him one day if he practises it early. He should learn to write exactly a column of his favourite newspaper, or exactly a paragraph. One of the most elementary faults of incapable journalists is the inability to write as much as they are told to write, and no more. It is surprising to find that even qualified writers when asked for a 1,000 words will often write 1,500, and if asked for a paragraph will write half a column.

Every day will bring its own events for the journalistic mind to exercise itself upon. The things of universal interest are the things that the average man talks about, and the young journalist should write a short account every day of something he has heard, or seen, or perhaps read. He should make it his business to discover the most interesting aspect of all that happens.

He will find, if he belongs to the elect of journalism, that the thought will constantly come to him, "Here is copy for a paper," and at all such times he will make a note and write a paragraph. These paragraphs he will submit to the editor of the paper in which he is most interested, to whose columns he has adapted them. There will in this way grow up between him and the editor a channel of interest which will serve him better than any introduction when he comes to seek an actual engagement.

In Touch with the Editor. He will find that the connection thus established is the best of all possible introductions to a newspaper, and he will find, if he lives with his eyes open, abundant opportunities of helping the paper by sending reports of events which it has missed through not being notified. If he is identified with a church or chapel, with a trade organisation, or with any social movement, occasions for giving the paper such help will be by no means few or far between. The time will probably come when, on a busy day, the editor will want special help, and his inclination will be at once to call upon his outside contributor. If he should live in the country he would have no difficulty in obtaining an appointment as local correspondent at a fixed rate of pay measured by the work done, usually a penny a line for all that is published, with a minimum payment of half a crown. If he should live in the town where the paper is published he may have to wait longer, but an enthusiastic cultivation of opportunities will bring its reward at last. Hardly a day passes in which it is not possible for a young man with the ability to write to send in an acceptable paragraph to a paper.

Education by Travel. The young journalist need not trouble about a university education. He need not despise it if the opportunity should come to him, but if he should have the choice, say, of going to a university or of travelling for a year, he will be wise to travel. "The only thing against him," a newspaper proprietor said in discussing an applicant for a post, "is that he has been to a university." And it was merely an extreme way of putting the truth that a university career does, unfortunately, too often detach a man from that side of life which comes very closely into journalism.

The opportunities of popular education are so great in these days that no man need go to a university to become a successful journalist, and it is impossible that two years in any university can contribute to his capacity for journalism anything at all comparable in value with the result of two years of contact with men and affairs, or two years of actual experience in a newspaper office.

Having assured himself of his fitness for the work, the young journalist will not wait for an opportunity to present itself. He should write to the local editor as soon as he feels that he has any real capacity to justify him. If he is fortunate, he will probably be asked to call and serve a little while on trial, preliminary to becoming an apprentice. He should accept a proposal of this kind with great satisfaction. Once the gate is open, his future lies with himself.

But he should pay no premiums; and in no circumstances should he pay down a sum of money for the privilege of learning journalism. The offices in which this would be insisted upon are seldom capable of teaching journalism. Nor should he become—unless, perhaps, in some small town it may be quite inevitable—a "reporter-comp," a reporter, that is, who sets up his own copy.

Sleepy Papers. It may be well, perhaps, to prepare the young journalist for some disappointment in beginning his career. He may find himself on the staff of a paper which does not fire his imagination or fill him with any stirring hopes, and he may be inclined to ask himself if, after all, journalism is the mighty thing that it is claimed to be. If he is wise, he will not allow himself to be depressed by any environment in which he may find himself placed. It happens often that a newspaper is the least representative thing in the town in which it is produced; just as it happens that a portrait is utterly unlike the man who sat before the camera. But a bad newspaper is no more a denial of the imagination and power in journalism than a bad photograph is a denial of the possibilities of photography.

The true attitude of a young journalist who is wide awake on a sleepy paper is one of philosophic patience. He must use the best machine he can find for initiating himself into the mysteries and difficulties and potentialities of a newspaper, and it may, indeed, happen that the very best field he could desire for his earliest work is just such a paper as we have considered. If he is attached to a paper which works him hard and pays him ill, that at least will teach him patience. If he joins a staff which is far too small, that at least will give him opportunities of distinction. If he joins a staff which needs lessons in enterprise, that at least will enable him to display originality.

The Young Journalist's Environment. It is unfortunately true that newspapers are often the commercial property of men who know nothing of journalism, who care nothing for its immense possibilities, its traditions, or its dignities. To many proprietors a newspaper is an article of commerce like soap, and nothing more. There are newspapers which send out ungrammatical advertisements every time they have a vacancy, and there are papers with a hundred glaring faults which we shall discuss in their place. But there are few ideal things in an unideal world, and only a pessimist will allow himself to be utterly depressed by it. And the pessimist has no business to be a journalist.

As sometimes the office in which the journalist finds himself is disappointing, so, too, the atmosphere of local journalism may fill him with despair. Too often it is the atmosphere of a third-rate club, with beer and skittles and a favourite room at a public-house. There is something, perhaps, in the conditions of journalism which brings about this state of things. Long hours, irregular meals, strenuous mental exertion combined often with great physical activity, are not the natural factors in an equable and steady life. But the good journalist will rise above the vulgar conditions in which he will often find himself placed. He will not allow either his pride in his calling or his outlook on life to be prejudiced because sometimes, somehow, it happens that newspaper men write their copy in the back parlour of a public-house and dissipate the hours of sleep in bad clubs and bad company.

The Unprosperous Tenth. General Booth has familiarised us with the idea of the submerged tenth. There is an unprosperous tenth in journalism, to which it is all too easy to belong. Who wants to join it may; it is a characterless army, with no high patriotism to inspire it, no great cause to serve. To it belong many figures sadly familiar in Fleet Street, and in the newspaper haunts of our great towns. No profession, surely, had ever more failures.

The young journalist, however, need not despair. There are sadder things in the world than the wreck of a man who has played with a serious profession. There are sadder things, even, than the man who fails because he chooses a career for which he is unfitted, who takes no heed of the warning which must come while still there is time.

The young man who comes into journalism bearing in mind all that we have considered together, testing himself in the ways we have discussed, full of enthusiasm and hope, eager to pick up an idea, to catch a thought, to feel an inspiration, to know the most that he can know about the best things worth knowing, may go forward without fear. With a full mind and a soul alive he will make his way and reach his goal.

NAVIGATION OF THE AIR

Balloon Construction. Varieties of Balloons. Gases Used for Inflation. Ascending and Descending. Parachutes. Airships

By PERCIVAL SPENCER

As a fish floats in the water so does a balloon float in the air. When the fish distends its air-bladder, it becomes lighter than the water, and rises; when the fish compresses its bladder, it becomes heavier than the water, and sinks. When a balloon is inflated with a gas so that it is lighter than the air, it rises in the air; when it loses some of its gas and becomes heavier than the air, it sinks to the earth.

Air at ordinary temperature weighs 75 lb. for 1,000 cubic ft. Hydrogen, coal gas, and hot air, are all lighter than the ordinary atmosphere, and are used for the purpose of inflating balloons. Hydrogen weighs only 5 lb. for a similar quantity, and is so light that there cannot be much advantage for the purpose of balloon inflation in discovering anything lighter, for the lifting power of hydrogen in air is 70 lb. per 1,000 cubic ft. For economical reasons coal gas is now largely used for ballooning purposes. It has a lifting power of 40 lb. per 1,000 cubic ft.

The system of obtaining levity by means of heating the air itself is practically successful, although it is considerably less efficient than the gases already mentioned. For each degree Fahrenheit that the air in a balloon is raised, it increases $\frac{1}{475}$ in bulk, so that should the temperature be raised 100 degrees the bulk has increased about one-fifth, and has a lifting power of 12½ lb. per 1,000 cubic ft. In practice it may be possible to raise the temperature to 150 or 200 degrees higher than the surrounding air, so that a lifting power of 25 lb. per 1,000 cubic ft. may be obtained.

To lift 70 lb. weight in air a sphere of 1,000 cubic ft. of hydrogen is required 12 ft. in diameter.

Materials for Balloons. The whole bulk of the inflated balloon and its load must be lighter than an equal bulk of air. The simplest form of balloon that can be imagined is the soap bubble. Experiments may easily be made with soap bubbles inflated with ordinary air, or with coal gas, or pure hydrogen. Small scientific balloons are sometimes made of a dry film of collodion, most delicate and fragile articles of 2 in. or 3 in. diameter which ascend when inflated with their quota of coal gas or hydrogen. Indiarubber toy balloons are made in sizes up to 60 in. in circumference. They may be inflated under tension with air, coal gas, or hydrogen, and are suitable for experimental as well as recreative purposes.

Paper Fire Balloons. Tissue paper is used to construct balloons of from 6 ft. to 50 ft. in circumference on the hot-air system. A large aperture is left at the bottom of the balloon, surrounded with a circle of cane or wire. A pad of cotton wadding is attached in the centre of this circle by means of cross wires. When this pad is soaked with methylated spirit and ignited, a flame of sufficient power is formed to heat and rarefy the air in the balloon to such an extent that the balloon readily ascends and, in the case of the larger sizes, is capable of carrying considerable weight.

Gold-beater's-skin Balloons. Gold-beater's skin forms the substance of which the most practical model gas balloons are made. This animal membrane makes a strong, light, and gastight envelope which is easily inflated with ordinary coal gas or hydrogen at the ordinary atmospheric pressure. The skin is used single for the very smallest balloons, for those of from 12 in. to 24 in. diameter. For larger sizes the skins are employed double, treble, or manifold, and are caused to adhere in the process of manufacture in such a manner that the whole balloon appears seamless, however large and thick it may be. Double and treble skin balloons are made from 2 ft. to 10 ft. in diameter for use with coal gas or hydrogen, and in larger sizes they are used in manifold skin by the British Government for military reconnoitring purposes.

Passenger Balloons. The materials, however, which are usually used for balloons to carry passengers are cotton or silken fabric coated with an oil varnish which forms a film over the fabric and thereby completely closes the pores and enables the envelope to hold gas. A proofing of vulcanised indiarubber is sometimes used; this is gastight, and free from tackiness, but somewhat costly. The varnished fabric is generally preferred owing to the fact that another coat of varnish is easily applied when needed, and renders the balloon again perfectly gastight. The network which is spread over the gas balloon naturally strengthens the material besides achieving its direct object of equalising the strain of the weight which is carried uniformly over the surface.

Hot-air passenger balloons are made of cotton fabric strengthened with webbing sewn over the surface, coated inside with a distemper earth colour, and without the netting of the gas balloon.

Smallest Man-carrying Balloons. We have explained that the lifting power of hydrogen is 70 lb. per 1,000 cubic ft., so that 5,000 cubic ft. will lift 350 lb., and a balloon containing this represents the minimum size that will carry a man. The 350 lb. may be divided up into the proportion of 150 lb. for the total weight of the balloon and its equipment, and 200 lb. for the weight of the man, ballast, and lifting power. This represents a balloon of slightly more than 20 ft. diameter, which must be regarded as the midget of all aerial craft.

For coal gas the irreducible minimum would be 10,000 cubic ft., which is represented by a sphere of 26 ft. diameter. The minimum for a hot-air balloon is considerably greater, and in practice never less than 30,000 cubic ft., representing a vessel of 35 ft. in diameter.

Shape of Balloons. The spherical form is the most natural shape for a balloon. The pear-shaped balloon, comprising a perfect sphere with a gracefully tapered neck, has some advantages of utility as well as appearance, and is frequently adopted.

The obvious advantages of the elongated forms used for navigable balloons or airships are obtained at the cost of considerable increase of surface and therefore of weight.

We shall now proceed to describe in detail the passenger balloon and its appliances. It consists of a number of gores sewn together by a sewing machine, and afterwards completely varnished to render it impervious to the coal gas which it is to contain. Its size varies with the weight it is to carry. In capacity, approximately 10,000 cubic ft. is required for each passenger to be lifted. Taking a balloon, therefore, of 50,000 cubic ft. as a model, this is capable of carrying five persons and a proportionate weight of ballast. It would have a diameter of 45 ft., be constructed in pear shape, and have an aperture at the bottom, and another at the top to contain the valve.

The Valve. The valve [1] consists of a bent ash hoop (A) of approximately 2 ft. 6 in. diameter, made of wood about 3 in. by ¾ in. It has a cross-bar of mahogany (C) which crosses its centre, and to this bar are hinged two semicircular mahogany doors (B, B) which open inwards, somewhat after the style of the wings of a butterfly. Fitting into the bar, and made removable, is a wooden bridge (D) which carries an elastic spring (E, E), and this elastic spring retains the doors in a closed position by means of metallic hooks which pass through eyes into the doors themselves. The effect of this arrangement is that the doors are normally closed.

The valve line (F) is attached to the under side of these doors from two points in each door. The four cords which leave these points join the valve line itself a few feet down, and hence one line only continues downwards through the aperture or mouth, which is always left open while the balloon is sailing in the air, to within reach of the passengers in the car. When the line is pulled from below, the doors are naturally opened, and when the line is released they immediately close by the force of the springs, so that the valve may be opened and closed at the will of those in the car. The valve is attached to the top of the balloon by being firmly whipped on with cords which pass over a collar of the material prepared for its reception. This collar is also strengthened, both underneath the cord and for some distance over the surface of the balloon, by means of an addition of leather which is shaped in regular festoons, and then sewn on. The valve is rendered gastight at the joints by means of "lute," a composition of soap and fat, forced into the crevice so as to seal it.

Netting. Made completely to cover the balloon proper is the net, the object of which is to carry the entire weight that is to be suspended from the balloon. It divides the strain very evenly over the whole surface, and it also plays an important part in the inflation of the envelope, enabling a large number of sandbags to be hooked on, thus retaining and steadying the balloon during inflation. This net is made of Italian hemp, and consists of a large number of meshes, which vary in number with the size of the balloon. In the model we have selected there would be 128 of these meshes. In size they would start at about 6 in. at the top, and slowly increase as they descended, until at the largest point they would be about 12 in. in length, which would make each diagonal nearly 24 in. from top to bottom.

The cordage would slightly increase in strength downwards, being rather lighter at the top than at the bottom. From the bottom of the net the meshes take a somewhat altered appearance, and are lessened in number and greatly increased in length for three rows.

These rows of the network are no longer meshed, but are known technically as *doubles.* From the lower of the three doubles, which are not knotted like the ordinary meshes, but run on brass thimbles, start the 16 leading lines which lead towards the hoop. All the meshes are confined at the top within a circle or grummet of rope, and this is held in position round the valve by means of eight straps, which are securely fastened to the rim of the valve. The net rests evenly all over the balloon, and supports the weight by means of its leading lines, which are fixed over the toggles of the hoop.

The Hoop. The hoop is an important feature of the balloon, and is made strong enough to stand great strains. It consists of bent ash about 1 in. in thickness, by 4 in. wide, formed in a circle of 3 ft. in diameter. Encircling its entire circumference is a woven hempen band, made of a number of cords and known as *sword matting* owing to the fact that when made by sailors on board men-of-war swords were used in its construction. It is simply a webbing, made like ordinary fabrics with the warp and the weft of hempen cordage. Its use is to act as a security in the event of any excessive strain breaking the woodwork of the hoop.

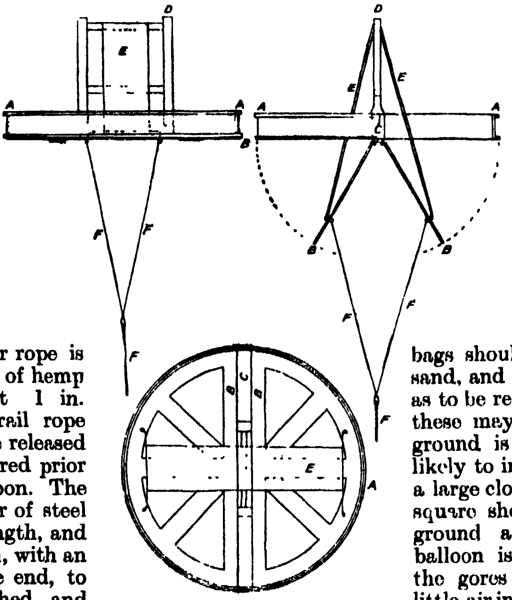
The toggles—shaped pieces of hard wood, which are 16 in number at the top—are attached to small pieces of rope which pass round the wood and sword matting. They afford a simple yet sure method of attaching the net by means of the eyes spliced at the ends of the leading lines being placed over them.

There are ten somewhat larger toggles at the lower portion of the hoop. These are also fixed to circular pieces of rope encircling the hoop, and serve as a means of attaching the ten car lines in the same manner as the leading lines. In addition to the wood, the sword matting, the toggles, and their grummets, the hoop has two ropes crossing its full diameter at right angles. From each of the joints where these join the hoop, loops are attached to which the grapnel rope, trail rope, captive rope, or any other rope by means of which the balloon is held, can be fixed.

The Balloon Car. The car consists of a rectangular wicker-work construction, measuring, say, 5 ft. by 3 ft., and having a depth of 3 ft. The ten car lines with which it is suspended pass right through the wicker-work underneath the floor and up the two sides so as to form a strong and efficient means of holding the weight. Wooden or wicker seats are slung from loops in the car.

Loops are also provided through which the valve line may be passed, in order to take the strain in holding the valve open. In this car the aerial voyagers sit or stand, and have with them the sandbags containing sufficient weight, more or less, to equal the ascending power of the balloon.

Grapnel and Trail Ropes. On the side of the car is attached the coils of rope which form the trail rope and grapnel rope, the ends of these ropes being fixed to the loops in the hoop above. The length of the trail rope is about 300 ft., while the anchor rope is about 50 ft. long, made of hemp or manilla, of about 1 in. diameter. Both the trail rope and the grapnel rope are released from. the car and lowered prior to the descent of the balloon. The grapnel consists of a bar of steel or iron, some 3 ft. in length, and 2½ in. by 1 in. in section, with an oval-shaped ring at one end, to which the rope is attached, and containing four flukes about 1 ft. long, placed at right angles to each other, and of somewhat smaller section than the bar of the grapnel itself. This forms the perfectly equipped balloon, and comprises all the details which are actually on the balloon when it ascends. The other necessary items are the hose-pipe for filling and sand-bags for controlling the balloon during its inflation.



1. BALLOON VALVE
(In section, transverse section and plan)

Ballast-bags. There are required 80 canvas bags, each about 18 in. high and 9 in. in diameter, fitted with ropes and galvanised iron hooks. They are filled with sand and form the ballast-bags. The hose-pipe consists of a varnished calico tube about 75 ft. long and about 10 in. in diameter. It is tied over the gas-pipe by means of tapes and is provided at the end which is to enter the balloon with a zinc tube 2 ft. long and 9 in. in diameter, which enables it to be tied with tapes into the mouth of the balloon.

Inflation. Coal gas supplied by the various gas companies, which passes through the ordinary street mains, is most frequently used. Carburetted water gas is very poor for balloon purposes. The speed with which the balloon can be inflated depends principally upon the size of the gas main which is available at the point of inflation. Through a main of 8 in. internal diameter, such as is laid at the Crystal Palace, 25,000 cubic ft. of gas per hour will pass. This quantity can be made to vary by the pressure put on at the works. A coal gas main 6 in. in diameter would take about double as long to give the same supply as an 8-in. under the same conditions, and a 4-in. pipe again double as long as a 6-in. Great care should be taken before attempting to inflate a balloon through a smaller size pipe than this, as the supply of gas will generally prove inadequate.

Assistance. A low-lying position is to be preferred for inflation, and if the site can be surrounded by trees or other means of protecting it from the full force of the wind, so much the better. It will be found that three or four assistants are required. The first proceeding is to have the ballast-bags filled with sand. If the sand should be stony, some bags should be filled with sifted sand, and in some way marked so as to be recognisable in order that these may be taken up. If the ground is in any way rough or likely to injure the balloon fabric, a large cloth measuring some 50 ft. square should be spread on the ground as a protection. The balloon is then opened out, and the gores carefully unfolded; a little air introduced by shaking the mouth will assist the easy opening of the material. The fabric should be drawn in such a manner that the valve lies in the centre of all, the seam lines radiating from it to its outer margin. The mouth should be placed nearest the gas outlet though the whole balloon may be 30 or 40 ft. distant from this. The folds of material are drawn over the mouth or inlet in such a manner that the inward flow of gas will not be checked.

Spreading the Net. The net is now taken in hand, opened, and carefully spread over the balloon so that the circular grummet at the top finds its place on the valve. This grummet is now strapped on to the rim of the valve by the eight small straps which are fixed thereon. The leading lines at the lower part of the net are loosely spread round the outer edge of the balloon, no particular care being needed to prevent their entangling, as they fall loose as the balloon fills.

Luting the Valve. The luting of the valve is now attended to, and the valve spring adjusted. Now the hose-pipe should be tied on to the gas outlet and on to the mouth or inlet of the balloon. Before turning on the gas it is necessary to attach a certain number of sandbags by their hooks to the network.

Placing the Sandbags. Starting from the hose-pipe the bags should be regularly placed round the balloon about one foot away from its edge [2]. Having settled upon the first mesh to hook the bag to, it is now essential to proceed round the balloon and attach the remaining bags along the same row of meshes, with one bag at every fourth mesh. This will utilise 32 of the sandbags, and the remaining 32 should be placed in readiness about a yard from the balloon and between each of the bags already attached, in order that they may be used in their turn. The gas may now be turned on, and as it flows into the balloon the sandbags will be found to hold the whole system with regularity. At this early stage care must be taken not to permit any creases to remain in the fabric towards the valve, as when the material ascends higher these cannot be removed. When the gas has tightened the fabric all round, it is time to lower the sandbags. This is done by unhooking the bag from its mesh and hooking it on one mesh lower [3].

Final Preparations. When the inflation is nearly complete [4], or sooner if the weather be windy, the hoop must be carried underneath the balloon and the leading lines collected and attached to the toggles. When the sandbags are on the lowest series of doubles, the car should be introduced and attached to the lower toggles of the hoop. The sandbags may now be placed on the leading lines and the balloon permitted to rise clear of the hoop and car until the inflation is complete.

Whenever the balloon is full, the gas must be turned off, and the hose-pipe detached and removed. By looking into the interior of the balloon (care being taken not to inhale the gas), the valve line may be secured, though not tightened, from the top. The mouth may now be closed with a temporary cord or india-rubber ring.

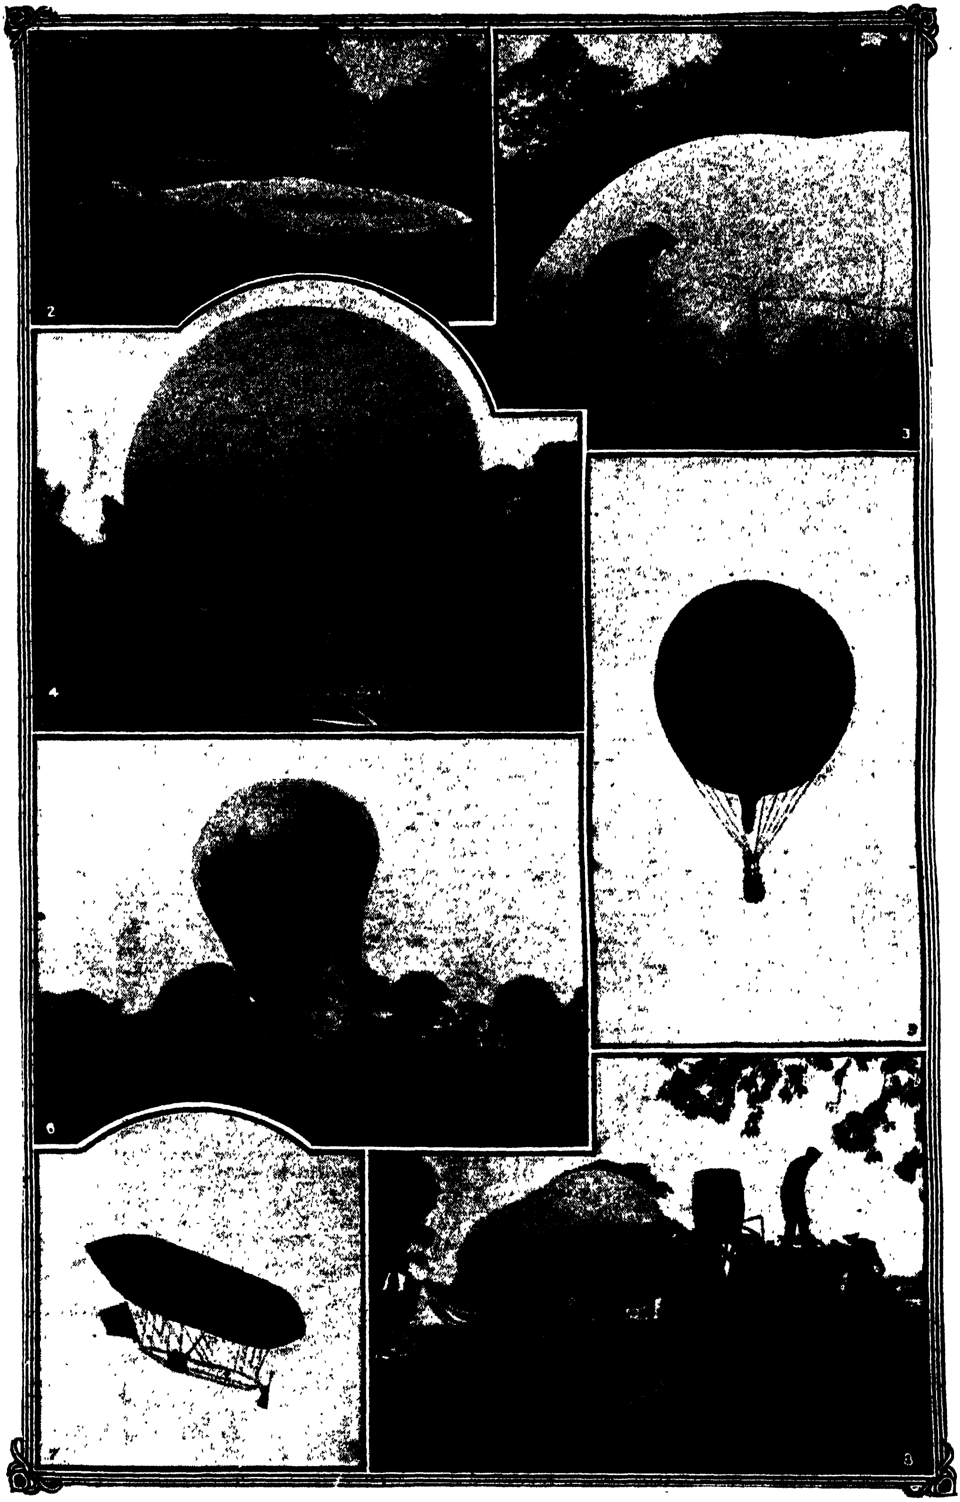
It is now desirable to remove two of the sandbags from each of the leading lines and allow an assistant to take his position in the hoop, then to remove further sandbags all round the balloon until the balloon begins to rise, and the bags get out of reach of the men. The assistant in the hoop then proceeds to unhook and lower the remaining bags until the lifting power of the gas causes the balloon to rise.

Entry of Passengers. At this period the individuals who are to ascend should take their positions in the car, after which more sandbags may be lowered from the leading lines. A number of sandbags containing fine sand should be placed in the car as well as all instruments and packages to be carried aloft. When the remaining sandbags are removed from the hoop, the lifting power of the balloon may be tested.

If the weather be calm, there is no difficulty about this; if windy, however, some trouble will be experienced. When the lifting power has been discovered, two or three extra sandbags may be placed in the car in order to compensate for the weight of the assistant in the hoop, who should now untie the mouth of the balloon, permit the valve line to drop to within reach of those in the car, and himself leave the hoop. The balloon may now be finally balanced and the lifting power arranged in accordance with the force of the wind. If calm, little lifting power will be required; but if windy, considerable margin of lifting power will be necessary to enable the balloon to rise rapidly and thus clear all obstacles on the earth.

Sensations in Ascending. There is no physical inconvenience, and nothing but the sense of sight to tell the passengers that they are moving. The balloon has now become, as it were, a part of the atmosphere [5], and moves onward with it, in a perfect calm. The aneroid barometer which is carried forms the only sure means of telling the height. It will be observed to fall rapidly as the altitude increases. Generally within half an hour of the start the maximum altitude will be attained, and at an altitude of perhaps 2,000 ft. the balloon first floats along at a uniform altitude for a certain time, and then commences to descend slowly. Having once commenced its descent, owing to the overflow of gas it will continue on its downward course unless checked by the discharge of ballast. The usual procedure is to discharge the ballast in small quantities when the balloon has attained its maximum altitude so that it may continue a more or less horizontal course at this height.

The Descent. The balloon continues to ascend and descend, ascending with the discharge of ballast, and descending with the natural overflow of the gas through the open mouth or safety valve. Eventually comes the time to look ahead and decide on the place to descend. If calm, any open field may be selected; if windy, however, great care should be exercised, and the descent preferably made after passing over a town rather than before reaching it. If windy, a sheltered spot should be aimed at; this may best be secured by waiting until hills have been passed, and then descending in the valley. Before permitting the descent to take place, the trail rope should be paid out to its full length; it will now hang from the hoop, to which it is secured, and descend downwards its full length of 300 ft. The grapnel rope, too, should be released from the edge of the car, and, being also fixed to the hoop, will hang pendant, but as the grapnel itself still remains on the edge of the car, it hangs doubled for half of its full length. It should not be omitted to secure the neck line to the cross rope on the hoop, leaving a yard or so slack rather than fixing it taut, so as to give the fabric of the balloon a little play. As the balloon descends preparatory to the landing, the trail rope will be the first to touch the ground, and the speed of the wind will be easily noticed by



AERIAL NAVIGATION

2. Balloon spread ready for filling 3. Lowering the sandbags during inflation 4. Inflation nearing completion 5. Balloon sailing in mid-air 6. Descent of a balloon 7. The Spencer airship in mid-air 8. Filling airship with hydrogen

the rate at which this rope is drawn across the country. If the balloon descend gradually, and with not too great a momentum—conditions which should be assured by small discharges of ballast if necessary—when about half of the trail rope is on the ground the balloon will no longer continue to descend, the loss of the weight of that portion of the rope which trails on the ground causing the balloon again to have an upward tendency. This has the effect of maintaining the balloon at a convenient height for watching the fields over which the balloon is passing.

Touching Earth. When a suitable landing field is observed, the valve line may be pulled, and sufficient gas released to bring the balloon to earth. Immediately on touching the earth the valve should be opened fully. If the speed across the field seem to demand it, and the weight of the passengers in the car does not stop the onward course of the balloon, the grapnel may be released, but not until the valve has been kept open as long as possible. To throw the grapnel too soon will give the balloon an upward lift, and produce unpleasant jerks, as the grapnel is ineffectively jerked over the land, but if it be not thrown until sufficient gas has escaped, the lifting power of which will be equivalent to its weight, then, when it is thrown overboard, the balloon and basket will continue to remain on the ground, moving along at the ground level and giving the grapnel its best opportunity of doing its work. On no consideration should any of the occupants of the car be permitted to alight until the bulk of the gas has left the balloon. By this time quite a number of local inhabitants will generally have arrived [6], and there will be no difficulty in enlisting their assistance. The balloon, when nearing emptiness, can have its valve-spring removed, so that the doors remain open without the valve line being pulled for the completion of the deflation. Conveyances by this time will have been requisitioned, the hoop and car untoggled from the net, and the balloon and its net folded up and placed in its linen wrapper, thus forming one package, while the remaining impedimenta may be conveniently placed in the car, thereby forming a second package to complete the luggage.

Scientific Ballooning. A large number of ascents are made for purely recreative purposes. Scientific work, however, can well be undertaken in connection with balloon ascents. The usual scientific observations made in a balloon consist of (1) the altitude attained, which is deduced from the height of the mercury in a barometer calculated with regard to the temperature at the time; (2) the temperature, which is observed, and recorded by means of the thermometer; and, finally, (3) the percentage of moisture in the air, observed by means of the hygrometer, which is generally in the form of a wet and dry bulb thermometer. The mercury barometer is invariably replaced by the portable aneroid in all except scientific ascents. In the latter it is generally carried, and its readings compared with the column of mercury. An exceedingly useful combination is the registering baro-thermo-hygro-meter, which indicates the height, the temperature, and the dampness of the air by tracing three blue lines in ink on a revolving chart.

Electrical work is also carried out, an electroscope being carried to determine the electrical condition of the atmosphere through which the balloon is passing. These experiments, however, generally have a negative result.

Glass containers, with the atmosphere exhausted, are sometimes taken up, and opened at the maximum altitude in order that the air which enters may be brought down and analysed as to its constituents. Scientists can see other uses, such as dust counters, microbe traps, ozone testers, and other means of observing phenomena which do not readily occur to those not acquainted with the latest developments of science.

The Parachute. The parachute consists of a circular-like shaped canopy of silk, cotton, or linen fabric some 30 ft. in diameter, to support the weight of an average man. Twenty or more lines are passed through its surface from the centre to the circumference and thence downwards to a length of 40 ft., where they are secured to a small wooden hoop 1 ft. in diameter with sword matting, a miniature of that used with the balloon. These lines are fixed to the circumference of the parachute and again are spliced round a ring of rope in the centre at the top. This rope ring has a diameter of 8 in. to 1 ft., and to it also the fabric of the parachute is fastened. the superficial foot or so inside being left open. This construction is a convenient one, and the hole in the top of the parachute is held by some to assist in steadying it at its descent; but the actual advantage of this small aperture seems very doubtful, the question of a correct proportion between the length of the lines carrying the weight and the diameter of the supporting surface appearing much more likely to conduce to a steadying descent than any small aperture not exceeding a 600th part of the surface.

Round the edge of the parachute is sewn a stiffish cord, which has the effect of keeping the mouth of the parachute somewhat open in order to catch the first inrush of air when commencing the descent. A hoop of 3 ft. to 4 ft. in diameter, too, is also sometimes slung from the top to assist to this end.

Using the Parachute. When using the parachute for the purpose of giving a display of its powers, it is usual to attach the parachute to the balloon by means of a thin cotton cord with a breaking strain of 80 lb. The fabric of the parachute itself weighs about 30 lb., so that it is well supported by this cord. The parachutist who is about to descend takes his position under the balloon holding the hoop of the parachute in his hand. Attached to this hoop is a swing-like cord in which he places his leg, and at the correct moment, when the altitude is sufficient and when the country beneath affords a suitable landing, he drops from the balloon.

When his weight is added to that of the parachute, the cord which supports it instantly breaks and the parachute and aeronaut commence the downward drop, the balloon in the meantime rapidly ascending. As the parachutist continues to gain speed the uprushing air enters the folds of the parachute and shortly the whole canopy is extended to its full size, and the downward drop is checked sufficiently to make the further descent safe and even pleasant. The slight oscillations of the parachute which sometimes occur give a wave-like sensation to the person who experiences it as if he were a bird with outstretched wings floating earthwards. The motions are vertical with the descent and horizontal in the direction and at the speed of the wind. The earth is reached at about the speed of 500 ft. per minute and the landing takes place with not much more force than alighting from a moving vehicle. If it were a passenger balloon from which the parachutist leapt, those remaining in the car would, of course, attend to the subsequent descent of the balloon. When the balloon is a special parachuting one it is arranged with a weight at the top and with a somewhat large aperture at the bottom. After the parachute and the aeronaut have left, the weight at the top naturally turns it upside down. The gas escapes through the large open mouth, and, devoid of its gas, the erstwhile balloon becomes a piece of falling material which speedily reaches the earth, a vehicle being sent to recover it.

Hot-air Balloons. When there is difficulty in obtaining a supply of coal gas for ballooning purposes and the great cost of hydrogen renders it impracticable, the hot-air balloon is adopted. For practical purposes one of 60,000 to 80,000 cubic ft. is used. It is of 60 ft. diameter and has a height of about 70 ft. It is constructed of a strong cotton fabric, and as the net would be both heavy and troublesome it is dispensed with, and in its place strengthening webbing bands are sewn on to the surface of the balloon. The mouth is some 12 ft. in diameter, and coming from that are four lines which carry the weight. No varnish is used on the outside, but the inside is covered with a distemper paint in order to render it airproof and to prevent its fabric from being scorched. This style of balloon is mostly used for parachute descents.

To inflate the hot-air balloon a 30 ft. trench 4 ft. wide and 4 ft. deep is dug in the ground. This is covered up with iron plates so as to make it into a tunnel. A portion at each end is left open—at one end to light a fire of wood and at the other end to receive a chimney 5 ft. high, most satisfactorily built of bricks. The balloon itself is suspended over this chimney by means of a rope passing over two pulley blocks attached to poles about 35 ft. high. These poles are securely stayed with ropes to the ground so that the weight of the balloon hanging on the rope stretched between them will be supported.

Filling with Hot Air. The balloon, having been drawn over the chimney, is carefully spread out in circular form so that it has the appearance of a large bell tent, having its apex at the horizontal rope and its base (about 50 ft. in diameter) occupying the space between the two poles, the chimney being in the interior.

A large number of persons are stationed round the balloon and hold on to the fabric. The fire is then lighted and maintained at a moderate heat until the rush of warmed air along the chimney causes the balloon to rise. The bell-tent-like appearance now gives way to a semispherical appearance and the strain from the supporting rope is taken off. As the balloon is filled the people round it permit it to rise higher and higher. When the inflation is nearing completion the parachute is attached to the lines from the mouth and the parachutist holds himself in readiness for the ascent. The suspending rope is now drawn through the pulley blocks and away from the top of the balloon, the pole to the windward is lowered, and the balloon finally inflated.

At this period the fire at the entrance to the tunnel is raised to its maximum and the heat within the balloon thereby increased. In order to prevent a premature departure, four stakes having rings on them are securely fixed in the ground, round the chimney, and through these rings extra ropes from the mouth of the balloon are passed so as to form efficient means of holding the balloon in addition to the persons who are holding the fabric itself.

These ropes may be held to a single point and fixed to a liberator by which they may be simultaneously released, or they may be entrusted to four assistants who can release them at the word of command. From fifteen to twenty minutes is all the time that is needed after once the fire is lighted.

The Ascent. When sufficient lifting power has been obtained the aeronaut from his position at the sling at the end of the parachute gives the word to let go and the balloon then rises, sluggishly at first, but gaining momentum every moment.

The aeronaut ascends with this hot-air balloon to the desired height, and then pulls the cord attached to the liberating trigger and descends in the same manner as described with the gas balloon, the hot-air balloon being weighted and arranged to turn over and empty itself also in the same manner.

Captive Balloons. For military purposes and for out-door entertainments captive balloons are employed. In calm weather, a balloon may be held by means of a rope, and permitted to ascend to some 1,000 ft. or so in height, where it will remain in position and enable those in the car to obtain more or less extensive views according to the condition of the air. From a height of 1,000 ft. a distance of practically twenty miles may be seen, and as the view extends all round to the horizon, this means an area of some 1,200 square miles. Naturally this fact renders the use of the captive balloon of eminent service for reconnoitring for military purposes, and forms the system of military ballooning adopted by our authorities. For purposes of amusement, a large balloon, capable of carrying from six to twelve persons, is generally used. It is similar in construction to the ordinary passenger balloon, with such modifications only as the particular requirements need.

It is fitted with additional network, known as the *equatorial lines*, which encircle the balloon so that they may be used as stays to hold the balloon steady by being attached to rings fixed on the ground. The car is a circular gallery construction, with a door to permit easy entrance.

The "Captive" Equipment. The captive rope of steel wire or hemp passes through a large circular aperture through this car, and thence over a pulley block having universal movement, firmly secured to an anchor in the ground. It then passes horizontally along the surface, or through a tunnel slightly beneath the surface of the earth, for some 200 ft., where a winding engine, fitted with a drum for its reception, is placed. This engine, which is usually of about 8-h.p., serves to pay the rope out at the ascent, and haul it in at the descent, until the car has reached the earth. Captive ascents are possible only in a moderately tranquil state of the air, but experience shows that in most places a very fair percentage of days during the summer season are practicable for actual working.

Captive ballooning for military purposes is conducted on a much smaller scale. A standard size of balloon is 10,000 cubic ft. capacity, capable of carrying two aeronauts to a suitable height for observations. It is always inflated with hydrogen gas, which is carried compressed in tubes to the site of the ascent.

Airships. In a balloon, we are able to start when we like, to ascend higher or lower, and by means of the valve to drop to earth at any moment we desire ; but we cannot decide beforehand the direction in which we shall proceed on any given day. An airship, with a speed of 15 miles per hour, will move at the rate of 25 miles per hour with a 10-mile breeze, but at only 5 miles per hour in a contrary direction. There are two classes of airships—the flying machine, which rises in the air purely by mechanism, and the navigable balloon. The problem of both is to propel themselves through the air, and the real question, therefore, is simply which can go at the greater speed. The answer to this question may eventually be the flying machine, but the great objection at the present moment is its want of stability in the air. Hitherto, the only successful journeys through the air have been made by the propelled balloon.

The Spencer Airship. In the most successful airship [7] ever used in Great Britain, and frequently navigated by the brother of the writer, the buoyancy vessel consists of an elongated balloon of fusiform shape, which is inflated with hydrogen gas [8], and has a capacity of 30,000 cubic ft.—the gas having a lifting power of 2,100 lb. This is necessary to carry the weight of the entire structure. The balloon portion is made of closely woven fabric, varnished several times inside and outside, to render it impervious to hydrogen gas. Running horizontally round it is a sailcloth band securely stitched on, the fabric being doubled and festooned for some distance up all round this band in order to give greater strength. The cordage is all attached to this band, passing through eyelets made within it, and hanging downwards to support the framework with all its mechanism. This buoyancy vessel has a valve in the upper part to release the gas when desired, and in its lower part an automatic valve which relieves any undue pressure before the bursting point of the fabric is reached. The framework or keel, which is a triangular-braced construction of bamboo, measures 50 ft. long, and hangs 12 ft. below the gas vessel. It carries in front a screw propeller or tractor of 12 ft. diameter on a steel shaft, which is supported by ball bearings and runs through gear wheels and a clutch to the motor.

Propelling Mechanism. The petrol motor is situated centrally in the framework, and one feature of its construction is that its exhaust-box is covered with wire gauze, on the Davy safety lamp principle, to guard against ignition should any gas approach it. Its fuel of petrol is carried in a brass container, connected with copper tubes, and a similar cylinder holds the water which circulates over the cylinder for cooling purposes. The car in which the aeronauts take their place is situated in the rear portion of the framework, and the mechanism of the motor is controlled by Bowden wires. Further to the rear is the rudder with two ropes leading to the car. A balance or trail rope hangs downwards from this framework, held by two points at the front and back so that its position may be changed so as to take its weight to the front or rear as desired, and thus alter the angle of the whole airship to the horizontal, as it is desired to point it upwards or downwards. At present there are two of these aerial craft in the balloon hall at Highbury ready for flights at short notice. One is of small horse-power, capable of travelling through the air at the rate of 10 miles per hour, and one of 24-h.p., capable of being driven at speeds of from 20 to 25 miles per hour.

To attain proficiency with these airships continued flights are necessary. When one first enters the water he cannot swim ; when a cycle has been obtained, it cannot be ridden without learning, and so it is with the airship—success comes by continual practice.

Naturally these experiments are expensive, and the amount of use to which these airships are put, therefore, depends upon the support and interest which are secured.

Vehicle Construction concluded

DOES THE HOUR BRING THE MAN?

True and False History. The Glorified Gossip of Courts and Kings. The Love of Personalities. Where do Great Men Come From? Man and His Environment

Continued from page 3872

By Dr. C. W. SALEEBY

FOR long years history has been taught in our schools and in the schools of all nations. The reader may or may not have been fortunate enough to escape the common, vulgar, and futile conception of history. This conception has been briefly epitomised by Herbert Spencer as "a record of royal misdemeanours," and since he is primarily responsible for the new conception of history, we may add to this phrase of his an amusing but deeply significant quotation from his Autobiography (II., 83). "I have a vague recollection of amusing Professor Youmans by my response to some remark or question coming from our guide at Holyrood—'I am happy to say I don't know.' Probably the remark or question referred to Queen Mary. On this, as on kindred occasions, I thus implied my satisfaction, partly in having used time and brain-space for knowledge better worth having, and partly in expressing my small respect for gossip about people of no intrinsic worth, whether dead or living." Elsewhere he refers to "those who look into the records of the past, not to revel in narratives of battles or to gloat over Court scandals, but to find how institutions and laws have arisen and how they have worked." Again, in the same wonderful book, Spencer's famous "Study of Sociology," which we shall afterwards discuss most carefully, we find a passage which, after our discussion of the book, the reader will surely study in full for himself.

What is True "History?" Speaking of sociology, Spencer says ironically, with reference to people who have the conventional notion of history:

"Of course, it is not to be put on the same level with those historical studies so deeply interesting to them. The supreme value of knowledge respecting the genealogies of kings, and the fates of dynasties, and the quarrels of Courts, is beyond question. Whether or not the plot for the murder of Amy Robsart was contrived by Leicester himself, with Queen Elizabeth as an accomplice, and whether or not the account of the Gowrie Conspiracy as given by King James was true, are obviously doubts to be decided before there can be formed any rational conclusions respecting the development of our political institutions. That Friedrich I. of Prussia quarrelled with his stepmother, suspected her of trying to poison him, fled to his aunt, and when he succeeded to the Electorate intrigued and bribed to obtain his kingship; that half an hour after his death his son Friedrich Wilhelm gave his courtiers notice to quit, commenced forthwith to economise his revenues, made it his great object to recruit and drill his army, and presently began to hate and bully his son—these, and facts like these about all Royal families in all ages, are facts without which civilisation would obviously be incomprehensible. Nor can one dispense with full knowledge of events like those of Napoleon's wars—his Italian conquests and exactions, and perfidious treatment of Venice; his expedition to Egypt, successes and massacres there, failure at Acre, and eventual retreat; his various campaigns in Germany, Spain, Russia, etc., including accounts of his strategy, tactics, victories, defeats, slaughters; for how, in the absence of such information, is it possible to judge what institutions should be advocated, and what legislative changes should be opposed?"

The History of Societies. "Still," Spencer proceeds, "after due attention has been paid to these indispensable matters, a little time might perhaps with advantage be devoted to the natural history of societies. Some guidance for political conduct would possibly be reached by asking—What is the normal course of social evolution, and how will it be affected by this or that policy? It may turn out that legislative action of no kind can be taken that is not either in agreement with, or at variance with, the processes of national growth and development as naturally going on; and that its desirableness is to be judged by its ultimate standard rather than by proximate standards."

These quotations will suffice to show what we mean by speaking of a new conception of history. What study can be named greater than the record of man? Yet do we not all know that, owing largely to the exceeding difficulty of teaching any real history, and to the examination system, and to the fewness of those who "seek the wider meanings of facts," history is too often concerned with the dates of battles, with the contemptible *amours* of men who are only the more contemptible because they were called kings—since, as Carlyle said, "the only divine right of kings is the right to be kingly men,"—and with such-like trivialities. It is time, then, that we who seek to make the best use of our intelligence should distinguish once and for all between that notion of history which regards it as merely a—more or less—glorified gossip, amusing but meaningless, delectable but despicable, and that conception of history which sees in it the record of the life of man or that mighty *Organism* which was Comte's conception of humanity, and which, to his mind, was no less than an object of worship.

Judge a Man by his Talk. You may estimate the intellect of a man, says Herbert Spencer, by observing the proportion of generalities to personalities in his conversation. Have we not all heard with our ears that "he" or "she"—according as whether the speaker be woman or man—is the main topic of conversation in the street; and do we not know that the person who does not dearly love a piece of gossip is scarce almost to vanishing point? The novel, the short story, the drama, and an enormous proportion of conversation among great and small, young and old, are concerned with what this or that person did, does, or is going to do. The teller of stories has been appreciated in all generations and in all ages of each generation. He is a power in the savage tribe.

The Universal Love of Personalities. We who believe in the theory that the history of the individual is a recapitulation of the history of the race may note the significance of the fact that children love stories, that savages do so likewise, and that people of scant intelligence prostitute their powers of reading almost entirely to this end. "But when are you going to write a book?" was the cruel question which Carlyle asked William Black, the well-known novelist. The love of personalities, in short, is universal in its distribution and its influence. Hence it is that the death of one king or another from eating too many lampreys is a historical fact as history is at present conceived. There is before the present writer at this moment the page of a child's instructor which nurtured his seven-year-old mind, and contains, in sequence, the portraits of the kings of England, with their names and the chief fact about each beneath the name. Here he finds, what his mind has retained for so many years, the following: "Henry I. Beauclerc. Died from eating too many lampreys." True it is that a magnificent lesson might have been taught even to a child from this fact, there being no facts, not even this, in all the universe, which are insignificant to the philosophic mind; but to the mind of the historian the fact was an end in itself. It was "history."

Persons and Things. The same love of personalities holds in politics, so that a politician may go about, let us say, proving himself ignorant of the first principles of his subject, and incapable of reasoning upon what he is under the delusion of thinking to be *data*, yet a certain number of people will follow him and "wonder with a foolish face of praise" because the love of his personality draws them on. Elsewhere the present writer has called the love of personalities the mainspring of fiction, and, except for the very few, it has hitherto been the mainspring of "history," which is mostly fiction. Most of us prefer talking about people to talking about things, and reading about people to reading about anything else that words can express. True it is that the proper study of mankind is man, as Pope said, and that if we analyse the love of personalities and try to recognise the element of sympathy, for instance, that may be found in it, we shall see in it not a thing to be sneered at or a thing that we may one day expect to overcome. As a matter of fact one cannot conceive of society as existing without it, for it is an inevitable concomitant of that sympathy and community of interest without which societies are impossible. And who shall pass a verdict on the desirability of a mental trait—this love of or interest in personalities—which may show itself in the abominable tittle-tattle of a smoking-room or boudoir, and yet is essentially one and the same with the force that impelled the observant genius of Shakespeare to depict a Iago or a Hamlet?

Descriptive Sociology. We are about to observe that there are two distinct theories of causation in history, and in so doing we shall note how the love of personalities may be made useful. The term *descriptive sociology* was coined by Herbert Spencer to describe a great book upon which he spent many thousands of pounds and which he was finally compelled to abandon, but which is now to be completed by means of the money which he left. He destined such a book for the day "when the love for the personalities of history is less and the desire for its instructive facts greater." The study which now goes by this name consists of "the collection and organisation of facts presented by societies of different types, past and present," since, in order to arrive at the principles of sociology there are required, "as bases of induction, large accumulations of data, fitly arranged for comparison." "These facts supply the student of social science with data, standing towards his conclusions in a relation like that in which accounts of the structures and functions of different types of animals stand to the conclusions of the biologist. Until there had been such systematic descriptions of different kinds of organisms as made it possible to compare the connections and forms and actions and modes of origin of their parts, the Science of Life could make no progress. And in like manner, before there can be reached in sociology generalisations having a certainty making them worthy to be called scientific there must be definite accounts of the institutions and actions of societies of various types, and in various stages of evolution, so arranged as to furnish the means of readily ascertaining what social phenomena are habitually associated."

Aristotle the Pioneer. It is very interesting to note that neither the conception nor its execution is new. Though Spencer was unaware of the fact, his mighty predecessor. Aristotle—whose intellectual resemblances to him in breadth of knowledge, magnificence of generalisation, and even in method, have been so often commented upon—conceived and carried out an essentially identical plan. The work which the great Greek called the *Politeiai* contained a descriptive history of the constitutions, manners and usages of 158 states. It would hardly be necessary to insist upon the immeasurable difference which time has wrought in the execution of the two enterprises. While Aristotle's horizon was only a few miles away, the later "Descriptive Sociology" discusses the English, Mexicans and other aboriginal New World races, the lowest races, such as Fuegians, Tasmanians, and Sandwich Islanders, the African races, the Asiatic races (excluding the yellow peoples), the races of Northern America, the Hebrews and Phœnicians, and the French; while there are now in preparation parallel accounts of the Chinese, the ancient Egyptians, and the Greeks.

Here, then, we see a conception of history which has only to be described for its importance and truth to be recognised, but of which the unbiassed sociologist must ask, "Is it the whole truth?" Unquestionably a true conception of history must include a descriptive sociology, perhaps the most striking indication of the character of which, and the most remarkable comment on its claim to be ranked as history, is furnished by the fact that the names of individuals have no place worth mentioning in it and are scarcely to be encountered at all.

Causation in History. And here we encounter a fascinating question which we shall have no further opportunity of discussing in this course, since we cannot possibly return to what is now often called the *philosophy of history*, which we shall discuss now. With very rare exceptions, one of which we must at least note, all history that called itself and was recognised as history until Spencer's time dealt with individuals as all-important and with circumstances or environment as secondary, subsidiary, and only in quite negligible degree as causes of the actions of great men whom the historian celebrated. In the beginning of his "Study of Sociology" Spencer discusses what he there calls the *great-man theory* of history. In so doing he makes an allusion to the doctrines of that mighty literary genius and mighty soul Thomas Carlyle, whose inherent energy and power of language and personal conviction persuaded Ruskin to call him "the greatest historian since Tacitus." The work of Carlyle we may take as typical of, and as representing in its highest form, the great-man theory of history. This theory is as old as history itself and reached its finest flower in its last hours—or, rather, in its last hours as the whole truth. It is incredible that the reader has not read Carlyle's "Lectures on Heroes, Hero-Worship, and the Heroic in History." If he has not done so we must apply to him the words of Prospero: he is one of those "that have more time for vainer hours."

The Great-man Theory. In a few words from the first page we may describe the fundamental conception of that great book:

"We have undertaken to discourse here, for a little, on Great Men, their manner of appearance in our world's business, how they have shaped themselves in the world's history, what ideas men formed of them, what work they did. Too evidently this is a large topic. Indeed, an illimitable one; wide as Universal History itself. For, as I take it, Universal History, the history of what man has accomplished in this world, is, at bottom, the History of the Great Men who have worked here. They were the leaders of men, these great ones; the modellers, patterns, and in a wide sense creators, of whatsoever the general mass of men contrived to do or to attain; all things that we see standing accomplished in the world are properly the outer material result, the practical realisation and embodiment, of Thoughts that dwelt in the Great Men sent into the world; the soul of the whole world's history, it may justly be considered, were the history of these."

This is a splendid passage, and it seems to bear in its forehead the stamp of truth; but here we are trying to be scientific, and we must not permit ourselves to confound splendour as such with truth as such. We may remember Huxley's description of rhetoric: "that pestilent cosmetic with which men varnish the fair face of truth." Is this great-man theory of history *true?*

The Kings of Thought. Now, it is all-important that we be fair and unprejudiced in our study of this great question. The present writer clearly has a bias in favour of Spencer, who, as we shall see, opposed the great-man theory; but, on the other hand, he can refer the reader to many previous parts of the SELF-EDUCATOR in proof of the assertion that he is also a hero-worshipper, who never loses an opportunity of quoting the lines of Shelley:

> "And he is gathered to the kings of thought
> Who waged contention with their time's decay
> And of the past are all that cannot pass away."

Or these lines of Wordsworth:

> "There is
> One great society alone on earth
> The noble Living and the noble Dead."

Or, greater still, this from Daniel:

"They that be wise shall shine as the brightness of the firmament, and they that turn many to righteousness as the stars for ever and ever."

We make the claim, then, that we are unprejudiced. But this is not an instructor, but a self-educator, and the reader will listen to no claim as final, but will decide for himself.

Spencer, and, following him, sociologists in general, urgently oppose the great-man theory of history. Spencer traces the genesis of it to the customs of savage life, where the great topic on a return from the warpath is always the doings of some chief or warrior. Such narratives, perhaps accompanied by a dance or a chant, constitute the whole history or chronicles of savage tribes. Similarly, the famous Moabite stone, the Egyptian frescoes, and the Greek epics follow the injunction to "praise famous men." The power of this theory is strengthened by the early upbringing of each of us. "Arms and the man" form the end of the story, as they form its beginning. The reader will remember the first words of the first line of Virgil's great poem, "*Arma virumque cano*" (Arms and the man, I sing). Hence, says Spencer, "you find but a scattered few likely to take anything more than a biographical view of human affairs."

The Genesis of Great Men. The valid and conclusive criticism on this view is that we are entitled to ask, Whence comes the great man? If we abandon, as we must abandon nowadays, the doctrine which has had its place in the history of every society, that the origin of the great man is supernatural, " then the origin of the great man is natural; and immediately this is recognised, he must be classed with all other phenomena in the society that gave him birth, as a product of its antecedents. Along with the whole generation of which he forms a minute part, along with its institutions, language, knowledge, manners, and its multitudinous arts and appliances, he is a resultant of an enormous aggregate of forces that have been co-operating for ages. . . . The genesis of the great man depends on the long series of complex influences which has produced the race in which he appears and the social state into which that race has slowly grown. If it be a fact that the great man may modify his nation in its structure and actions, it is also a fact that there must have been those antecedent modifications constituting national progress before he could be evolved."

The Truth Between Two Extremes. In a very early society, according to Spencer, the great-man theory "approximately expresses the fact in representing the capable leader as all important." But "just as fast as war ceases to be the business of the whole male population, so fast do societies begin to develop, to show traces of functions and structures not before possible, to acquire increasing complexity along with increasing size, to give origin to new institutions, new activities, new ideas, sentiments, and habits—all of which unobtrusively make their appearance without the thought of any king or legislator. And if you wish to understand these phenomena of social evolution, you will not do it, though you should read yourself blind over the biographies of all the great rulers on record down to Frederick the Greedy and Napoleon the Treacherous."

Let us consider whether now, after thirty years, we can pronounce any judgment upon this quarrel between Spencer and the historians. It seems to the present writer—who expresses his views merely as subject matter for thought, and all of whose ends will be defeated if the reader accepts anything whatever simply because he says so—that the truth lies somewhere between the two extremes.

Destruction of Pre-Scientific History. Spencer overstated his case, as he was almost bound to do in the circumstances. He has achieved the final destruction of what we may call pre-scientific history, and that is indeed well. But many of his critics have pointed out with force and justice that history cannot be made comprehensible—no, not even the history of the most advanced races—on any view which reduces the importance of the hero, or great man, to the Spencerian estimate. Truth is many-sided, and we all tend to see the side that is nearest us—whether owing to our training, temperament, or bias—to the exclusion of the other sides. But it is the business of the philosopher to act, as Spencer himself urges, in another and higher connection: "In proportion as we love truth more and victory less, we shall become anxious to know what it is which leads our opponents to think as they do. We shall begin to suspect that the pertinacity of belief exhibited by them must result from a perception of something we have not perceived. And we shall aim to supplement the portion of truth we have found with the portion found by them." And the common view *does* represent a portion of truth. No one will question that the history of the world is other than it would have been had Napoleon or Cæsar or Moses not lived. It is true that these men were the products of their environment; but it is far truer to say that, though they were conditioned by their environment, and would not have been what they were in other environments, yet their environment does *not* give an adequate account of their causation.

The Hour and the Man. No better instance of the truth which we are trying to recognise can be found than in the case of great crises in society, whether political, or religious, or other. The truth of the Spencerian theory is recognised—and exaggerated—by those who say, with too little qualification, that the crisis always produces the man, that when an evil system has reached a certain point the social environment invariably causes the evolution of the necessary individual, instances of whom we may find, according to our beliefs, in Martin Luther, or John Wesley, or Savonarola, or in any of the leaders who have freed an oppressed people. But, in point of fact, this generalisation, which implies that the great-man theory is entirely untrue, is itself imperfectly true. Further study teaches us that, in point of fact, the tyranny, the abuse, the evil of whatever kind, has only too often continued long after it should, according to this theory, have produced the man necessary to end it. Sober history does not support the comfortable doctrine that, as soon as the circumstances urgently demand a great man, they produce him. On the contrary, time and again we find that the evil was no greater at the moment of its overthrow than it was a century before. In short, the hour was ripe but the necessary hero was not forthcoming. Thoughtful people, looking at the present state of Russia, believe themselves to see in that unhappy land such sociological phenomena as, according to the view which denies the great-man theory entirely, should long ago have produced the necessary man. They think, however, that not only has this man been wanting in the past, but he is wanting to-day. They believe that all the conditions are ready in Russia for the inauguration of a newer and better era, except one. The oppressed have not produced the all-essential hero.

Man's Relation to Environment. These things may or may not be so. We submit them to the reader's judgment. The proposition which we would have him consider and, if he can, accept, is that what we have called causation in history is twofold—that the doctrine which regards all influences save individuals as important is only a half-truth, and that the doctrine which regards no influences except the power of individuals as important is only another half-truth. In other words, the history of societies is determined neither by the inanimate and impersonal alone nor by the animate and personal alone, but by the interaction of both; just exactly as the history of an individual organism is determined, not alone by its inherited or innate characters, not alone by the environment in which it finds itself, but by the interaction of both. It seems to the present writer that opinion, having swung too far away from the older direction, may now be allowed to rest in the reasonable doctrine that in the making of history neither are external conditions naught nor are individuals naught. Both are essential, and neither can be ignored And for ourselves we do not think it worth while even to enter into any argument as to which of these factors has been the more important Let the reader consider and he will see that such an argument, if it went deep enough, would soon find itself to be meaningless. At any rate, we have here offered an introduction to the reader of that mighty study which is called the philosophy of history, which, he must take our word for it, is possessed of far greater dignity and interest than we are likely to have been able to suggest

A Landmark in the History of Thought. Here, certainly, is the place in which we may discuss and dismiss the relation of sociology to geography. We have already asserted that sociology is the synthesis and crown of all the sciences, an assertion of which we shall find support in every paragraph. But the relation of sociology to geography is of special significance because we must take it into conscious account in our conception of history, and also because it will ever be associated with the name of a great English historian. We often hear it said that a given race displays given characters—as, for instance, extreme conservatism and hatred of change, because of the hot and enervating character of the climate in which it lives; or that the literature of a certain people displays a great intimacy with Nature because of the mountains, the valleys and the lakes among which the poets of that race have lived; or that a superstitious element is conspicuous in the religion of a certain people because they are familiar with some of the most terrifying and awe-inspiring phenomena of Nature—thunder, tempests, earthquakes. We feel that there is a truth here, though it is much more difficult to estimate its measure, and there is a great classic in which this doctrine is expressed, with exaggeration no doubt, but still with extraordinary erudition and force that make it, within its limits, a landmark in the history of thought.

"The Secret of Europe." The fame of Buckle (1821-1862) depends upon the only work of his to which we need here refer—his "History of Civilisation in England." This book, of very great size, is really no more than an introduction to the complete work of which the author's premature death has deprived us. Perhaps the central doctrine of the work is the intimacy of the relation between geography and sociology, the doctrine "that climate, soil, food, and the aspects of Nature are primarily causes of intellectual progress—the first three indirectly through determining the accumulation and distribution of wealth, and the last by directly influencing the accumulation and distribution of thought, the imagination being stimulated and the understanding subdued when the phenomena of the external world are sublime and terrible, the understanding being emboldened and the imagination curbed when they are small and feeble" and, as a corollary, "that the great division between European and non-European civilisation turns on the fact that in Europe man is stronger than Nature, and that elsewhere Nature is stronger than Man, the consequence of which is that in Europe alone has man subdued Nature to his service." It is almost a necessary complement of these doctrines that "individual efforts are insignificant in the great mass of human affairs, and that great men, although they exist and must at present be looked upon as disturbing forces, are merely the creatures of the age to which they belong." In short, we may say that the theory of Buckle is a theory of physical fatalism—that human history might have been inferred from a knowledge of climate.

Many though his exaggerations are, Buckle undoubtedly enunciated great truths, and, notwithstanding many inaccuracies of detail such as, of course, no historian can free himself from, his book must be read to-day by any who would make a serious study of history. It has recently been published in the "World's Classics," so that it can be obtained for a very small sum.

The Greatest Study in the World. The reader must not infer from the space which we have occupied in discussing the new conception of history that sociology is no more than scientific history. If it were no more it would still be, perhaps, the greatest study in the world. Yet this is really only one of its parts. We have placed it in the forefront of our study because of its great importance, and because by means of history and geography we are able to show that sociology, though a science, is most intimately related to other studies which we do not customarily think of as sciences—though we certainly should do so. On the other hand, the present course has been designed to follow in a rational and educative sequence the courses on Biology and Psychology. It is upon these sciences that our science is essentially based, and it is from their side and not from the side of history that we seek to approach it. An American observer has said that only too many professors of sociology in the United States have just "happened into" the subject—that when a man is unfit, whether by training or intelligence, for anything else, he can, at least, take up sociology, just as teaching in former days was the last resort of the incompetent. On the contrary, it is difficult to say whether the study of sociology or the profession of teaching is the more difficult and demands the greater training and devotion and skill on the part of the aspirant. The men who "happen into" sociology are the men who make it a laughing-stock and a byword amongst serious people, and we must try to avoid anything so discreditable as their performances.

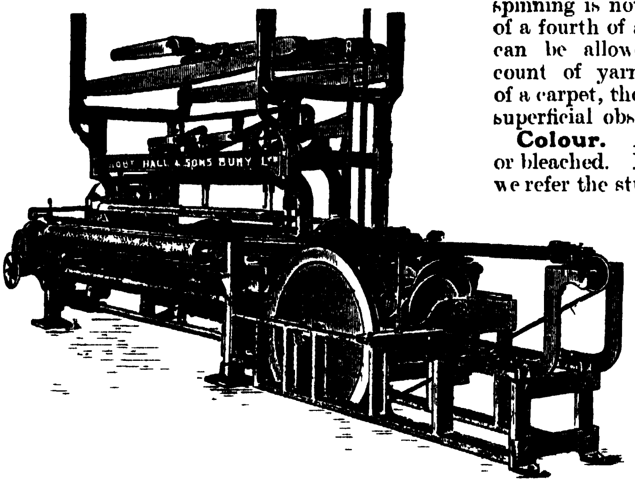
CARPET WEAVING

Selection of Carpet Yarns. Setting in Brussels and Wilton Carpets. Weaving Axminster. Patent Axminster. Tapestry and Velvet Pile Tapestry Carpets

By W. S. MURPHY

Carpet Wools. The carpet industry stands out so distinctly from the cloth-weaving trades as to call for special study. In the weaving department most notably the particular differences are essential, not accidental. The carpet weaver uses a quality of yarns all his own. What are called *barbarian* wools serve the carpet manufacturer's purposes as well as, and in some cases better than, domestic wools. The wild sheep of India, Persia, and other quarters of the globe furnish wools of a hard, wiry character, which, utterly unsuitable for cloth manufacture, supply the hard strength and elasticity the carpet requires. We are far from asserting that fine, soft wools are not used in carpets, or that the finest wools would not make the finest carpets; but it must be kept in mind that we are producing for the market. Wild wools are cheaper, and give the desired results at less cost than common wools. Our supplies of wools are not always easy to trace, and the carpet manufacturer need hardly trouble whence the supply comes so long as it serves his purpose. East India, Persia, and Argentina, are the main sources of carpet wools; from Oporto we gather a supply of wools for the best classes of carpets; and the coarser home breeds of sheep, with the skirtings and higher sorting numbers of the finer wools, make up the rest of our raw materials.

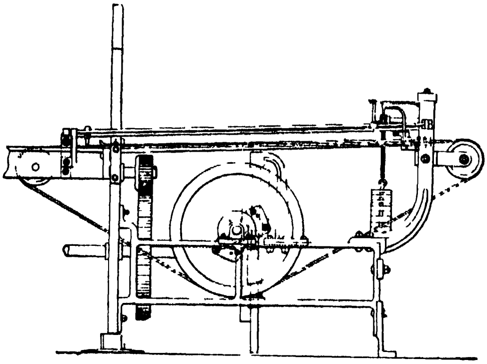


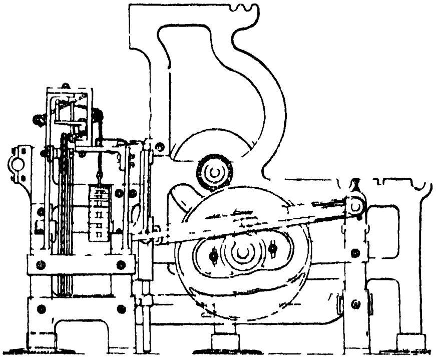
179. BRUSSELS LOOM

Yarns. Many carpet manufacturers buy their yarns ready made; but the greatest manufacturers carry through the whole process from beginning to end, from the fleece to the finished carpet. So far as the weaver is concerned, it matters little whether he gets his yarns from a hundred miles away or the adjoining room; he is concerned with the quality of his material. Uniformity and good colour are the primary requisites of carpet yarns. A good yarn is free from lumps and kemps, and is properly and regularly twisted throughout. The fault of lumpy and kempy yarn is obvious; but the unobservant weaver may not readily perceive why the uniformity of twist is so important. Carpets naturally show a good length of the yarn; if an irregularity of twist occurs, the surface of the carpet will show it, and no amount of treatment can hide the fault. The cut pile of the Wilton, for instance, will turn in every direction, like the grass-blades in a badly-mown lawn. To make sure that the quality of the yarn is up to the standard, the weaver should test a sample hank by scouring it and comparing it with an unscoured hank; if the difference in twist and weight be very marked, the yarn should be rejected, or put into an inferior class of carpet. If a large quantity of one make of carpet is being woven, the tests should be repeated several times, because variations in quality are apt to occur. We do not in the least suggest fraud; it is merely a question of workmanship, and should be treated as such. In heavy yarns, such as are needed for carpets, exactness in spinning is not to be expected; but a variation of a fourth of a count is the utmost limit which can be allowed with safety. Uniformity in count of yarn adds much to the appearance of a carpet, though it may not seem likely to the superficial observer.

Colour. All carpet yarns are either dyed or bleached. For a knowledge of these processes we refer the student to the dyeing section of our course. But the weaver has an interest in the colouring of the carpet which cannot be passed over. To every weaving department one or more colourists are attached, whose duty it is to match the yarns. Selection of the colours is one of the most important functions in the making up of a carpet. Badly matched or unevenly coloured yarns would ruin the finest design conceivable. Each form of carpet has its own system of apportioning this work, and it may be better to study it in the course of each manufacture.

Warps. Carpets have two kinds of warp; the one is the *surface* or pile warp, with which is our chief concern, the other is the body or binding warp, which is composed of linen, cotton, or jute, and in a few cases of wool. Linen is both warp and weft in the highest class of loop pile carpets; lately, strong cotton yarns have come into favour, because they are lighter and cheaper. The value of cotton as a carpet warp has not yet been thoroughly tested, and we do not undertake to dogmatise in comparing it with linen. Jute has gone greatly out of favour as a warp, because it does not stand well the hard wear to which carpets are subject. For weft, or *shoot*, linen is almost universally used for all classes of carpets; it is softer and weaves better than cotton of the same weight and class. For tapestry carpets we use a warp significantly called *stuffing*, because it fills up the spaces between the threads of the warp. Stuffing is made of low-grade cotton yarns, or jute. It is very soft, and possesses very little tensile strength. Both warps and wefts are sized or dressed with strong size of a gluey nature, generally a weak gelatine.

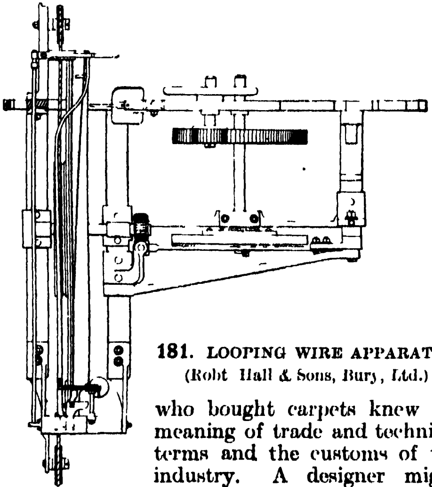




Having collected our various materials which are general to all forms of carpet, we must now proceed to examine the special constituents of each different kind. This may be done more simply and quickly in the actual process of manufacture than by any other method.

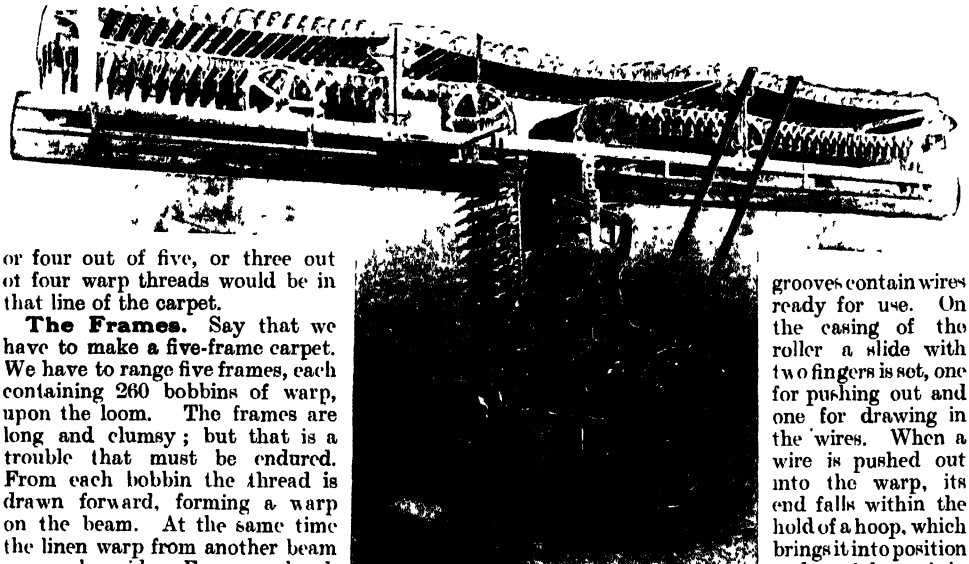
180. LOOP-CUTTING KNIFE

Brussels Carpets. According to trade theory, Brussels carpets are classed by the number of pile warps put into them. "Six-frame," "five-frame," "four-frame," and "three-frame," are the classes woven, the first being the heaviest and costliest, and not often sold on the market; "five-frame" is most in demand. In dealing with this part of our study, we must work warily, and make statements with due caution. First, let us understand clearly what is meant by a *frame*, and how the number of frames determines the class of the carpet. Beginning to build up our pile warp, we lay down a creel of yarn bobbins, each one of which will supply a single thread to the warp. As there are 260 threads in the warp breadth, we require that number of bobbins. That is one frame. If the carpet is to be a five-frame—that is, a carpet with a pile five threads thick—we require other four creels or frames, each containing 260 threads or bobbins. According to the trade theory of former days, every frame contained yarn of a different colour, and a five-frame carpet was also a five-coloured carpet. Under this theory, any attempt to put more colours than frames into a carpet was regarded as a kind of fraud. It was said that manufacturers were cunning who made six colours appear in a five-frame, five colours appear in a four-frame, and so on. This was sheer and utter nonsense. Our good moralists supposed that the people who bought carpets knew the meaning of trade and technical terms and the customs of the industry. A designer might put ten colours into a carpet, but no one would buy it because he supposed it contained ten frames of yarn. The buyer is more concerned in buying a carpet to get a pretty pattern and a reasonable bulk, or wearing quality, than with the adherence of the weaver to a trade tradition of which he has probably never heard. One way of thinning the pile warp, however, is resorted to which can hardly be regarded as altogether fair to the buyer. We can put in the required number of frames, but, instead of filling them with the 260 threads required, we may put in only two-thirds of the number and cover up the deficiency. There are various ways of doing this. Obviously, we may spread the impoverishment over the whole pile warp, or we can confine it to one or two frames. Even this, however, is not more heinous than the putting of a small number of warp threads into an ordinary cloth.



181. LOOPING WIRE APPARATUS
(Robt Hall & Sons, Bury, Ltd.)

The Gammot. If the carpet is a five-frame with five colours, the duty of the "putter-on" is very simple. All he has to do is to procure the bobbins of the five different colours, put in the creels or frames, and his duty is ended. But when there are more colours than frames, and missing threads here and there, his position is one of more responsibility. From the design a plan of the warp called a *gammot* must be made out, and this is the guide of the putter-on. In the gammot are shown the threads which appear and those which do not appear in a given line of the warp. It is very simple. One line of squares on the paper is assigned to each frame, and there are 260 squares in each line. Where all the warp threads are to appear, the whole of the squares will be coloured; where any thread is to be omitted, the square of that colour would be left blank. That is to say, five out of six, or four out of five, or three out of four warp threads would be in that line of the carpet.



182. COMPTON LOOM
(R. Smith & Son, Kidderminster)

The Frames. Say that we have to make a five-frame carpet. We have to range five frames, each containing 260 bobbins of warp, upon the loom. The frames are long and clumsy; but that is a trouble that must be endured. From each bobbin the thread is drawn forward, forming a warp on the beam. At the same time the linen warp from another beam comes alongside. From overhead, the jacquard cords, the apparatus of which is already geared up, come down, and each thread—say, 1,300 in all—is looped in its separate cord and passed through the dents of the reed.

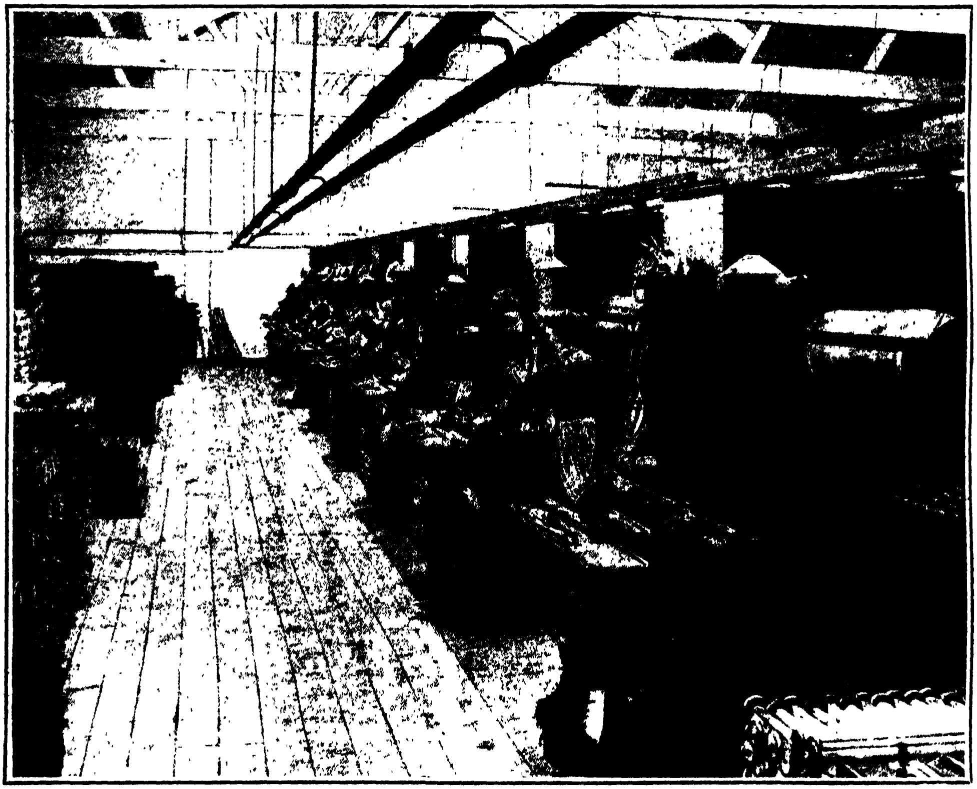
Weaving the Carpet. The carpet loom is simply a large power-loom [179], with an enormously heavy warp. We have studied the loom at considerable length, and can understand how it works. But the formation of the carpet pile is a feature which here demands full explanation. When studying design, we acquired the general idea that all pile fabrics derive their special form from the insertion and binding into the warp of wires. The way in which this is accomplished is worthy of examination. A Brussels carpet looping wire is a thick knitting wire 27 in. long, and it is made to lie under the warp threads called to the surface by the jacquard cords. How to insert and withdraw those wires automatically was, for a long time, a serious problem. On some old looms still in use the first attempt at solving the problem may yet be seen. It consists of a reciprocating rod with a catch at the end, which hooks into one of a set of wires, and draws it into the shed. By a similar mechanism the wire is withdrawn, after other five have been put in, and returned loose, the weaver placing it again in the groove, whence the rod can draw it out again and insert it into the shed.

Looping Wires. More common, however, and certainly more convenient, is the roller-wire mechanism which inserts and withdraws the wires automatically. Several methods of applying the principle have come into use, but all work on the same basis. A roller is grooved into six sections so that any one section will cover the space occupied by the number of wires inserted, and into those grooves the wires are inserted. The grooves contain wires ready for use. On the casing of the roller a slide with two fingers is set, one for pushing out and one for drawing in the wires. When a wire is pushed out into the warp, its end falls within the hold of a hoop, which brings it into position and straightens it in the warp. At the same moment the wire to be withdrawn comes into contact with the drawing-out hook; it acts, and with the backward movement of the slide, is drawn into the groove of the roller. The roller performs one-sixth of a revolution, and brings the next wire and the emptied groove into position. In this way we have always four wires in the fabric, while one is coming in and one is being withdrawn. An improved application of the principle, with apparatus much simplified, is shown in 181. On the front elevation we see the rope-drum and pulleys which drive the mechanism; from the end elevation and plan, we can observe the connections between it and the whole loom.

Order of Weaving. The weft shuttle is in the box and the loom is ready for starting. From the midst of the pile warp the jacquard selects the threads which are to form the surface at this moment; the wire inserts itself under the raised threads; now the half of the linen warp comes up, and forms the shed; through this the shuttle darts with its thread of weft, binding the wire in; the pile warp goes down, and the linen warp crosses, leaving a shed through which the shuttle darts again. In this way we form the pile and build up the body of our carpet.

Wilton Carpet. Roughly speaking, the difference between the Wilton and the Brussels is that the pile of the former is cut to form a velvet pile, while the loops of the latter remain intact. But the technical differences are much greater than that. Wilton carpet looping wires are oval in form, standing higher and forming a larger loop than the round Brussels wires; and the extremity of each, as if the end had been hammered out and sharpened on the edge, is a knife blade [180], which, when the wire is withdrawn, cuts the loops. But the weaving of Wilton carpets differs in a very important particular from its rival fabric. On the Brussels, the picks of weft alternate, one up and one down; but in the Wilton weave there are two picks of weft up to one down, each wire having its own binding weft. This keeps the pile securely bound after it has been cut.

Axminster. The production of the older form of Axminster, which, in all but price, is the rival of the best Persian and Turkish carpets, belongs to a class of artistic handicrafts which, for various reasons, can hardly flourish in this country. No very considerable number of British artisans can ever be employed in that branch of the carpet industry, and those who may be, must be specially trained in all the practical details, from the first operation to the last, unless, indeed, they are mere labourers to the skilled workers. The essential characteristic of the Axminster and all the Oriental carpets is the knotting of the worsted pile, tuft by tuft, into the body of the fabric, involving hand labour of a tedious nature. This fact not only brings the cost of the carpet up to a figure prohibitive to all but the very wealthy, but it also gives the Easterns, with their cheaper standard of living, a great advantage over us.

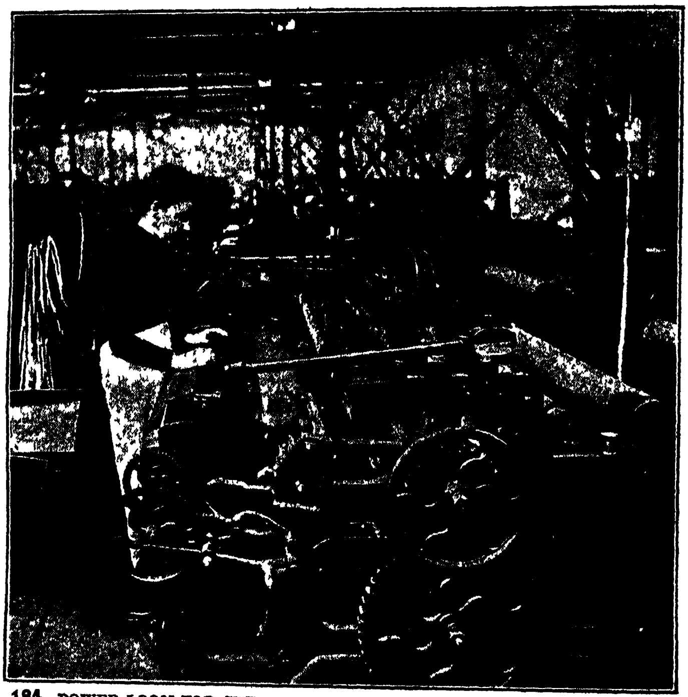


183. SETTING FOR COMPTON LOOM (R. Smith & Son, Kidderminster)

Compton Loom. But the Axminster has been brought within the machine factory by a series of inventions, of which the Compton loom is a fair representative. The Compton loom accomplishes the knotting of the tufts of worsted into the warp by mechanical means. The main feature of this loom [182] is an endless lattice chain, on which are swung rollers wound with the worsted from which the pile warp is to be formed. Other features of the loom must be carefully studied.

Setting. Our first duty is to prepare the rollers which supply the pile of the carpet. The worsted has been washed, dried, and wound on large bobbins. According to the design, the worsted bobbins are selected and placed on the setting machine. On the creel at the back of the machine [183] the bobbins are arranged in order, and a roller is put into the machine. When the required amount of yarn has been wound, a knife comes up and severs the worsted, and another roller is ready for work. Thus, with swift facility, the rollers are wound.

Weaving. The roller holders are taken to the loom and hung in proper order on the endless swivel chain, geared on the frame above. On the loom the warp beam has been placed, and in the slay the shuttle is ready. Just when the linen warp sheds, the holder with the pile yarn comes into contact; it automatically turns over; nippers come up and grip the ends; on the tense worsted a swift knife strikes, leaving a set of short threads in the gripping jaws. The nippers turn over, and insert the short threads into the warp of the loom. Warp and weft loop round the pile, and the slay drives them tightly together. A row of tufts has been accurately woven into the carpet. In this way Axminster carpets, as heavy and strong as any knotted by hand, are made at the rate of forty yards per day. The lattice chains of rollers can be made any length, and therefore the possible variations in pattern are practically limitless.



184. POWER LOOM FOR CHENILLE WEAVING (Jas. Templeton & Co., Glasgow)

Patent Axminster. In the year 1839, long before anyone else had been able to suggest a way of lessening the cost of the hand-knotted carpet by the application of mechanical invention, a Paisley manufacturer named James Templeton, conceived the idea of forming a pile of the tufted carpet by weaving into a warp the chenille fringes then being largely used for edging shawls. Obviously, if we fasten strings of fringe together, a pile surface will be produced. There are two weavings in the making of the patent Axminster carpet, but neither involves any new principle. Adaptation is the word which gives the key to the process of making this fabric.

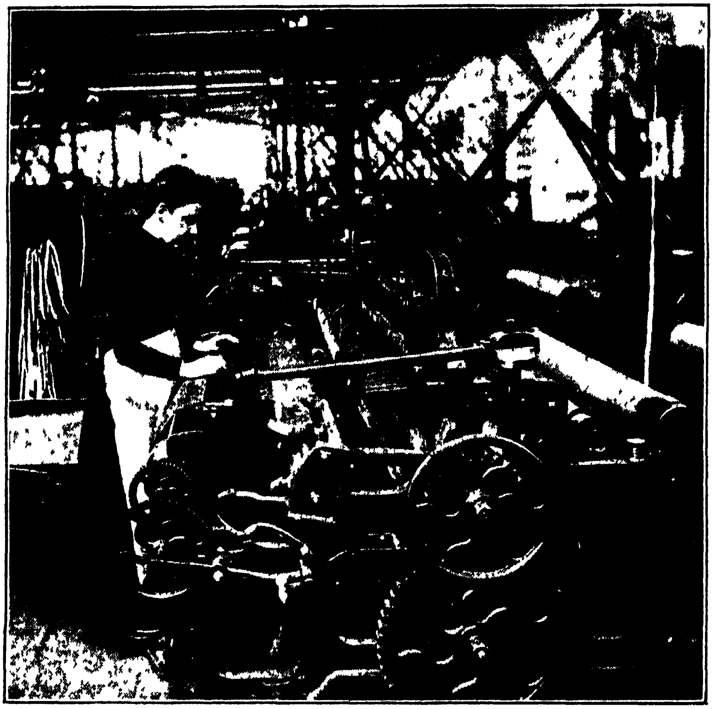
Forming the Pile Weft. When the design of the carpet has been put on the working paper, it is cut into vertical strips, which are laid end to end. The long strip thus made constitutes the length of the chenille web. By following the variation of colour marked on the strip, the weaver [185] will make chenille of the pattern required for forming the design of the carpet. He must be careful, however, to see that the strips, when folded one on the other, will remake the pattern. The right-hand end of the second strip must be joined on to the right-hand end of the first strip, the left-hand end of the third strip on to the left-hand end of the second strip, and so on, right to the last strip of the pattern. This strip is given over to the weaver, who lays it parallel with the warp on the loom.

The chenille loom, as we have already learned, has a linen warp the threads of which are set in sections wide apart, so that the weft may float free between the warp threads. Otherwise the loom is simple, when worked by power [184]. Say that there are five colours in the carpet. We have five shuttles of different colours ready to place in the shuttle-box. Looking at the pattern fixed on the side of the loom, we find that the first four squares are green; therefore, we take four picks of green. Next two squares are bronze, and we make two picks of bronze weft; next is a pick of black; and right on. By this action we produce a fabric of coloured stripes. When fully woven, the web of chenille is taken off the loom. Now the web is brought to a cutting machine, whereon the warp threads are cut into halves, and the whole web is formed into strips exactly resembling the pattern strip, this is the chenille weft for the carpet.

Weaving the Patent Axminster. If the chenille be light, it is wound on spools and put into shuttles, like ordinary weft; but

worsted has been washed, dried, and wound on large bobbins. According to the design, the worsted bobbins are selected and placed on the setting machine. On the creel at the back of the machine [183] the bobbins are arranged in order, and a roller is put into the machine. When the required amount of yarn has been wound, a knife comes up and severs the worsted, and another roller is ready for work. Thus, with swift facility, the rollers are wound.

Weaving. The roller holders are taken to the loom and hung in proper order on the endless swivel chain, geared on the frame above. On the loom the warp beam has been placed, and in the slay the shuttle is ready. Just when the linen warp sheds, the holder with the pile yarn comes into contact; it automatically turns over; nippers come up and grip the ends; on the tense worsted a swift knife strikes, leaving a set of short threads in the gripping jaws. The nippers turn over, and insert the short threads into the warp of the loom. Warp and weft loop round the pile, and the slay drives them tightly together. A row of tufts has been accurately woven into the carpet. In this way Axminster carpets, as heavy and strong as any knotted by hand, are made at the rate of forty yards per day. The lattice chains of rollers can be made any length, and therefore the possible variations in pattern are practically limitless.



184. POWER LOOM FOR CHENILLE WEAVING (Jas. Templeton & Co., Glasgow)

Patent Axminster. In the year 1839, long before anyone else had been able to suggest a way of lessening the cost of the hand-knotted carpet by the application of mechanical invention, a Paisley manufacturer named James Templeton conceived the idea of forming a pile of the tufted carpet by weaving into a warp the chenille fringes then being largely used for edging shawls. Obviously, if we fasten strings of fringe together, a pile surface will be produced There are two weavings in the making of the patent Axminster carpet, but neither involves any new principle. Adaptation is the word which gives the key to the process of making this fabric.

Forming the Pile Weft. When the design of the carpet has been put on the working paper, it is cut into vertical strips, which are laid end to end. The long strip thus made constitutes the length of the chenille web. By following the variation of colour marked on the strip, the weaver [185] will make chenille of the pattern required for forming the design of the carpet. He must be careful, however, to see that the strips, when folded one on the other, will remake the pattern. The right-hand end of the second strip must be joined on to the right-hand end of the first strip, the left-hand end of the third strip on to the left-hand end of the second strip, and so on, right to the last strip of the pattern. This strip is given over to the weaver, who lays it parallel with the warp on the loom.

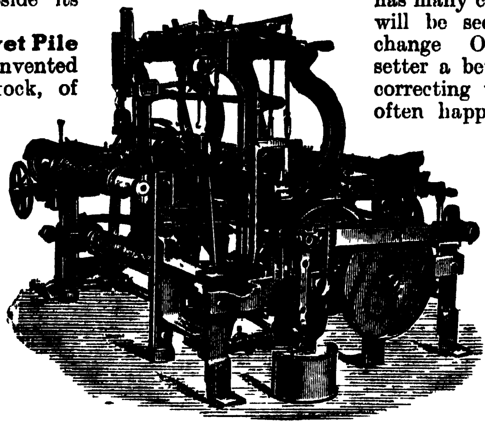
The chenille loom, as we have already learned, has a linen warp the threads of which are set in sections wide apart, so that the weft may float free between the warp threads. Otherwise the loom is simple, when worked by power [184] Say that there are five colours in the carpet. We have five shuttles of different colours ready to place in the shuttle-box. Looking at the pattern fixed on the side of the loom, we find that the first four squares are green; therefore, we take four picks of green. Next two squares are bronze, and we make two picks of bronze weft; next is a pick of black; and right on. By this action we produce a fabric of coloured stripes. When fully woven, the web of chenille is taken off the loom. Now the web is brought to a cutting machine, whereon the warp threads are cut into halves, and the whole web is formed into strips exactly resembling the pattern strip; this is the chenille weft for the carpet.

Weaving the Patent Axminster. If the chenille be light, it is wound on spools and put into shuttles, like ordinary weft; but

185 HAND LOOM FOR CHENILLE WEAVING (Jas Templeton & Co Gla

186 WEAVING PATENT AXMINSTER CARPET (Jas Templeton & Co Glasgow) for the large carpets we have still to depend on manual labour [186]. The chenille is wound on to spools, certainly ; but the heavy threads are let out by hand, one man holding the one end and another the other, while they place it on the warp of the great carpet. At the same time another weaver gives the picker a stroke, and sends the binding shoot of linen thread across the web ; then all pull forward the heavy slay, and drive home the binding weft and weft pile into the warp. As we have said, the weaving is all plain and easy work ; there is no new principle involved ; but the work calls for considerable care and judgment as well as the skill that comes from practical experience. We should say that the patent Axminster gives a strong and compact carpet, and no design is outside its compass.

Tapestry and Velvet Pile Tapestry Carpets. Invented by Mr. Richard Whytock, of Edinburgh, about the year 1840, this form of carpet has gained a larger sale than any other. One very plain reason for this is its cheapness ; but it has other merits, and people who are beyond considering a few pounds in the furnishing of a house frequently prefer the tapestry carpet for the floors of some of the smaller rooms of the home. This apart, the tapestry carpet appeals to the largest carpet-using public, and in consequence the tapestry-carpet loom [187] has been brought to a higher productive capacity than any other carpet loom. One who has studied and worked the ordinary power-loom need have no fear about undertaking to weave in the tapestry-carpet factory ; but some experience and careful observation will be needed before the requisite expertness can be attained. Females may work the light and narrow looms, but the broad looms are almost exclusively in charge of men.



187. TAPESTRY CARPET LOOM
(Robt. Hall & Sons, Bury, Ltd.)

Putting in the Web. On the tapestry-carpet loom we have practically three warps—the pile warp of worsted, the linen warp, and the filling, composed sometimes of cotton, but generally of jute. Upon the delicate adjustment of these depends a great measure of our success in weaving. The filling must always lie exactly between the linen warp threads and form the backing of the worsted. On the other hand, the worsted must start even, every thread in its place, or our pattern is ruined. If the setter has done her work accurately, and all the threads of the pile warp are of equal tension and set exactly to the pattern, we have not much to fear. But many things may happen, and the displacement of a single stitch may mean disaster. Suppose, for example, one tick of green tips the pink point of a rosebud all the way through the web, and the thread on which it is printed has got slightly drawn out of range, the slight divergence may not be observable elsewhere in the masses of colour, but always at that one point the defect will appear. If this particular thread has many changes of colour, the flaw will be seen at the edge of every change Of course, this gives the setter a better chance of seeing and correcting the defect, and it more often happens in the former case suggested. The time of getting in a web is an anxious one for all the parties concerned, and no one breathes quite freely till everything has been shown to have come out correctly.

Weaving the Tapestry Carpet. The loops of the tapestry carpet are formed by the wires in the same way as in the Brussels, and the mechanism employed is similar. We have here no jacquard or other elaborate apparatus to mind ; the whole operation is simple and straightforward plain weaving. Of one thing the weaver must be wary. Because of the force demanded from the reed in driving home the weft, the loose reed has not been adopted on the tapestry loom to any extent. In consequence, accidents with the shuttle are not uncommon. The weaver should always see that the race is plumb with the shuttle-box, and that the shuttle does not jump, even to a slight degree. Balance is difficult to maintain in a loom so heavily driven, and the temptation is to trust to luck and get through with the work ; but the weaver who makes a study of his loom and readily detects the merest disturbance of the harmony of its working is most likely to weave quickly and well.

THE AGE OF ELIZABETH

The Queen and the Woman. Her Treatment of Mary Queen of Scots. The Spanish Armada. Walter Raleigh. The Great Age of Literature

Continued from page 3834

By JUSTIN McCARTHY

ELIZABETH now came to the throne. She was twenty-five years old, and had been brought up in the principles of the Reformation. She had received a liberal education, and was an accomplished scholar. She loved literature, knew the great classic authors, spoke French and Italian fluently and read the literature of those countries. She was fond of music and skilled in its expression, and was a brave and well-trained horsewoman.

Character of Elizabeth. Her character was made up of contrasting emotions and inclinations; she was sensual and vain, and could enjoy any amount of flattery, no matter how extravagant, yet she had an unusual amount of clear and practical common-sense. While she passed with many of her courtiers as a merely frivolous creature who could easily be won by the most fulsome praises, she was quietly taking their measure and making them her instruments and puppets. Her coming to the throne was received with rejoicing by the Protestants, who saw that her reign would put an end to the persecution of the Reformed religion; and it was also received with hope by many Catholics, who believed, from their reading of her character, that she would trouble herself little about religious questions so long as she had a brilliant Court and could amuse herself according to her own tastes.

It is not probable that Elizabeth felt very deeply on religious matters, but her shrewd understanding soon taught her that her place in life must be that of a great Protestant ruler. The Pope, Paul IV., declared that he regarded her as illegitimate and could not sanction her claim to the succession, and that as England was under the control of the Papacy she must resign her pretensions to the throne. The Pope's action only served to convince the Protestants of England that they must stand by her sovereignty or submit to England's becoming a servant of the Papal rule. It seemed to them that to be an English Protestant was to be an English patriot. Elizabeth adopted the policy of the persecution of the Catholics, probably believing that she could not secure the safety of her throne, or the independence of England from foreign interference, by any other course.

Elizabeth and Mary Queen of Scots. One of the events of Elizabeth's reign most damaging to her character in history is the manner in which she acted towards Mary Queen of Scots. Mary has ever been one of the most romantic figures in history. She was a woman of great beauty and charm, and of much intellect and culture. She went through many successes and misfortunes before the time when, in a moment of despair, she threw herself on the protection of Queen Elizabeth. Mary went to France in 1548, and was affianced to the Dauphin. She passed the next ten years at the French Court, where she received an excellent education. In 1558 she was married to the Dauphin, who on the death of the French King succeeded to the throne; but he died in the following year, and some struggles then began in France for the succession and control of the administration.

An Unfortunate Marriage. In Scotland the death of Mary's mother had left the State without a head, while the country was much disturbed by the followers of the old religion and the new. Mary had no desire to enter into that contest, and as the Reformers claimed to have the sanction of the Scottish Parliament she allowed them to take their course, while maintaining her own right to follow the teaching of the Catholic Church. Her reign went on for some time in comparative peace and prosperity. It was soon thought necessary, however, that she should find a husband, and the Archduke Charles of Austria, Don Carlos of Spain, and many other nobles at home and abroad were suggested as candidates for her hand. Mary would have chosen Don Carlos, but this not being satisfactory to her Parliament, she suddenly decided to marry her cousin, Lord Darnley, whose mother was a granddaughter of Henry VII. of England. The marriage was in every way most unfortunate for Mary. Darnley was worthless and vicious, and she was soon repelled by his immorality and alarmed by his selfish ambition. Darnley had obtained from her the title of King, but when he tried to induce her to secure the crown to him for life, and to his heirs if she should die without leaving a child, Mary refused to give her consent.

Rizzio and Lord Darnley. Mary's leading Minister since she returned to Scotland had been her half-brother, the illegitimate son of James V., James Stuart, a Protestant, whom she had made Earl of Moray. On Mary's marriage with Darnley, Moray and some other Scotch nobles had rebelled against her, but the rebellion was easily suppressed, Mary dealing mercifully with the offenders. Since then Mary's principal adviser had been David Rizzio, an accomplished but not judicious or trustworthy Italian, whom Darnley had hitherto regarded as one of his most devoted friends. When Mary refused to satisfy Darnley's ambitious designs he at once regarded Rizzio as the cause of her refusal, and believed that he was her lover. Darnley persuaded some of the great Protestant nobles that Rizzio was influencing the Queen against the Protestant Church, and on March 9th, 1566, he broke into the Queen's room with a number of his new allies, and held her while they dragged Rizzio away and murdered him.

Notwithstanding this, Mary still received her husband as before, and even succeeded in drawing him away from his recent allies. She may have forgiven him on account of his jealousy, or she may have determined, as a Catholic, not to renounce the man to whom she was married. Another reason may have been that a child of their marriage was about to be born. On June 19th, 1566, Mary gave birth to a boy, afterwards James I. of England and VI. of Scotland.

But before long Darnley's character became more repulsive than ever, and there was again some question as to the possibility of a divorce. The separation, however, was not destined to be accomplished by mutual consent or the operation of the State. In January, 1567, Darnley was attacked by smallpox at Glasgow, where Mary visited him and brought him back to Edinburgh. He was placed in a house outside the walls of the city, close to the Kirk o' Fields; and throughout his illness Mary attended him constantly, sleeping in a room below his bed-chamber and passing the evenings with him. On the night of Sunday, February 9th, she left him to go to a festival in Holyrood Palace in honour of the marriage of a favourite servant. About two hours after midnight the house in which Darnley was lying was blown up by gunpowder, and his body was found afterwards in the garden.

Bothwell. Public opinion in Scotland at once ascribed the crime to James Hepburn, Earl of Bothwell, a Scottish noble who had been much favoured by the Queen Regent, and raised to high official position by her although he had long declared himself a Reformer. In 1560, he was sent by Mary of Guise on a mission to France, and there he first met the Queen of Scots, who, when she returned to Scotland, made him a Privy Councillor. He was an ambitious and audacious man, and his schemes brought on him imprisonment in Edinburgh, and, later, exile to England and to France. After her marriage Mary recalled him, and restored to him all his dignities. Bothwell was brought to trial as the author of Darnley's murder, but was acquitted, and the trial was regarded by the public as a mere sham. Within less than a fortnight after his acquitttal, he captured Queen Mary as she was passing from Linlithgow to Edinburgh. She offered no resistance, and he carried her to his place at Dunbar. Bothwell had been married not long before to a charming young woman, from whom he now obtained a divorce. Mary gave him a public pardon for his seizure of her person, and created him Duke of Orkney, and within three months after her husband's murder became the wife of the man whom the whole country regarded as the author of the crime.

This brought all her leading nobles into open rebellion against her, and the feeling of the country now condemned her as it condemned her new husband. It was believed by some that Mary was a party to the plot for the murder of Darnley, or at least a tacit accomplice, although this was never proved. The army she had raised to resist the forces of the nobles dissolved without striking a blow when they showed themselves in battle array, and Mary was compelled to surrender. She was consigned to a prison in the island of Loch Leven, and forced to sign an act of abdication in favour of her son, who was immediately proclaimed King at Stirling. After a long imprisonment, she contrived to escape and to rally to her side a small army of about 6,000 soldiers, which was utterly defeated by the Regent, Moray. Then it was that she threw herself on the protection of Queen Elizabeth, and by that act brought about the close of her strange career. Although she was kept a prisoner, her presence in England was a source of continual trouble to Elizabeth and her counsellors.

Execution of Mary Queen of Scots. Mary had still many supporters among the Catholics of these countries and of France, Italy, and Spain, who refused to believe her guilty of any crime, and regarded her as the last hope of the restoration of the old Faith. Several plots were made for her release, and even for the assassination of Queen Elizabeth. It was said that letters from Mary were discovered during the trial of some of the plotters showing that she was a consenting party to their projects. She was put on her trial in September, 1586, found guilty, and sentenced to death. Elizabeth was for a time reluctant to sign the death warrant, and seems to have felt some doubt of the genuineness of the conviction, and some consideration for her unhappy captive. The Queen was at last prevailed on to sign the warrant, and on February 8th, 1587, Mary was put to death on the scaffold. To the last she bore herself with a composure and a queenlike dignity which deeply impressed all the beholders. She was buried at Peterborough, and some years after her body was removed to the Chapel of Henry VII., where it still remains in a tomb raised by her only son, James I.

After the death of Mary, the Government of Queen Elizabeth increased in severity towards the Catholics. An Act passed in 1585 declared the presence of a Catholic priest in England to be treasonable, and his protection to be felonious, measures which were in many instances enforced. Such enactments, and the unsparing rigour with which they were carried out, aroused the strongest feeling of hostility among the Catholic nations, especially in Spain.

The Spanish Armada. Philip II. of Spain was himself a persecutor of faiths not his own, but he was none the less fervent in his denunciations of the persecution of the Catholics by Queen Elizabeth. He had other grudges against England as well as religious and political ones, for he had not only been an unsuccessful suitor for the hand of Elizabeth, but his policy in the Netherlands had been much opposed in England. He had long contemplated an attack on England, and had even allowed his intention of invading England to avenge the death of a

Catholic queen, and to restore her religion, to be publicly known. He had spent some years in maturing his plans, and the Armada of 1587 consisted of 130 large ships, more than 3,000 cannon, 8,000 sailors, 10,000 galley slaves, 20,000 soldiers, and some 1,400 volunteers, chiefly noblemen and their attendants. The whole Armada was commanded by the Duke of Medina-Sidonia. The English fleet, hurriedly prepared to encounter the invasion, consisted of 80 vessels under the command of Lord Charles Howard, Sir Francis Drake, and Sir John Hawkins, and there were three armies on shore to repel the invaders should they effect a landing. The Armada sailed from Lisbon in May, 1588, but was dispersed by a violent storm. The fleet was soon got together again, and it actually entered the English Channel off Cornwall on July 28th, 1588. A series of engagements followed, in which the Armada suffered heavy losses, was dispersed by fireships, and had many vessels captured or sunk by the English.

Elizabeth had been slow to admit the seriousness of the danger, and her endeavours to keep down the expenses of the naval preparations led to the English victory being less rapid and complete than it would otherwise have been.

But in spite of this it soon became evident to the Spanish commanders that the day was lost, and they began their retreat to Spain in the opening of August, suffering heavily from the stormy weather. The Spanish are computed to have lost 35 ships and 13,000 men.

The Age of Literature. The reign of Elizabeth was the greatest age of literature England has seen, and may challenge comparison with any era of the world. The name of Shakespeare alone would immortalise the reign. It was also the era of Edmund Spenser, of Sir Philip Sidney, of Marlowe, of Massinger, of Ben Jonson, and of many other great men whose works, if they do not retain at the present day their full popularity, are yet standard productions of poetic and dramatic literature. [See LITERATURE]

Another great man of a different order, also an author, was Sir Walter Raleigh, a daring and successful soldier and explorer, some of whose highest triumphs were achieved during the reign of Elizabeth. But her chief favourite was Robert Dudley, Earl of Leicester, an attractive and brilliant but insincere and self-seeking man. Elizabeth was so taken with Leicester that she would undoubtedly have married him but for the remonstrances of some of her most influential advisers. After Leicester's death, Elizabeth took into her special favour Robert Devereux, Earl of Essex, but it is generally believed that her affection for him was maternal rather than lover-like. A quarrel arose between them, and according to stories told at the time, Essex turned his back upon her, and the great Queen forthwith boxed his ears. The two were never thoroughly reconciled. Essex afterwards plotted against Elizabeth, was found guilty of high treason, and on February 25th, 1601, was beheaded in the Tower.

Elizabeth and Ireland. Whatever may have been Elizabeth's faults, she unquestionably had a sincere devotion to what she believed to be the interests of England. In a speech to her first Parliament, she declared that "Nothing, no worldly thing under the sun, is so dear to me as the love and goodwill of my subjects." In this we may credit her with sincerity, and it is certain that she was a most popular sovereign with all those of her subjects who clung to the principles of the Reformation. She was unpopular in Scotland among those who favoured the cause of Queen Mary, and as unpopular in Ireland, where she suppressed several rebellions and where her name is held to this day in detestation by the majority of the people. One of the most famous of her opponents in Ireland was Shane O'Neil, who belonged illegitimately to the great house of O'Neil, on the head of which Henry VIII. had conferred the Earldom of Tyrone. The title carried with it, according to English law, the principle of hereditary descent, but in Ireland the clan or family were allowed to choose any member of the house to be its chief. Thus, on the death of the first earl, Shane O'Neil was chosen as his successor.

The endeavour to enforce the Reformation principles in Ireland had aroused bitter resentment and hostility among the Irish, and the national cause had become a religious one as well. Shane O'Neil, already distinguished in his country by his devotion to the Irish cause, proclaimed himself the champion of Ireland's restoration to national independence. Elizabeth, amid all her troubles with foreign States, had to send a large army into Ireland, for Shane proved a formidable enemy. The Queen seems to have been attracted by the character of the rebel, and to have been inspired by the idea that she might win him to loyalty if she had an opportunity of discoursing with him. She invited him to visit her at her Court, and expressed a hope that she and her Irish people might be able to come to terms. O'Neil accordingly went to England with a number of his retainers.

An Unsuccessful Ambassador. The negotiations, however, came to nothing, and he was retained in London rather as a captive than as an ambassador. Eventually the Queen made it known that O'Neil was to be regarded in future as a loyal subject. But when he went back to Ireland he declared that he had been compelled to accept the terms under peril of captivity or death, and again rebellion broke out.

O'Neil came to his end in a manner unworthy of his position as an Irish leader. In June, 1567, a quarrel broke out at a drinking festivity between him and some men who had been tribal enemies of his. The quarrel became serious, and Shane and some others were killed, and Ireland remained in a state of rebellion against England, more or less, through several generations.

In her later years Elizabeth sank into ill-health, and she died at Richmond on March 24th, 1603. With her death came to an end the dynasty of the Tudors.

CHAIN GEARS AND CLUTCHES

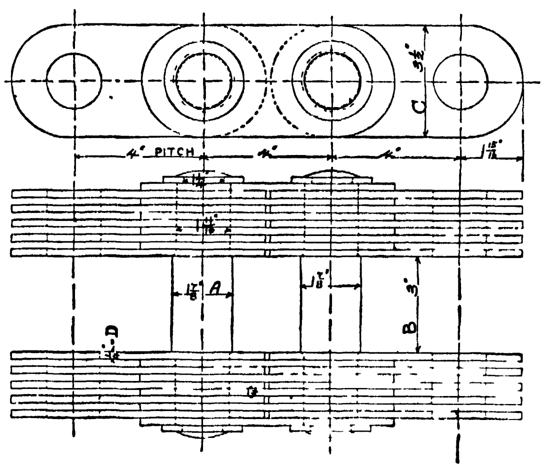
Stud Chain. Block Chain. Bush Roller Chain. Renold Silent Chain. Friction Wheels. Friction Cones. Friction Clutches

By JOSEPH W. HORNER

Gearing Chains. Gearing chains are used for transmitting power in cases where a flexible yet accurate drive is required. Their leading applications may be enumerated as follows: Driving steam-engine governors; driving line shafts from electric motors; driving motor-car axles; driving pumps and machine tools from electric motors; driving feed gears of machine tools; driving grain elevators and general conveyor work; travelling gear of steam and electric cranes; agricultural machinery, etc; hoisting tackle for pulley-blocks and cranes. There are various types of gearing chains in use and each type has its sphere of application more or less distinct from its fellows.

The leading types are the *stud chain*, the *block chain*, the *bush roller chain*, and the *patent silent chain.*

The Stud Chain. Fig. 119 shows a heavy stud chain as used for hoisting tackle. It is designed for a working load of 10 tons, and a factor of safety of 10, consequently its breaking load would be 100 tons; a chain of this nature is designed simply for strength, and has not sufficient wearing-surface to render it suitable for transmitting power except at very slow speeds, not exceeding, say, 50 ft. per minute.



119. STUD CHAIN

A table is given on this page showing the principal dimensions of this type of chain for various loads. The factor of safety varies in practice from 6 to 10; the loads given in the table are breaking loads, and must be divided by a factor of safety to obtain working loads. This chain is sometimes termed *pin and link chain.*

The Block Chain. This is suitable for speeds up to 500 ft. per minute. The block may be hollowed, or flat; the design of this chain, as well as those which follow, is based upon the provision of ample wearing-surface rather than upon actual strength; the proportions are settled by practice rather than by calculation. Accordingly the selection of a chain for any particular duty is best left in the hands of expert manufacturers such as Hans Renold, Ltd., of Manchester, whose reputation is world wide. Fig. 120 illustrates a working drawing used in the manufacture of such chains.

It will be seen that not only are all the details fully dimensioned, but the drawing-sheet contains data with regard to quantities and to material; the perspective view of the block gives a good idea of its shape at a glance. Another feature to be noticed is the extreme exactness of the dimensions, vulgar fractions being inadmissible with the accurate machinery used in the manufacture of the chain.

The Bush Roller Chain. Suitable for speeds up to 800 ft. per minute, the construction of this chain will be seen from 123 A and 123B, which is a reproduction of a Renold working drawing. The rivets of the chain carry hardened bushes, which form a bearing for the anti-friction rollers which engage with the wheel teeth. The latest practice of Hans Renold, Ltd., in the matter of issuing shop drawings is to show each component part on a separate card, each 6 in. long by 5 in. wide [121]. The advantages of using the cards are briefly these: (1) The workman has only the drawing of one item in front of him, and since that is the one which he is

DIMENSIONS OF STUD CHAINS

Breaking load in tons.	Pitch in inches.					No. of plates
	1					
	1¼

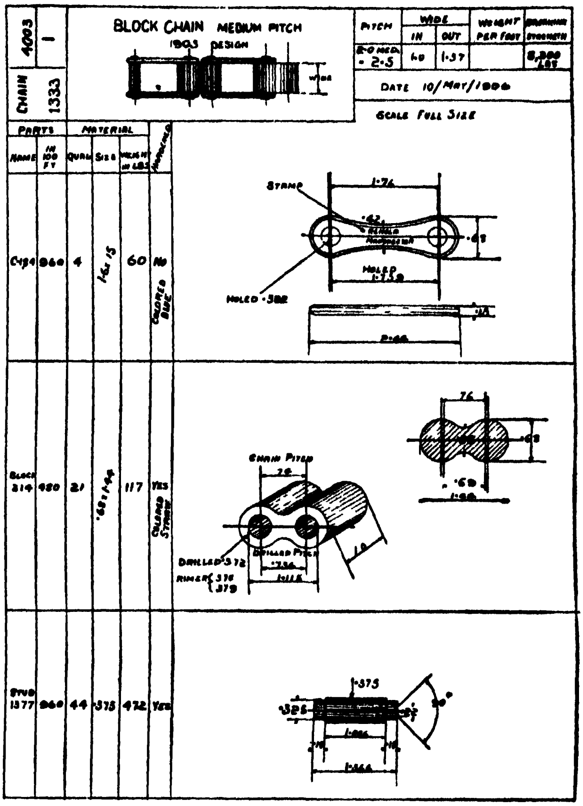
60						8
80						10
100						10

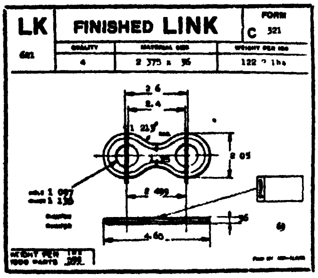
concerned with, no time is lost in having to pick his part off a drawing containing other work; (2) if an alteration is to be made it entails only the calling in of a few cards and the issuing of revised ones, the incoming cards being destroyed, but when the whole drawing [123] is involved, it is a much more troublesome and expensive matter to put right; (3) the whole drawing is retained in the drawing office, and assembly cards, as 122, are issued for putting the parts together.

The Renold Silent Chain. The honour of designing and constructing the only satisfactory high-speed chain belongs to Hans Renold; 1,250 ft. per minute can be attained with this chain [124]. The construction is unique, and the action of engaging with the wheel teeth is entirely different to ordinary chain gears. In order to understand this better we will first investigate the action of ordinary chains and the formation of wheel teeth.

Fig. 125 illustrates a wheel suitable for working with the chain shown in 119; the tooth curves are involute, and there is just enough space at the roots for the easy working of the studs as the chain enters and leaves the teeth. This is the simplest form and works satisfactorily with slow speeds and uniform loads. As speeds increase and loads vary, this construction must be modified; the best-made chain will stretch, and then the wheel has to accommodate a varying and an increasing pitch. Another complication has also to be met; the driving wheel has a tendency to run faster than the chain, while the driven wheel tends to lag behind the chain; this effect is seen in 126, which is slightly exaggerated in order to show the clearing allowances made. The pitch of the teeth is greater than the pitch of the chain in the case of the driving wheel, and the tooth spaces are much wider than actually required for the accommodation of the roller alone; by such construction the above-mentioned difficulties are overcome, but the life of the chain is seriously impaired if run beyond a speed of, say, 800 ft. per minute. The difference in pitch between the chain and the wheel gives rise to a series of little shocks as the load is transferred from tooth to tooth while running, such shocks being the cause of the wear and noise which limit the speed.

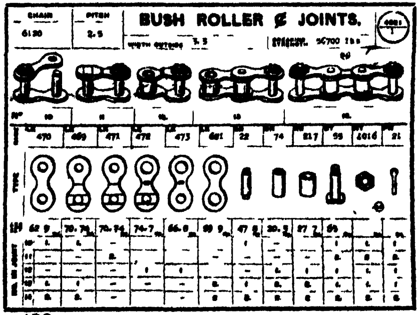


120. BLOCK CHAIN DRAWING

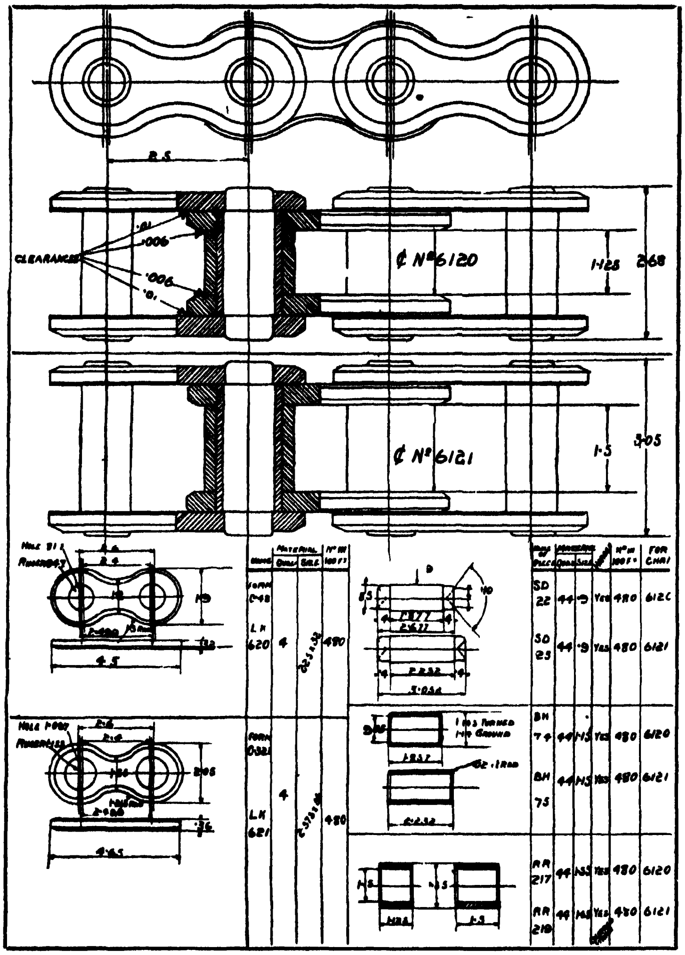


121. FINISHED LINK DRAWING CARD

The Patent Silent Chain. Referring now to the patent silent chain [124], we see that the action of the links is to come quietly into position without slide or shock; when the teeth are worn, or when the chain is stretched, the chain rises automatically up the wheel tooth, as in 127, and so accommodates itself to altered conditions, and maintains a silent drive. The chain consists of a number of links of the outline shown, there being from 4 to 12 abreast according to power transmitted. There are various modifications of construction adopted to suit



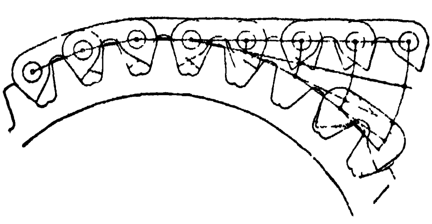
122. ASSEMBLY CARD FOR BUSH ROLLER CHAINS



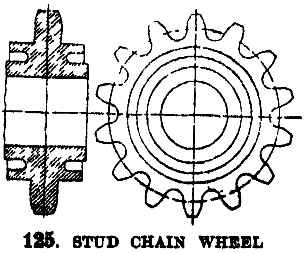
123A. BUSH ROLLER CHAIN DRAWING

different drives, but the above principles do not alter.

Chain Wheels. Chain wheels are ordinary castings for heavy stud chains, but are invariably machine-cut for all other types. The diameter of a wheel is naturally kept as small as possible in order to keep the chain speed down, and also to save expense. When using *block chains* the limit of teeth in the pinion may be taken as six, although smaller ones have been employed for special work. With *roller bush chains* eight teeth are considered to be small enough for ordinary work, while the ratio of the wheel and pinion should not be more than 7 or 8 to 1. The smallest wheels for the patent silent chain should not contain less than 15 or 18 teeth, according to construction of chain; the *gear ratio* recommended should not be more than 5 to 1.



124. RENOLD SILENT CHAIN



125. STUD CHAIN WHEEL

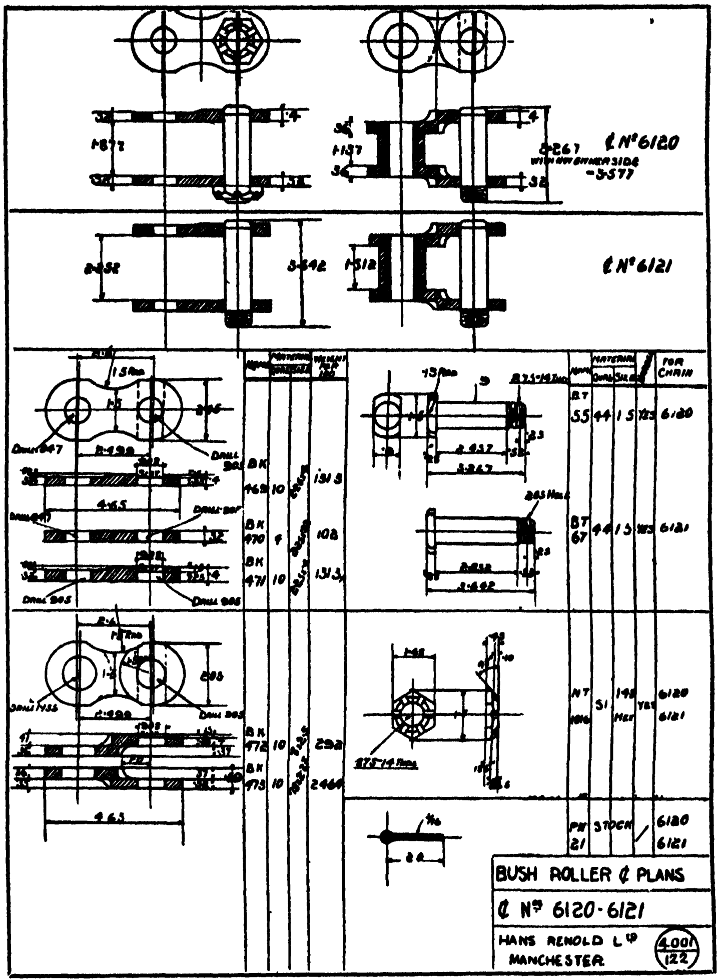
It is desirable to arrange a gear drive so that it contains an even number of links or pitches; when this is unattainable recourse is had to special links as shown in the top right-hand corner of 123B, where they are cranked to fit outside of the links they would come abreast of.

Chain Belting. A chain belt is a form of metallic chain used largely for elevating and conveying machinery; the links are invariably of malleable cast iron. The design and manufacture of this chain is even more in the hands of specialists than that of the foregoing types, consequently the draftsman is rarely or never called upon to design them.

Friction Wheels and Clutches. These are used for the transmission of power, at intermittent intervals, from constantly-moving machinery; or for rapidly disconnecting a portion of moving mechanism; or for connecting machinery to engine after it has started up. A common application of the latter form is met with on motor-car work, where the engine is not capable of starting up against full load.

The principles underlying this class of mechanism are discussed on page 958, and applications are illustrated on page 961 and 963 in MECHANICAL ENGINEERING. We therefore proceed to delineate more fully several leading types.

Fig. 128 shows a flat-faced friction wheel and pinion as used on a friction hoist. The wheel is keyed to the rope-barrel of the hoist, and the barrel runs loose upon the shaft. The end of the shaft is formed eccentrically, and is moved through a portion of an arc by means of the lever



123B. BUSH ROLLER CHAIN DRAWING

and cord. This movement brings the friction wheel into contact with its pinion, which latter is running constantly; the friction set up between the two surfaces causes the wheel to revolve. The barrel, being keyed to the wheel, must go with it, and so the load is lifted. The calculations involved are simple, and may be stated thus: The load to be lifted is 1 ton, the corresponding load on the periphery of the wheel is

$$\frac{\text{load} \times A}{B} = \frac{2{,}240 \times 9}{51}$$
$$= 395 \text{ lb.}$$

Assuming the coefficient of friction to be ·2 (cast iron on cast iron), then the pressure required between the wheel and pinion is

$$\frac{395}{\cdot 2} = 1{,}975 \text{lb.},$$

and the load on the operating cord is therefore

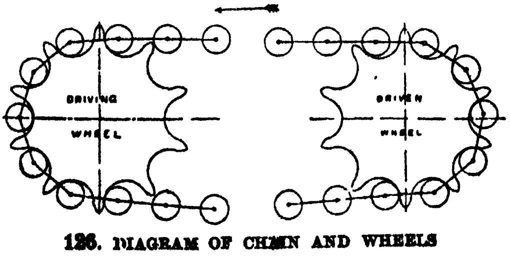
$$\frac{1{,}975 \times C}{D} = \frac{1{,}975 \times \cdot 75}{70}$$
$$= 21 \text{ lb.},$$

which is quite within the capacity of an average man to manipulate. The pulleys are designed as ordinary belt pulleys, but are somewhat heavier throughout, to withstand shocks due to the sudden application of the load. An enlarged view of the eccentric formation of the shaft is given in 128, which is a neat way of making a very short lever arm. The weight near the end of the long lever is so placed in order to ensure the large pulley returning to contact with a brake block arranged overhead, when the hand cord is released. The width of the wheel is 6 in. in the case illustrated, and this works out to

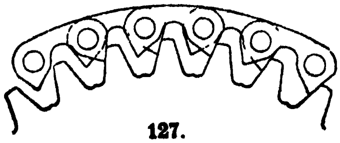
$$\frac{1{,}975}{6} = 329 \text{ lb. per inch of width.}$$

This represents average practice. High pressures per inch of width tend to heat the pulleys.

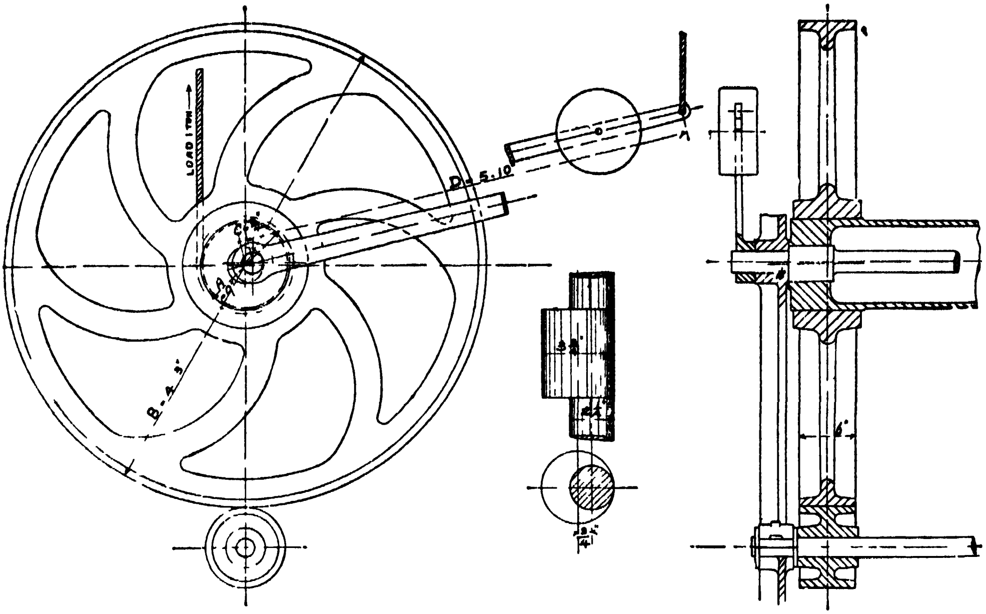
Friction Cones. Friction cones, or *cone-couplings*, as they are sometimes termed, are used for coupling shafts together while one of the shafts is running, or for taking power from a revolving shaft. The latter application is shown in 129, the view illustrated being a section, and all portions circular. The outer cone piece A is bushed and runs loose on the shaft, being kept in its place endwise by means of the collars B and C. Teeth are cast on the outside periphery, which engage with corresponding teeth of a spur wheel. The inner cone piece D slides upon feathers fitted in the shaft, and is moved by suitable lever gear fitted to the groove E. Driving of the spur gear takes place when the cones are pressed together



126. DIAGRAM OF CHAIN AND WHEELS

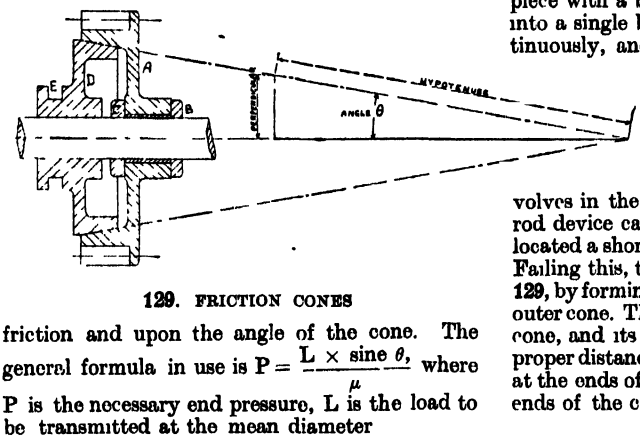


127.
RENOLD SILENT CHAIN WHEN WORN



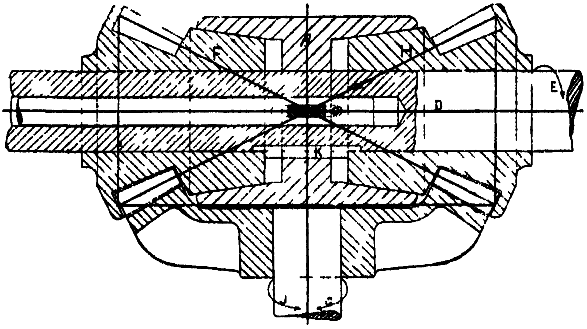
128. FRICTION WHEELS

with sufficient force to overcome the resistance to slipping between their surfaces. The end pressure required depends upon the coefficient of friction and upon the angle of the cone. The general formula in use is $P = \frac{L \times \text{sine } \theta,}{\mu}$ where P is the necessary end pressure, L is the load to be transmitted at the mean diameter of the cone. θ is used to denote the angle; "sine" is a trigonometrical ratio of the angle θ, and is found by dividing the perpendicular by the hypotenuse; μ denotes coefficient of friction. The angle θ is usually 10 deg., and μ may be taken as ·2 for cast iron on cast iron.

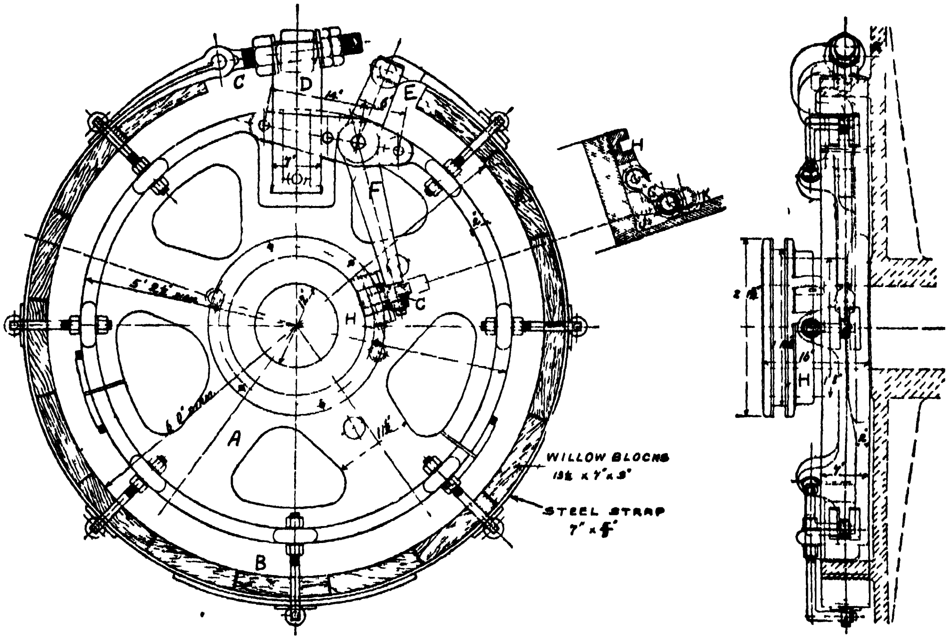


129. FRICTION CONES

Reversing Cones. Another application of the foregoing type of cones is shown in 130. The outer cone A is in this case driven from the shaft by means of the cottar B, which passes through a slot, C, in the shaft. This cottar also passes through a central rod which is moved endwise at the centre of the shaft. The outer cone is double-ended in order to engage with either the right or left hand inner cones, and these latter are each cast in one piece with a bevel pinion, and both pinions gear into a single bevel wheel; the shaft D runs continuously, and carries the outer cone with it. When the shaft is running in the direction of the arrow E, and the cone F is engaged, then the bevel wheel runs in the direction of the arrow G; but if the cone H be engaged, then the bevel wheel revolves in the direction of arrow J. The central rod device can only be used when the cones are located a short distance from the end of the shaft. Failing this, they may be moved, as in the case of 129, by forming the groove around the centre of the outer cone. The feather K assists to drive the outer cone, and its ends keep the inner cones at their proper distance apart. Sometimes collars are fitted at the ends of the feather in order to prevent the ends of the cones being cut by the feather.



130. REVERSING FRICTION CONES

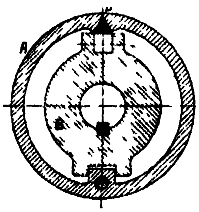


131. THE "WELLMAN SEAVER MORGAN" CLUTCH

Friction Clutches. The principal objection to the use of the friction devices just described is the resulting end pressure upon the bearings of the shafting. Figs. 131 and 132 show two friction clutches which are practically free from this defect.

An *expanding ring clutch* is seen in 132. It is double-ended or reversible. The expanding ring A is driven from the shaft by key and by the piece B. It is expanded to drive the hollow of the mitre wheel C. In order to effect the expansion, the ring is divided at D, and receives a steel wedge piece, which is forced up by another wedge formed on lever E. This lever is moved by striking the cone piece F to the right or to the left. The angles of the wedges and of the cone are such that they slip back when the pressure is removed. The adjusting screw G on the end of the lever provides means for following up the wear on the working parts, and so keeping the relative stroke of the cone a constant.

A friction clutch which has wide applications amongst mill work and winding engines, and can be built to transmit thousands of horse-powers, is shown in 131. It is made by the Wellman Seaver Morgan Co., Ltd. It consists of a centre driving disc A, which is keyed to the shaft, and carries with it a wood-lined strap, B, which is adjustable by means of its anchored end, C, on driving piece D, and is tightened by the end marked E and the lever F, the tail end of which has a spherical connection with the link G. The sliding collar H is moved by suitable striking levers, and causes the link G to move the ball end of the lever F from position J to position K. The strap is thus tightened upon the rim of any drum or wheel which may be interposed between the strap and the driving disc A, as shown in chain dotted section. Such interposing rim does not have any contact with disc A.



The leading dimensions of one of these clutches are given on the drawing [131], which is a 6-ft. diameter example, and can transmit 11-horse power per revolution, with a maximum load of 20,000 lb. on the rim.

THE USE AND ABUSE OF DRUGS

Remarkable Properties of Drugs and Beverages. Value of Tea and Coffee. The Ridiculous Claim for Alcohol, Morphia, Opium, Tobacco, Strychnine, Quinine

By Dr. C. W. SALEEBY

Opium and Civilisation. We must now turn to a detailed discussion of a few of the most important vegetable alkaloids, and we shall begin with what for ages has been recognised as the most valuable of them all—a substance which has no rival in relieving pain, and which, unfortunately, by a perversion of the power of science has lately become accessible to all and has added another and a most terrible vice to our civilisation. The juice which exudes from the ripe capsules of the poppy is known when dried as *opium*. The complexity of the composition of this product is amazing. Besides morphine, it actually contains at least seventeen other alkaloids, together with some peculiar acids, and a whole host of different salts as well as some neutral principles, albumen, glucose, fats, a volatile oil, etc.

We insist upon this complexity of opium because it is obviously a very serious objection to the use of this substance in medicine No wonder it upsets many people. Of all these constituents, however, there are only two that are of the slightest value. Both are capable of ready isolation. Hence, except on the ground of expense—which in such connection is not worth considering—there is really no adequate reason why opium or its preparations should ever be used as drugs. Opium should be used merely as a source of the alkaloid *morphine*, which it contains to the extent of about 10 per cent., and of the alkaloid *codeine*, which is a methyl-morphine. The alkaloid *thebaine*, which has already been mentioned, is yearly responsible for a very large number of infant deaths since, in the case of infants, it is the most dangerous ingredient of the various patent medicines containing opium, with which the wicked and ignorant state of the law still permits many mothers unconsciously, or half consciously, or even deliberately, to kill their babies.

The Preparation of Morphine. The preparation of morphine may be briefly described, since it is fairly well indicative of the general process by which alkaloids are isolated A cold, concentrated, aqueous solution of opium is treated with the chloride of calcium or barium. This precipitates various ingredients of the opium and converts the morphine into a hydrochloride, which is precipitated in turn by the addition of ammonia. The morphine thus obtained is washed, dissolved in hydrochloric acid, and crystallised out in the form of the pure hydrochloride, which is the most commonly employed salt. This is fairly soluble, like the salts of alkaloids in general. Morphine itself is not soluble in less than 1,000 parts of cold and 300 parts of boiling water. The most important fact of the pure chemistry of morphine is that its decomposition, as might be expected, yields pyridin and chinolin.

Unfortunately, the higher chemistry has not yet reached a point which permits us to say anything whatever about the chemical actions involved in the effect of morphine upon the brain and other parts of the body.

Opium Poisoning. We can here briefly discuss, however, the chemistry of the very interesting subject of opium poisoning. The first fact worthy of notice is that the most efficient means of persuading the stomach to rid itself of the morphine it contains is to be found in the prompt use of the substance called *apomorphine*, which, as we have seen, is morphine minus one molecule of water. This little difference is sufficient to deprive apomorphine of all the actions upon the nervous system which are so characteristic of morphine itself; but, on the other hand, the loss of this molecule of water endows it with the property of being by far the most powerful of all known emetics.

The second point about the treatment of opium poisoning is the very great value that attaches to the administration of the permanganate of potassium, $KMnO_4$. About ten grains of this should be dissolved in one ounce of water. If Condy's Fluid is at hand it may be diluted and administered, this being a solution of the salt. Similarly, if the stomach pump is employed, eight or ten grains of the permanganate of potassium should be dissolved in every ounce of water to be used, or the stomach may be washed out with diluted Condy's Fluid. The value of the permanganate lies in the fact that it immediately oxidises any morphine with which it comes into contact, producing substances which are entirely harmless. In short, morphine is a reducing agent, and one of the tests for it consists in the decolorisation of solutions of potassium permanganate—this being due to the simultaneous destruction both of the morphine and of the salt in consequence of the transference of oxygen.

Obviously, the chemical aspect of the treatment of opium poisoning is concerned merely with the morphine that remains in the stomach. Unlike the case of carbolic acid, which can be pursued even into the blood by chemical antidotes, as we have seen, morphine, after absorption into the blood, can unfortunately not be attacked by chemical means.

The Chemistry of Morphia. Chemistry, however, has been of the greatest value in elucidating the facts, long familiar to physicians, of chronic opium poisoning or the similar poisoning due to the habit of using subcutaneous injections of morphia. The chemical elucidation of this subject is of the greater interest because parallel facts are more than likely to be demonstrated in the case of other chronic poisonings, such as that by alcohol, which is, of course, vastly more important than even this.

Let us keep in our minds what we have already noted regarding the remarkable fashion in which the simplest and most easily effected change in the constitution of the molecule of an alkaloid may cause it, so to speak, to turn upon itself, and thus to possess pharmacological properties directly antagonistic to those which were formerly characteristic of it. Further, let us note that in many plants we find pairs of antagonistic alkaloids of which, in all probability, one is derived from the other by some such simple change as we have already illustrated. Remembering these facts, let us consider the case of chronic opium poisoning, or what, to give it its technical term, we may call *morphinomania.*

The Victim of the Morphia Habit. We find that the patient becomes depressed, irritable, weak, nervous, sleepless, and ill in many other ways at a certain definite point after taking a dose of this drug. But a new dose taken at this point will relieve all his symptoms, though this relief will inevitably be followed by a recurrence of them, to be similarly relieved. Now, this cycle of symptoms is much more extreme than one could reasonably explain on the mere theory of reaction in the nervous system. If a victim of the morphia habit be suddenly deprived of his drug entirely, he will not only be miserable, but will exhibit all the well-marked physical signs of very grave and dangerous prostration. In short, the patient looks as if he were poisoned—*actively poisoned,* not merely suffering from the loss of an accustomed stimulant. Furthermore, as time goes on, a whole series of changes occur in his body, and these are not changes which tally with the known properties of morphine. Now, in all probability these results are due to an oxidation product of morphine which is known as *oxy-di-morphine.* This is formed in the body itself by a very simple change in the molecule of morphine, and it illustrates once again the remarkable fashion in which a slight change in the molecule of an alkaloid may reverse its chemical properties in contact with living matter.

A Problem for Chemistry. From this discovery it follows that the larger the amount of morphine taken the greater is the amount of oxy-di-morphine which is produced and causes the subsequent symptoms ; hence, suddenly to cut off the supply of morphia is suddenly to leave the patient under the unantagonised influence of its derivative, which may be so powerful as to threaten death. Already the recognition of these facts has led to great improvement in the treatment of these cases, which are daily becoming more common. It probably remains for organic chemistry to provide us with some substance which will precisely destroy or neutralise the oxy-di-morphine. To do so would be to cure the habit. These wretched patients must not be conceived of as deliberately doing what will hurt them. On the contrary, the craving must be regarded as the demand of the body for some substance which will neutralise the appallingly distressing action of the poison which is circulating in the patient's blood. The whole existence of the evil is due to the fact that the substance which is demanded and taken in order to neutralise the effects of this poison is itself the source of a fresh supply. Obviously, here is a practical problem which awaits its solution by the higher chemistry, and which that chemistry will certainly solve one day.

The Essential Ingredient of Tea and Coffee. After morphine, *caffeine* may, perhaps, be regarded as the most interesting of the alkaloids. It is of very great interest, in the first place because of its chemical relations, secondly, because of its remarkable properties, and thirdly, because of its extremely extensive use by mankind—a use more extensive even than that of opium or possibly alcohol. This alkaloid is the essential ingredient of tea and coffee. The name *theine* used to be applied to it when it was derived from tea, but it is one and the same substance in both cases. In this country we actually drink about four million gallons of tea every day, and the one and only ingredient which determines this enormous use of the plant is its *caffeine.* The percentage of the alkaloid in a typical leaf may be from nearly three to just over four per cent. The proportion of it in Indian and Ceylon teas is slightly higher than in China teas. Whether the tea be properly or improperly made [see page 3822], practically all the caffeine in the leaf enters the infusion. An ordinary cup of tea contains about a grain of caffeine.

Caffeine is also the substance on account of which men drink coffee. The proportion of caffeine in coffee, after roasting, is about 1 per cent. The roasting involves the loss of about one-fifth of the caffeine originally contained in the leaf. If the leaf be over-roasted much more caffeine is lost. Neither the taste nor the flavour of coffee or tea depends upon the essential ingredient. An ordinary cup of coffee does not contain appreciably more caffeine than an ordinary cup of tea, despite the common notion that it is much less harmful to drink tea than coffee. People who are upset by coffee and not by tea are usually affected not by the alkaloid, but by the volatile oil known as *caffeol,* which is formed in the bean during the process of roasting, and to which the aroma of coffee is due.

Now, cocoa contains no *caffeine,* but, in place of it, an alkaloid which is very closely allied to caffeine, as we shall shortly see, and is known as *theobromine*—from Greek *theobroma,* food of the gods, the botanical name for cocoa. The proportion of theobromine in cocoa is about the same as that of caffeine in tea and coffee.

What Caffeine is. The empirical formula of caffeine—which we may note is the essential ingredient not only of coffee and tea but also of Paraguay tea, or maté, and of the beverages made from kola nut and of the substance called *guarana*—is $C_8H_{10}N_4O_2$, but this empirical formula, like most of its kind, is extremely uninstructive. Chemically, however, caffeine is a product of a very well known and important body known as *xanthin*. This has the formula $C_5H_4N_4O_2$. Now, if the reader will recall the formula of uric acid, the simplest statement of which is $C_5H_4N_4O_3$, he will see that uric acid may be regarded as an oxidation product of xanthin. In point of fact, xanthin represents a very important stage in the series of chemical changes by which the body-substances known as *nucleo-proteids* break down into uric acid.

Now, theobromine is none other than dimethyl-xanthin, while caffeine may be called either *methyl-theobromine* or *tri-methyl-xanthin*.

Effect of Caffeine in the System. These facts give us some key to the manner in which we may conceive caffeine and theobromine to be produced by the numerous plants in which they are to be found. Plainly, they must be derived in the course of the breaking down of the nucleo-proteids which are found in those plants, as in all other living things. But the relations of these alkaloids are of even greater practical importance, because it is generally supposed that when they are taken into the body they become sources of uric acid like xanthin itself. Now, since the excessive presence of uric acid in the body is characteristic of gout and various other diseases, many people have joined in a crusade upon all articles of diet that yield uric acid. This crusade furnishes a very good instance of bad reasoning in matters of science. It is argued that because uric acid is found to be produced in excess in gout, any article of diet which produces uric acid in the body will itself tend to favour the production of gout. When we consider the matter we see that this does not follow in the least. The essence of gout is not the production of uric acid but a disordered cell chemistry which, as it happens, leads to the production of uric acid as one of its symptoms or indications. Unless it can be shown that tea, coffee and cocoa, for instance, lead to the production of this morbid cell chemistry, nothing can be alleged as to their supposed malign action. It is ludicrous logic to argue that because caffeine or tri-methyl-xanthin is a source of uric acid, it is therefore capable of disordering the cell life of the body in such a fashion as to make the contents of the cells themselves yield uric acid. Thus, the logic of the argument is worthless. Still more amusing is the quite recent research (communicated to the Paris Academy of Sciences on June 18th, 1906), which shows that caffeine and theobromine do not yield uric acid at all in the body, but leave the body in the form of more complex substances, against which no evil action has been alleged.

The Chemistry of Consciousness. Both the facts and the logic of this doctrine having been refuted, let us summarise, as briefly as possible, the main facts of this compound tri-methyl-xanthin, of which mankind daily consumes such gigantic quantities. The first noteworthy fact is that, unlike alcohol and opium, caffeine is a true stimulant. An increased rapidity of the vital functions is not merely, as in these other cases, a preliminary to retardation of them, but constitutes the essential action of the drug. It is not then, a pseudo-stimulant but a true stimulant. Furthermore, its stimulation extends from the lowest to the highest tissues. So far as is known the drug is unique in that it stimulates the highest functions of the brain. In certain persons morphine stimulates the imagination; everyone knows that Coleridge wrote a wonderful poem under the influence of morphine. But morphine does not stimulate the reasoning powers; caffeine, on the other hand, definitely does. There is no other drug which, like caffeine, has the remarkable property of preventing sleep, purely by its immediate action upon the brain. What exactly is the part that this alkaloid plays in the chemistry of consciousness, preventing those changes which result in sleep, no one yet knows. But the chemistry of consciousness is incomparably the most interesting and important problem of all chemistry; and it is an extremely interesting fact in this connection that tri-methyl-xanthin, itself so closely allied to a degradation product of the substances which are characteristic of the nuclei of living cells, should have this remarkable effect upon the functions of the most wonderful living cells which we know or which we can conceive.

The Great Value of Tea and Coffee. Caffeine not only keeps one awake, and is not only vastly superior to any other known substance as a stimulant for any special intellectual exertion, but its stimulation on the brain is even and balanced, and has no subsequent reaction. The caffeine yields no product that antagonises its own actions as morphine yields oxy-di-morphine.

We submit these very brief statements to the reader, and will ask him to observe the noteworthy fact that this alkaloid, beverages containing which have become practically a necessity of human life wherever and whenever they have been introduced to a people, stands the test of critical scientific investigation in a manner which explains its well-earned popularity. We are far from saying that tea and coffee are not capable of abuse, like most other or all other good things. But we will insist that chemistry has done a great service in enabling us to analyse these beverages and to distinguish between the actions of their various ingredients. The result of the inquiry is to show that of the injury which these beverages do—an injury which is quite trivial when compared with the sum of their value to men—at the very least nine-tenths must be attributed either to the tannic acid which tea and coffee both contain, or to the powerful caffeol contained in coffee, and not to the alkaloid, unique in its combination of potency and all but innocence, to which these beverages owe their popularity.

Caffeine crystallises out from aqueous solutions in light, silky, colourless crystals having one molecule of water of crystallisation. It is soluble only to the extent of 1 part in 80 in cold water. At the temperature of boiling water it melts, and then volatilises. It can be obtained quite readily from a cup of tea by treatment with an alkali and chloroform, in which it is highly soluble. Like other alkaloids, it forms salts, but these are very unstable. The most convenient of them, and one which is more largely employed every day, is the citrate, prepared by adding caffeine to a hot solution of citric acid and evaporating. This is very much more soluble than the alkaloid itself, and has the same properties.

True and "False" Stimulants. No better proof of the stupid way in which the word *stimulant* is used, even in scientific writing, can be furnished than the contrast between alcohol and caffeine. Alcohol is a sedative which has a period of preliminary stimulation. The ultimate explanation of its sedative action doubtless depends upon its interference with oxidation, which is the source of all the energy of the body. As we have already seen, alcohol retards the vital processes by increasing the stability of oxy-hæmoglobin. In none but a superficial sense, then, is it a stimulant. A drug which interferes with oxidation and lowers the temperature is essentially the reverse of a stimulant. On the other hand, caffeine, which is a pre-eminent example of a true stimulant, has been proved to increase the oxidation of the body, as is evidenced by the increase in the amount of urea which is produced under its influence; and, furthermore, in considerable doses, caffeine raises the temperature of the body—this rise having been shown to be due not to any interference with the loss of heat by the surface of the body, but to the increased production of heat consequent upon the more rapid oxidation which is caused by the drug.

If the word stimulant is to be retained, either in scientific or popular language, it is highly desirable that it should be used so as to mean something, and not so as to darken counsel by words without knowledge. The present writer has already, in the scientific journals, insisted upon the need for an intelligent use of the word stimulant, and he here submits to the reader the proposition that any substance which, like caffeine, increases the amount of oxidation in the body is fundamentally a stimulant, while any drug that does the reverse is fundamentally a sedative, oxidation being the very source and essence and condition of vital activity. Some such opinions as these are now steadily gaining ground. They furnish a good illustration of the general proposition that in all matters of the living body the analysis of phenomena is imperfect, and will only too probably be misleading, *until it has reached the chemical stage.*

Atropine. The next important alkaloid that we must consider is called *atropine*, being the characteristic alkaloid of the natural order of plants known as the *Atropaceæ*, or sometimes as the *Solanaceæ*. Its chief source is the "deadly nightshade," the botanical name of which is *Atropa belladonna.*

Atropos, the reader may remember, was the eldest of the Three Fates. She held the "abhorred shears," and it was her function to cut the thread of life. Keeping this in mind, the reader will be able to co ordinate his knowledge, as knowledge should be co-ordinated in every well-made mind, so that Greek mythology, botany, an immortal English poem, chemistry, and toxicology—the science of poisons—may each suggest the other.

The first point worthy of note is that there is a whole series of plants, belonging to the same natural order, which yield atropine. Not so long ago different names were applied to the alkaloid according as it was derived from, for instance, the deadly nightshade or the thorn-apple; but the alkaloid is one and the same in each case, and it is infinitely better to use the same name for it. The reader will not fail to observe the significance of the fact that a series of plants which resemble one another in their external characters sufficiently to be classed in one order by botanists, also resemble one another so closely in their internal vital chemistry that they each yield the same substance.

The Standardisation of Drugs. Atropine occurs both in the roots and the leaves of the deadly nightshade, the percentage in the latter—about 0·4—being the more constant. The time has finally passed, however, when we can permit ourselves to make tinctures, extracts, and so on, of leaves and roots, and trust to chance for the proportion of the alkaloid that these preparations may contain. Either the alkaloid itself must be employed for medical purposes, or else these preparations must be standardised. This is now the rule; at any rate, to the extent that the tincture of belladonna, for instance, in this country, is standardised so that it must contain 0·5 per cent. of the total alkaloids of the root. Other alkaloids occur in belladonna.

These are very closely allied in molecular structure to atropine, and are also found in other plants belonging to the same natural order. The empirical formula of atropine is $C_{17}H_{23}NO_3$, and it occurs in the belladonna plant in the form of a malate or salt of malic acid. It is dissolved out from the leaves or root by means of chloroform, and can be obtained in colourless crystalline needles. It can be decomposed into a somewhat simpler body called *tropine*, and an acid called *tropic acid*. This is important, because tropine can be used as a source of other artificial alkaloids, one at least of which, called *homatropine*, is very useful. It has also to be remembered that if drugs containing atropine be mixed with alkalies, the alkaloid is decomposed into tropine and tropic acid, which are of no value. The belladonna plant also yields another alkaloid, which is known as *hyoscyamine*, since it is more especially characteristic of the henbane plant or *Hyoscyamus niger*. The two alkaloids have the same empirical formula, but differ in the structure of the molecule, the difference being indicated by the melting point, the optical properties, and the action upon the body. They seem capable of ready conversion one into the other.

A Remarkable Influence upon Nerves. We must not here discuss at length the physiological properties of this extraordinary alkaloid, which has the most marked action upon nearly all the functions of the body, even when it is administered in doses of one-hundredth of a grain, and one five-thousandth part of a grain of which is quite sufficient, when used by the oculist, to dilate the pupil of the eye for many hours. In general, it may be said that atropine paralyses the terminal part—not the trunk—of all those nerves of the body the business of which is to stimulate involuntary muscular tissue, and also the terminals of all the nerves that stimulate glands to pour forth their secretions ; hence the dryness of the mouth in cases of belladonna poisoning. We need scarcely comment upon the extraordinary significance of this selective action of the drug, which proves that the chemistry, or the physical chemistry, of the extreme tips of these peculiar kinds of nerves is utterly distinct from that of the ordinary motor nerves that supply voluntary muscular tissue, such as the muscles of the limbs. Atropine is an extremely valuable drug in medicine, and is the essential ingredient of nearly all the drugs that are given in asthma, whether those are patented or unpatented.

The Mysterious Power of Hyoscine. We can say no more here about hyoscyamine, but henbane also contains a remarkable alkaloid known as *hyoscine*, which is very closely allied to atropine and hyoscyamine, and has the formula $C_{17}H_{21}NO_4$. This drug is of unique interest in relation to the chemistry of consciousness. The comparatively trivial difference in its molecular constitution suffices to endow it with properties not only totally distinct from those of its allies, but also unique in character and potency. It may be said that even in cases of the most violent maniacal excitement of the brain, one-hundredth part of a grain of this alkaloid injected under the skin, anywhere, will arrest consciousness and cause sleep within sixty seconds. Neither morphine nor hydrocyanic acid, nor any other known body, can remotely approach hyoscine in its power of arresting what are, of course, incomparably the most marvellous and incomprehensible of all chemical processes—those with which consciousness is associated. Here we simply state the facts ; no explanation of them can be suggested, but the significant thing for those who look ahead is that it is from such indisputable facts as these that the science of the future will be enabled to elucidate the greatest problems of chemistry—those associated with life and consciousness.

Tobacco. The tobacco plant belongs to the same natural order—the Solanaceæ or Atropaceæ—as the deadly nightshade and the henbane, and it also yields an extremely potent alkaloid, *nicotine*. Nicotine, however, differs very markedly from atropine, for instance, in its relations to the chemistry of life, and this we may associate with the fact that nicotine differs notably from the great majority of the alkaloids in that it contains no oxygen. Its empirical formula is $C_{10}H_{14}N_2$, and it is also noteworthy as being a liquid alkaloid. It occurs in the tobacco leaf in proportions varying between 2 and 8 per cent. The alkaloid is an oily, volatile, colourless liquid. Unlike most alkaloids, it is readily soluble in water. It resembles other alkaloids in being extremely soluble in alcohol and ether. It is a very powerful antiseptic. The alkaloid itself is one of the most horrible and potent of poisons.

Nicotine a Deadly Poison. A dose of nicotine will kill in a few minutes, even when taken by the mouth. The extreme rapidity of its action doubtless depends upon its volatility. It is probably poisonous to every kind of tissue, and it alters the hæmoglobin of the red blood corpuscles, as is proved by the modification which it causes in the spectrum of blood on which it has acted. In many respects nicotine contrasts very markedly with the typical action of the alkaloids of the natural order to which it belongs. It has extremely slight effects, if any, upon the chemistry of consciousness. This fact is of considerable interest in relation to the practice of smoking. Nicotine is never used in medicine, though before the discovery of the anæsthetic properties of ether, chloroform, and nitrous oxide, tobacco was occasionally used, so that, by poisoning the motor nerves, and relaxing the muscles, it would permit the surgeon to reduce a dislocation. Any smoker who remembers the early effects of tobacco poisoning will appreciate the superiority of modern anæsthetics over this alkaloid, which was of value simply because it made the patient miserably weak.

The Chemistry of Tobacco Smoking. Smokers often describe as nicotine the oily mess which is apt to accumulate in a pipe, and of which they sometimes get a mouthful. If this, or 1 per cent of it, consisted of nicotine, one such mouthful would end the smoker's career. As a matter of fact, nicotine is not merely oxidisable, as its physical characters and its formula would suggest, but is so at relatively low temperatures. The whole of the nicotine in the portion of tobacco that is undergoing combustion at any given moment is oxidised away. Probably, also, nearly the whole of the nicotine in the portion of tobacco that is immediately about to undergo combustion undergoes decomposition. It has therefore been asserted, in all probability much too hastily, that tobacco smoke contains no nicotine. If this were so, it would certainly be remarkable that the symptoms of poisoning by it so strikingly resemble those of poisoning by nicotine.

How Nicotine Enters the System. As a matter of fact, tobacco (smoke) *does* contain nicotine, which is volatilised from the tobacco that is so remote from the part undergoing combustion as not to undergo decomposition but is yet near enough to acquire an amount of heat that suffices to volatilise it. In this gaseous form, then, the alkaloid is taken in by the smoker. The portion of it in tobacco smoke is, of course, exceedingly small, as the possibility of smoking without fatal results proves, but it is nevertheless sufficient, the alkaloid being extremely potent, to cause very definite physiological effects. These vary considerably with varying conditions. As in the case of most other poisons, the body can acquire a relative immunity from its effects. Again, different individuals vary in their susceptibility to it, so that some can never smoke, while others cannot smoke a pipe, or can only smoke very mild tobacco in a pipe.

Inhaling Tobacco Smoke. Furthermore, the effects of the poison must obviously depend, other things being equal, on the actual quantity of it that enters the blood, and this depends upon the amount of absorbing surface which is exposed to the smoke. There is a very marked difference indeed between the amount of nicotine absorbed from the mouth and that absorbed by the lungs. This is the reason why the practice of inhaling the smoke of cigarettes is so extremely undesirable. Different tobaccos vary very widely indeed in the proportion of nicotine which they contain. There is exceedingly little in Turkish tobacco.

This fact alone shows how completely smokers —who really ought to have some acquaintance with the chemistry of the subject—are misled The nicotine in tobacco smoke determines its strength alone. It has no influence upon its flavour or aroma. These are mainly due to an essential oil. Any smoker will say that a Turkish or Egyptian cigarette is "stronger" than a Virginian cigarette, but, as a matter of fact, the former contains very much less nicotine—though it doubtless contains more of the essential oil, and of various other imperfectly investigated —not to say artificially added—compounds which may themselves have very marked properties.

We can merely note a few of the substances which are usually found in tobacco smoke; nearly all are constantly present. They are nicotine, hydrocyanic or prussic acid, sulphuretted hydrogen, nitrates, nitrites, carbolic acid, various compounds of ammonia, of sodium and of potassium, salts of acetic and other acids, creosote, sulphur, a volatile fatty acid, together with a considerable percentage of pyridin and several of its allies.

Smoking Should not Begin till 21. We desire to emphasise the definite fact that nicotine, not to mention various other substances found in tobacco smoke, is essentially, fundamentally, characteristically a poison. This statement holds good, and is not affected by the fact that, as in the case of arsenic and a hundred others, the adult organism is capable of acquiring an immunity from its action, and thereafter may obtain from it advantages of one kind and another. But if the reader will consider the question of growth in living things from the standpoint of chemistry, and will try to realise the exceptional and peculiar complexity and delicacy of the chemical processes which are involved in growth, and incomparably more so in *development*—which is an infinitely more subtle thing than increase in bulk—he will be prepared to accept the general proposition that, in the first place, the adjustment to the constant introduction of a poison, which is possible at a very small cost, for the relatively stable adult organism must involve far more serious modifications in the vital chemistry of the developing organism; in short, that a poison which may be tolerable for the man will be intolerable for the child, even if the dose be diminished in proportion to the ratio between their body weights. In naming the age at which the use of tobacco may be excused, most authorities are more or less influenced by the actual facts as to the age at which boys begin to smoke. The general proposition is that the use of such a substance should be begun, if at all, only after the developmental period has passed; and when Sir William Broadbent named the age of 21 as the minimum he was undoubtedly nearer the truth than those who—looking more upon the mere expediency of the matter—name such an age as sixteen. At any rate, it is a perfectly outrageous thing that irresponsible urchins of a dozen years should ever be permitted to injure themselves by the absorption of this poisonous alkaloid.

The Alkaloid of Hemlock. From the spotted hemlock, or *Conium maculatum* (Nat Ord. *Umbelliferæ*), there is obtained an alkaloid known as *conine*, which may be considered here, since, like nicotine, it is liquid, oily and volatile, and also since many of its physiological properties are similar to those of nicotine. Its empirical formula is $C_8H_{16}HN$. This body is of a yellowish colour, has an odour which is usually described as "mouse-like," and its taste suggests tobacco. It can be obtained readily from the fruit or the leaves of the hemlock by distillation with alkalies. Conine is extremely unstable, being readily decomposed, both by light and heat. Furthermore, the proportion of it present in the plant varies widely. Its methyl derivative, known as *methyl-conine*, also liquid, is found associated with it in the hemlock plant. All the preparations of hemlock prepared for medical purposes are to be condemned by a more advanced chemistry, since they are not standardised, and since the proportion of conine in them is quite inconstant. A classic and tragic interest attaches to the symptoms of poisoning by conine. An account of them, scarcely less precise and accurate than any that could be written to-day, when conine has been isolated from the plant and studied in detail, is to be found in the greatest of the dialogues of Plato, known as the *Phaedo*. At the end of this great dialogue there is described the death of Socrates, one of the supreme immortals of all ages, whom his Athenian fellow-citizens condemned to death by hemlock.

Strychnine. The plant known as the *Strychnos nux vomica* contains a remarkable alkaloid known as *strychnine*, which occurs in the nut to the extent of 0·2 to 0·6 per cent. In this country preparations of nux vomica are now standardised so as to contain precise quantities of strychnine. The alkaloid has the formula $C_{21}H_{22}N_2O_2$, and can be obtained in the form of small colourless crystals. It is remarkable as the bitterest of all known substances, being able to cause in the nerves of taste those chemical changes which lead to their stimulation, even in the dilution of one part in thirty thousand. It is extremely insoluble even in hot water, but is soluble to the extent of one part in six of chloroform. This dangerous alkaloid must never be prescribed with alkalies, iodides or bromides, for these precipitate it, so that, while the early doses taken from the bottle are of no value at all, the last may be fatal. Strychnine unites with hydrochloric acid in similar fashion to that of ammonia, yielding a fairly soluble salt, of which as much as one-fifteenth of a grain may be taken by an adult with safety. Allusion has already been made to the most important of the remarkable properties of this alkaloid. It constitutes, perhaps, the most appalling of poisons, since it has no action on consciousness whatever. The treatment of strychnine or nux vomica poisoning is an urgent matter. Any alkaloid that remains in the stomach may be precipitated by tannin or charcoal, or oxidised by permanganate of potassium. A large number of other antidotes have been tried, but there seems to be no doubt that the best hope for the patient lies in the administration of chloroform, which arrests the convulsions that would otherwise lead to the patient's agonised death from exhaustion.

Alkaloids of Aconite. We may briefly allude to the alkaloids contained in various kinds of aconite plant, since, though this drug has fallen into deserved disrepute in these days, its principal alkaloid, *aconitine*, is of interest as one of the most powerful of all poisons. It has the formula $C_{33}H_{43}NO_{12}$, and is accompanied in the plant by several other alkaloids which are closely allied to it. One of these is called *aconine*, and can be prepared artificially by heating aconitine in the presence of water, of which it takes up one molecule, then yielding aconine and benzoic acid. A plant belonging to this genus and known as the *aconitum ferox* contains an alkaloid, *pseudo-aconitine*, which is the most poisonous of all known substances. About one-three-hundredth part of a grain would probably kill a man. Apart from such curiosities the root of the aconite plant may be regarded as the most powerful of all non-volatile poisons.

Quinine. The last alkaloid which we need consider is the most valuable of all with the exception of morphine. It is contained, together with four other closely allied alkaloids, in the bark of the red cinchona—*Cinchona succirubra*. This beneficent plant grows in South America, and was wisely introduced into India many years ago by Sir Clements Markham.

The empirical formula of quinine is $C_{20}H_{24}N_2O_2$. It is found in the bark in the form of its hydrate. It can be obtained in the form of bitter, colourless, needle-shaped crystals, which rotate the plane of a ray of polarised light to the left. Solutions of the oxy-salts—not of the chloride, for instance—of quinine are fluorescent. (The meaning of both of these statements will be intelligible to the student of the course on Physics.) *Quinidine*, an isomer of quinine, also occurs in the cinchona. Its most important distinction from quinine is that it is dextro-rotatory. Two other alkaloids, differing only from these in containing one atom of oxygen instead of two in the molecule, are also found in the plant. Of this second pair of isomers one is dextro- and the other lævo-rotatory. Preparations of cinchona bark, now very rarely used, are standardised in this country as to their percentage of total alkaloids.

Quinine is used in the form of one or other of its salts. The salt chosen is almost invariably the sulphate, which, however, is soluble only to the extent of one part in eight hundred of water, and is quite insoluble in alkalies. From these considerations it follows that when this salt is administered the patient benefits only by such a small proportion of it as can be absorbed before the salt reaches the first part of the bowel, the reaction of the contents of which is invariably alkaline. The truth is that the sulphate is used perhaps more because it was the form in which quinine was first discovered, and so had a long start, than for any other reason. A salt vastly superior is the hydrochloride, which has one molecule of hydrochloric acid to each molecule of quinine; and still better is the acid hydrochloride, which has two molecules attached to each of the alkaloid. This last is soluble in less than its own weight of water.

Quinine and Vital Chemistry. Since quinine is the one known specific against malaria—the disease which causes more illness, though tuberculosis causes more deaths, than any other—its properties in relation to living matter are necessarily of the first interest. Needless to say, they have been studied with the utmost care, though even yet there is much to learn. We may say, however, that quinine appears to be one of those substances which in some degree or other directly interfere with the processes of vital chemistry. This is as good as to say that it is an antiseptic. Malaria is now known to be due to the presence in the blood of minute parasites, and the value of quinine depends upon the fact that it directly kills these organisms. Students of the problem of impregnating the blood with an antiseptic know how all but impossible this is to effect, except at the cost of life itself. We have already seen, in the case of carbolic acid, the typical antiseptic, that the acid is altered into an inert sulpho-carbolate, and can exist as an antiseptic in the blood only at the cost of life. Quinine, however, though by no means a powerful antiseptic, can exist in the blood as quinine. It is well worthy of note, as proving the fundamental identity of vital chemistry in various forms of life, that quinine paralyses not only the malaria parasite, but also the white cells of the blood. Doubtless many of these are killed by it, but fortunately the body can replace them, while the malaria parasites, when killed, cannot be replaced.

Quinine and Alcohol in the Body. One other point is well worth noting for its significance.

In the case of alcohol we saw that one and the same substance both arrests the movements of the white blood corpuscles, and interferes with the decomposition of the oxy-hæmoglobin of the red blood corpuscles. Now, the same is precisely true of quinine and of some other substances. We naturally seek, then, for some reason which will furnish an explanation of what would otherwise look like a curious coincidence. The suggestion which may be here made is one dependent upon a consideration of the causes of motion in living things. The student of physics and of the doctrine of the conservation of energy is well aware that a white blood cell, like a bullet or a star, cannot display energy of motion, or kinetic energy, except in virtue of the transformation of pre-existing energy. Now, the source of energy in the case of the white cell—and this is true of the whole or all but the whole of the energy displayed in any living thing whatever, whether an oak or a man or a microscopic cell in the man's blood—is the potential chemical energy which is liberated in the act of oxidation. Now, it would appear reasonable to infer that the reason why alcohol, quinine, and other substances which interfere with the reduction of oxy-hæmoglobin also interfere with the motion of the white cells is that these substances similarly interfere with the reduction of compounds comparable to oxy-hæmoglobin, which must be present in the white cell as in every living cell, and which are its storers of oxygen ; for the oxidation of protoplasm, as we saw long ago, is not only intracellular but even intra-molecular.

Quinine and Oxidation. Two further facts may be correlated with the theory which we have suggested. One is that the amount of uric acid excreted by the body after the administration of quinine is greatly diminished. Now, uric acid, as we have already seen, is an oxidation product of the particular kinds of proteids which are found in the nuclei of living cells, and are called *nucleo-proteids.* White blood cells practically consist of little more than nuclei, and are a most important source of uric acid, for when their numbers are greatly increased, as they are in certain diseases, the amount of uric acid excreted is also increased. Similarly, in this case we see that the amount of uric acid excreted is diminished when the amount of oxidation in the leucocyte is diminished.

The second fact is that quinine interferes with the process of oxidation in many other kinds of living matter, in addition, as we suspect, to white blood cells. The absorption of oxygen by various fungi is interfered with under the influence of quinine, and various lowly vegetable organisms which normally display phosphorescence—known to be due to rapid oxidation—cease to display this property when they are subjected to the action of quinine.

Why quinine should interfere with oxidation is as yet quite beyond the power of chemistry to say; but it is a step thereto to have included under this one proposition—interference with oxidation — so many and apparently diverse properties of this substance.

There are two important groups of compounds which are related to the alkaloids, but are, nevertheless, quite distinct from them. The first of these go by the name of *neutral principles.* They are not *alkaloids* because they are not basic, but neutral, and they are not *glucosides* because they do not yield glucose, but they are related to both these groups of substances, and many of them are extremely potent drugs. Typical of them is the body known as *aloin,* which is the active principle of *aloes,* the valuable purgative, and by selling which at a price a few hundred times too high to persons, all of whom are ignorant and to many of whom a shilling is a serious matter, most of the patent medicine manufacturers derive their monstrous incomes.

Glucosides. More important are the *glucosides.* They have long been known to be of the utmost interest because several members of this group are amongst the most potent of drugs. But we shall also see that quite recently—indeed, within the present year—a new interest has come to attach to the glucosides in general because of the part which they are believed to play in the body. Glucosides may be defined as complex organic substances which are compounds of glucose. Until quite recently they were supposed to be confined to plants. They are crystalline. When hydrolysed by various agencies, such as certain acids and alkalies, or by means of such a ferment as the emulsin found in the almond, they yield glucose and some other substance, most commonly an alcohol, an aldehyde, or a phenol. We have already alluded to an example of a glucoside in salicin. In this, and in all other cases, the name of the body must be spelt with a terminal *-in,* thus distinguishing it from the alkaloids, the names of which are marked by a final *e.*

The Most Valuable Heart Tonic. The glucoside *salicin,* though exceedingly valuable, is not often employed in medicine now, because sodium salicylate is more convenient. But it may be noted that the most valuable stimulants which are employed as favourable to the health of the heart are glucosides. The leaves of the common purple foxglove (*Digitalis purpurea*) have long been in use as by far the most valuable of all known heart tonics. Of recent years they have been very carefully studied, with results which significantly resemble those obtained in the case of many other plants—that is to say, the recognition of the presence within the plant of substances whose molecular construction is all but identical, but which, nevertheless, exercise upon the body properties diametrically opposed to one another. We have already striven to make it plain to the reader that there would be relatively little interest for us, as chemists, in the mere fact that molecules, slightly different, exercise different properties. This we should expect. The significant thing is that the properties are not merely different, but directly antagonistic, and this is found to occur again and again in the case both of alkaloids and of glucosides.

The Chemistry of the Foxglove. The leaf of the foxglove contains four glucosides, very closely allied; possibly there may be more. It contains no alkaloids whatever. Of these glucosides, one (which is identical with a glucoside found in other plants, such as the senega plant of the New World) is a powerful poison to the muscular tissue of the heart, and thus directly opposes the action of its neighbours and relatives. Obviously, then, as soon as it is possible to obtain the valuable glucoside without the worse than worthless one, the use of crude preparations of the leaves must be superseded.

The one serious rival of the foxglove as a heart tonic is the seed of the strophanthus plant, used as an arrow poison by the natives of West Africa. The cotyledons of the seed may actually contain as much as 50 per cent. of an extremely powerful glucoside called *strophanthin.* This extraordinary substance (the function of which in the plant is entirely unknown) has a unique chemical relation with the muscular tissue of the heart. This markedly differs from its relation to muscular tissue elsewhere, and is true alike of the heart of man, the highest of mammals, or of the heart of the frog, which is a mere amphibian.

A Remarkable Identity. The reader will ponder upon the necessary inference that there is a chemical identity in heart muscle wherever found. This glucoside, and the same is true of many other substances, proves that the chemical relationship between the heart muscle of a man and the heart muscle of a frog is actually nearer than that between the heart muscle of a man and the muscular tissue of the midriff or diaphragm on which that heart rests. To the best of the writer's knowledge the significance of these facts has never hitherto been insisted upon, but it is surely evident enough, once considered. A solution of one part of strophanthin in ten millions will so violently stimulate the muscular tissue of the heart of a frog as to arrest it in a state of continuous spasm.

New interest has lately been attached to the glucosides by experiments which seem to show that the glucose that is found in human blood, and that represents the form assumed, as the result of digestion, by all carbohydrates, does not exist in the blood as such but as a glucoside. The fact seems to be that uncombined glucose would be treated as a foreign body in the blood, and would promptly be removed from it. Existing as a glucoside, however, the glucose may remain, and when it is needed by the muscles, which find in it a source of the potential energy which they transform into work, the glucose can readily be obtained from the glucoside by means of hydrolysis, under the influence of one or other of the body ferments. We have already seen that plants contain ferments capable of effecting this decomposition.

Chemistry of Plants and Animals. Special interest attaches to these researches because they afford one more illustration of synthetic power within the animal body—the synthesis in this case being that involved in building up into a glucoside the glucose which the blood derives from the bowel. It used to be stated positively that the fundamental distinction between the chemistry of the plant and the chemistry of the animal is that synthesis—as in the making of proteids and carbohydrates—is peculiar to the plant alone. All the chemistry of the animal body, or practically all of it, was supposed to be analytic. The animal body could merely break down the compounds which had been built up by the plant. In general, this great distinction is undoubtedly true, and is absolutely fundamental to our conception of the chemical balance between the various kinds of living things.

But it is of great interest to know that there are not a few cases in which the animal body is capable of effecting synthesis for itself. A more accurate manner of expressing the distinction will have to be found, and perhaps we may find it here. The animal body may build up glucose into a glucoside for its own convenience; but, both in the case of the glucose and of the other compound with which the glucose is combined to form the glucoside, the animal body is first dependent upon the synthetic power of the plant.

"No Sun, no Shakespeare." Now, the plant is dependent upon nothing at all. The very elements suffice for it. On the other hand, whatever synthetic powers the animal body may yet be shown to possess, we may take it as certain that it is absolutely destitute of any power of building up compounds *from elements.* The blood of every animal contains a large proportion of elemental nitrogen, but nothing ever comes of it. The lungs of every civilised person contain large quantities of elemental carbon, but nothing ever comes of it. Elemental phosphorus may be administered to an animal, but though phosphorus is a necessary constituent of living matter, nothing ever comes of it. The necessary nucleo-proteids—containing phosphorus—of the animal cell, it owes one and all to the synthetic activity of the vegetable cell. The world of life is so wholly one that, in the natural order, we may say *No green leaf, no Goethe*; just as we may say, *No sun, no Shakespeare.*

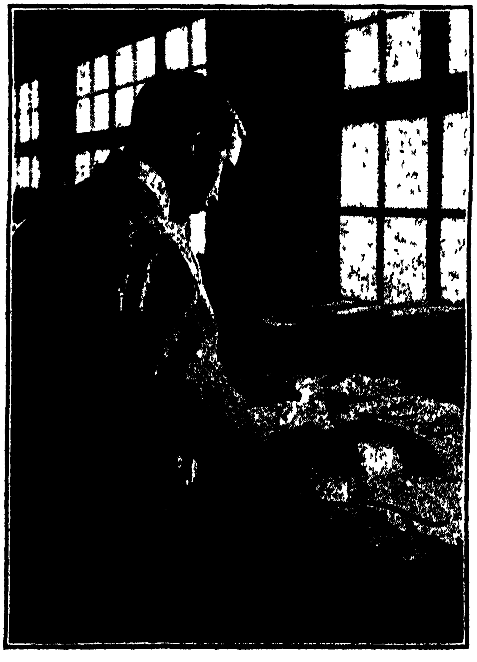
MAKING BOOTS AND SHOES

Measuring the Feet. Cutting, Skiving, Sewing, Stitching. Making the Thread. Machine Sewing. Buttoned and Elastic-sides Boots

BOOTS AND SHOES continued from page 3877

By W. S. MURPHY

BADLY FITTED boots are extremely annoying to the wearer, and sometimes dangerous. If the fashionable shape fits no human foot, the fault lies with the customer who chooses to wear—for the vanity of appearing fashionable—a boot that injures the foot. But let not the shoemaker whose customers complain lay that flattery to his mind too much; he, and not fashion, may be to blame. The first condition of comfortable boots is accurate measurement. Feet vary as much as individuals; you will never see two persons with feet exactly alike, and there are even differences between the right and left foot of the same person. In the ready-made trade we have got over the difficulty presented by these facts by a careful gradation of sizes and classes of boots, which shall be explained in due time; but every hand-made boot is formed for the foot of the customer by whom it is ordered. Actual measurement is the obvious way of arriving at the proper sizes of the boots to be made. Simple as the proposition appears, many shoemakers ignore it one way or another. To spare the customer trouble, the length of the foot and the height from heel to front of the instep are taken, and the rest worked out to a scale of averages. Both from a technical and a business point of view, this is a mistake. Customers like to feel that we are taking trouble with them, and doing our best to please. If it is done in a polite manner, additional bother gratifies a customer.



30. CLICKING, OR CUTTING OUT UPPERS

Outlines of the Feet. An outline of the soles of the customer's feet is very useful. To obtain this, lay a piece of paper on the floor, and ask the customer to stand on it. Carefully go round the foot with a pencil held perfectly upright, and trace its outline, marking the *positions* on this tracing where all the cross-measurements are taken. [See page 1330.]

The Measurer. The measurer should use two standards, the size-stick [29 H, page 3879] and the tape. A size-stick is a thick foot-rule with a fixed block at one end for the heel to rest against, and at the other end a sliding block that comes up to touch the toe of the foot. The stick is marked with inches, divided into sixteenths, and the boot sizes divided into halves. Let the two blocks gently enclose the foot from heel to toe, and mark down the number indicated.

Method of Measuring. The diagram on page 1330 illustrates the best method of taking measurements. On the foot itself we have three dimensions corresponding to the main features in its structure. The tape marked "joint" indicates the direction of measurement across the joint. In a properly formed foot the toes are not in line, and the tape must be slanted round the foot, and the exact angle registered on the tracing. The rule is to take the root joints of the large and small toes and to draw the tape neatly round. Mark down the number of inches and fractions. Put the tape round the foot at the instep, as shown on the diagram. This is meant to show the thickness of the foot round the centre of the instep arch. Mark that measurement down, and then shift the tape to the heel, or bend of the foot. The tape marked "ankle" shows the direction in which the measurement should lie.

Accuracy. It is of prime importance that this measure should be accurately taken. For button boots especially, the size from heel to front determines a great deal; if too slack or too tight at that point, the symmetry of the whole boot is lost. Discomfort can be avoided by simply sewing on the buttons according to the width required, or lacing the boot slackly; but though comfort is assured, the boot remains a botch. For men's boots, one "leg" measurement only is usually taken. The point of measurement is at the slenderest part of the leg, about 2 in. above the ankle-bone, as shown on the figure. Many men are rather careless about the tops of their boots, and bootmakers are apt to fall into the same moods as their customers. No well-dressed man wears boots slack at the ankle, and our object is to make our customers capable of being well-dressed. The trousers, like the grave, hide much bad work, but it is wrong to count on hiding anything.

Long Boots. Ladies are more particular about footwear than gentlemen, and the fair sex gives the shoemaker many a hard problem to solve. Every now and then the fashion brings in a form of long boot, reaching almost to the knee, or shorter perhaps, but still a long-legged boot. The shoemaker must take the height desired from the lips of the fair customer, and measure accordingly. In addition, the height from the heel to the top of the boot should be taken.

Notes. For his own guidance, and without showing it to the customer, the shoemaker should make a note of peculiarities in the feet. Very beautifully formed feet are round at the instep, and measure more than feet of a lower-class model, and apparently broader. In some feet the toes spread out, while in others they are close and compact, seeming almost cramped, but not really so We do not refer to defective feet at the moment, but simply to the actual differences among average healthy feet. Large joints of toes and ankles are very often a cause of trouble, and lowness of arch or instep produces frequent disputes with customers, the high instep being a coveted mark of breeding, according to a popular fallacy.

A Shoemaker's Duty. Defective feet, the number of which only the shoemaker knows, bring special problems of their own. Deformities are out of the question. What we mean are slight defects produced by long standing, over-exertion, tight, ill-fitting boots, and such like. A shoemaker is not a doctor, but he takes on himself, if he is wise, some care and thought for the comfort and health of his patrons. Towards those little failings in the pedal equipment of his customers the bootmaker has a duty, which may be summed up in the words, "hide, help, heal." Unfashionable shapes of boot, square toes, low heels, and other remedies are not recommended by wise bootmakers; if a man knows his business thoroughly he can hide, help, and heal those minor ills of the feet, and no one, not even the customer, be one bit the wiser.

Working at Boot Tops. For a good while the making of tops has been a special branch of the boot trade; but that, for the present, may be left out of view. The duty of the bootmaker is to learn how to make a boot.

Variations in Value of Boots. We have first to select our leather, and cut it. To the average outsider, the wide range of prices charged for boots must be somewhat puzzling, and it is here the mystery begins. In bootmaking by hand we have not the same wide range of quality as in the factory, because no one thinks of asking for a hand-made boot unless prepared to pay a fair price. You can buy boots in the retail shops at 7s. 6d. a pair, and that money would not pay for hand labour alone. Cheap boots are machine-made; but there is more in it than that. Some machine-made boots are priced as high as 25s., and may be seen in the same shop as the cheapest class. The reason for this may well be sought. The secret is partly in the leather, but not wholly. The difference in the cost of material used for the highest and lowest class of boot is not over 5s. or 6s., taken in the mass. That is to say, take pound for pound of leather, web for web of lining, mounting for mounting, and the difference is not so very great. But you will get more pairs of low-class boots out of a hide than you can get of a better class. The cutting-out proceeds on quite different principles. A first-class boot top has no side seams; it is one solid front. This means a large amount of waste in a hide. Even the most skilful cutter has to lay aside for inferior purposes, or fling into the waste bag, a large portion of costly hide. A seamless boot is an altogether finer foot-covering than one with three seams, but it has to be paid for.

Economic Facts. Another thing that has sometimes been questioned may be explained here. How is it that you can occasionally get boots with uppers of fine leather at factory prices? The answer is, that these boots are made from the scraps left over from high-class boots. The fronts of all boots are fairly large pieces of leather; but take the half of a back, and you will see how you could get any number of them out of pieces of leather otherwise useless. Bootmakers are not exempt from economic law any more than any other class of workers, and the public may depend upon it that where a higher price is openly charged a higher value is given.

Cutting. We have taken in hand a pair of good average strong boots, of medium class. The uppers are to be of one class of leather, with side seams, and therefore in three parts, quarters, golosh, and vamps or fronts, properly so-called. The fine grain leather is laid on the cutting-table, with the measures. Near the table are hung files of shapes cut out of strong paper. These are the model patterns for every conceivable size. You can get them to buy; but in the old days, every bootmaker built up his own stock of patterns, and the practice made good workmen. The patterns for the size measured are selected, and the figures of the measure compared with those on the patterns. The foot of the customer may be built on finer lines than the pattern, or it may be shorter and broader. In the former case the cutting has to be fined so as to make a higher top with less breadth; in the latter case, the ends of the fronts and backs are to be shortened, and the fore parts of the fronts broadened.

Practical Method. Having settled the leading points of size and shape, we now take the cutting knife in hand [20]. Lay the pattern of the fronts on the leather laid flat on the board, and draw the point of the knife round the edges, making a clear sketch for the path of the cut.

Then drive the knife steadily along the lines. Place the two fronts separate, so that you can keep the whole material of right and left boots together and without risk of mixing. The quarter, golosh, and vamps are cut, and then the linings and bindings are got. When you have piled together the makings of a pair of boots, the heap is of a size much larger than might be expected. A wise plan is to tie all the pieces of each top together and take out as required. Even though you are going to start to make the left upper next minute, it is right to place all the parts together, and see that they correspond. Many a member of the craft has had many bitter hours because he neglected that simple precaution, and landed in confusion.

Skiving, Sewing, and Stitching. The parts of the top have to be joined together, and it is desirable that the joints should be neat and smooth. A double thickness of leather at every joint would produce an ugly and uncomfortable boot. Obviously, the proper course is to thin the edges of the leather at the joints, and this is done by a process named skiving [31]. The skiving knife is a crescent of thin steel, with a sharp edge; but we have seen a good old workman doing it neatly on his lapboard with an ordinary cutting-knife. What is needed in the operation is steadiness of hand and a good eye, for the thinning must be graduated regularly all round and leave a clean edge on the front. Model skiving is about ⅛ in. broad, and true all round. Careful practice alone makes good skiving.

31. SKIVING, OR REDUCING THE EDGES OF THE UPPER PARTS

Stiffening. Before sewing the parts of the top together, we have to stiffen the backs; we have provided a good piece of leather for it, though some use linen. Carefully skiving the upper edges, we paste it firmly to the inside of the back, and leave to dry, preparatory to sewing.

Thread. Now we have to prepare our thread. Shoemakers are the last of the users of threads to retain the making of them in their own hands; tailors have surrendered their threads to the great manufacturers. Our thread is peculiar and special. It is composed of several strands of fine flax twisted and waxed into one. Take hold of the loose end of the ball of flax as it lies in its box, and draw out the length you can handle; double it back and draw out another skein of equal length, repeating till you have a thread of the thickness required—four-ply, five-ply, or six-ply. Cut off from the ball, and roll and twine the threads over your knee, and make a uniform cord.

Waxing the Thread. Left dry and free the threads would quickly separate, and wear out singly; unprotected from water and weather, they would rot. Wax is the binder and preservative. Holding the piece of wax in one hand, the sewer draws the thread through the wax, and soon clothes the length in a fine, brown, shiny coat.

Bristles. The hardened threads taper to a point, but we could hardly make speed in sewing with only those points for needles. From time immemorial the trade has used bristles for this purpose, and modern ingenuity has not been able to improve upon the device. The bristles are from 4 in. to 5 in. long, and very strong. They have been specially selected by the bristle merchants who import the bear bristles for the brushmakers. Every bristle has what is technically called a *flag*; but to the common eye it looks like a split. Our neighbours, the brushmakers, like the flag to be as small as possible, and might be pleased to be without it if Nature would oblige; but to a moderately-sized flag or split is useful. The thin section of the bristle can be made into a tie to twist on to the end of the thread, and the bristle secured without a knot.

Sewing. Tailors join the pieces of cloth about to be sewn with long stitches of white thread; but that is hardly practicable with leather. We fasten the pieces of the top together in a temporary way, by means of tacks. Let it be tacked together to see how it looks, and how the pieces form with each other. Having worked the top into shape, we can mark the lines where the sewing is to be, and pull out all the tacks excepting at the joints where the sewing has to be begun. Fix the parts in the boot clamp; bring it between the knees; pierce the two plies of leather with the fine awl; insert the bristle of the waxed thread, and draw it half way through. Sew the seam right up to the end, making small, even, regular stitches, pulling the thread tight at every stitch.

Machine Sewing. After the sewing-machine came into use, topmakers had frequent disputes with the bootmakers as to what seams might be stitched with the machine and what should be sewn by hand. The practical and honest solution of that question is very simple. At least it was simple in the early days, because the machine could not sew as strongly and surely as the hand; but improved machines have done away with the difference to almost a complete extent. It is a safe rule, however, to sew with the hand those seams on which the stress of wearing is put. Reliability is one of the chief qualities of the hand-sewn boot. In the class of boot we are making, the stitching of the machine must be confined to ornamental uses, and for tacking in the lining.

Ironing. When the whole top has been sewn, the seams require to be ironed down. Smoothing irons are little bars of steel, of various breadths, from ½ in. to 2 in., and these are heated cleanly at the gas, or in the gas stove, and applied to the seams one by one. Heavy pressure is needed, and you bear your weight on the top of the iron handle, and rub firmly to and fro till the seam is flat to the leather. With heavy seams the smoothing iron may be helped with a gentle tapping of the hammer.

Linings. Faulty lining is a frequent cause of trouble to both bootmaker and bootwearer. It may be too tight and draw the top out of shape, or it may be too slack and form wrinkles inside the boot. Besides selecting the best and most suitable materials and cutting accurately, we must pay close attention to the sewing and tacking of the linings. Chamois leather is the highest class of lining, but it is too warm for many people; fine split leathers are ready to cut and break; and the most sensible material for ordinary wearing boots is a strong twilled cotton, with leather bindings. It is a waste of time sewing linings by hand. The best plan is to paste them carefully together and pass them through the sewing machine.

Tongue. This piece of soft leather, shaped like the section of a truncated cone, is tacked on to the mouth of the boot by the sewing that holds upper and front together, with an additional tack to the inside of the upper, making it like a two-hinged door.

Mountings. Fancy boots have mountings of various kinds, such as toecaps of enamel leather, and other trimmings; but plain boots have only the eyelets and hooks or fasteners. Punch the holes in a regular row up the two fronts, half an inch from each edge, fully half an inch apart, with the hand punch. Put the eyelets in the holes and clench them on the inside. The operation is simple; but it may be done carelessly. The eyelets of hand-made boots are generally neater than those done by the machine, the eyelets in the latter being, as a rule, broken out at the inside by the force of the clenching.

In this state the top goes into the hands of the shoemaker, as we curiously term the man who puts in the soles. We leave the final finishing touches till the hard work of the welting, soling, and heeling is all done. But it would hardly be fair to pass on without mentioning some others of the boots we have to make.

Button Boots. Most of the button boots on the market are made in the factory. Essentially of light style and material, this class of boot lends itself specially to the sewing machine. All the same, a capable workman can make a better and more lasting button boot than any combination of machinery. The fronts and backs may be the same as above described, but the uppers are quite different. Though, to outward appearance, the addition of the buttoning flap and the buttonholes seem the sole novelty, the fact is not so. The uppers are made full, so that the side under the flap comes close up to the other side.

Flap. This gives unity to the front, and at the same time protects the foot from the sewn seam of the flap. No matter how fine a seam may be, the double thickness of the leather is felt, and to a sensitive foot the irritation of the hard ridge would be intolerable. When sewing on the flap, this should be kept studiously in mind. The head of the flap continues the line of the upper round the leg, and curves round above the ankle-bone.

Elastic Sides. At present this form of boot is greatly out of favour, but there is yet a good trade done in them about the North of England, and among well-to-do elderly people who stick to the fashions of their early days. While elastic sides were fashionable, the artistic faculty of the bootmaker was not allowed to sleep. Uppers and fronts were decorated in various styles and some of the designs were really pretty. A common style was the long upper, reaching down to the toe-joints, coming from above the ankle and covering the whole instep, joining a golosh or bottom formed of one solid piece and sewn up the back. The upper of fine kid, and the golosh of enamelled leather, made an attractive boot.

Parts of the Upper. Spread out on the cutting-table, the upper-front had the appearance of a flounder without the fins. In cutting the bottoms, regard has to be paid to the rise of the foot above the toes. The front is cut to come almost within touch of the ankle-bone, the whole breadth of the ankle being left open for the elastic insertion or gusset. Of course, the backs are insignificant, and mere bits of triangular leather, but it must be remembered that these small pieces support the gussets and largely determine the balance of the whole boot. Backs of elastic sides have to be well cut, firmly and evenly sewn on the bottom, and stiffened with care. Gussets are woven silk or fine cotton, the indiarubber enclosed in the fabric, slender elastic strings giving a good spring. Round the gusset space, the lining is left open, and the gusset, cut to size, is sewn in, either by machines or by hand.

A style of elastic-side favoured by many has the appearance of a top boot. The whole front of the top is one solid piece. The back, also one piece, is joined in a side-seam. The gusset is oblong, narrow and circular at the bottom.

HOW TO VENTILATE OUR ROOMS

Entrance and Exit of Fresh Air. Exclusion of Dust and Draught. Methods of Securing Effectual Ventilation in Dwellings. Artificial Aids

Continued from page 3802

By Dr. A. T. SCHOFIELD

IN an ordinary room there are three openings for air, besides what can enter through the walls; and these are the window, the chimney, and the door.

The Chimney. There is no doubt that the great safety valve of most rooms is the open chimney, which is of far more importance as an air-shaft than as an outlet for the smoke. Were it not for the English love for an open fireplace, and hence an open chimney, it is hard to say what would become of large numbers of the population. No chimney ought, therefore, to be stopped up; and, under ordinary circumstances, no room should be without one.

Ventilation really consists of a double process—the removal of foul air and the admission of fresh. Now, the chimney is principally of use for the former part of the work. Carbonic acid gas is very heavy, and with care can actually be poured from one glass into another. When it is expired, it is, of course, heated, and, being lighter than air, ascends to the ceiling. This is the time for getting it out of the room, and the best way is by an opening near the ceiling right into the chimney, with some simple valve (Arnott's) to prevent the smoke from coming out into the room. Without such a contrivance the carbonic acid gas cools and falls to the floor. This makes it very dangerous to sleep on the floor in close rooms without open chimneys. When CO_2 has thus fallen, the draught to the fireplace and up the chimney quickly carries it off.

The Window. The window is the second great means of ventilation. It ought, in the majority of rooms, to be so arranged as to be always open, by night as well as by day. It is impossible to overrate the beneficial advantages arising from this simple procedure.

No doubt considerable surprise is felt by some that no mention has been made of the escape of foul air by the window, and especially at the top. The window may be opened at the top as much as you like, but it cannot be too clearly understood that when so opened, as long as the air inside is warmer than that out of doors, the fresh air enters there, and the foul air does not go out. The window in this country is practically always an inlet—whether open top or bottom does not matter—and not an outlet. The chimney is *the* outlet. There should be, however, as we have shown, an inlet of 24 sq. in. for each person, and this can be made in various ways. One is by a simple window board about three inches deep, on which the lower sash shuts, so that while the bottom of the window is still closed there is an opening between the two sashes, admitting fresh air in an upward direction; or a board can be fixed across the front of the lower window-sill about six inches high, so that the lower sash can be raised behind it, and a double upward draught formed, the one between the two sashes, the other between the lower sash and this board in front.

Windows should always be open an inch or two at the top, and if at all large, a small pulley and a double cord should be fixed so as to pull the upper sash up and down easily without having to push and pull from the outside. The draught can be directed upwards in various other ways. The air can enter upwards behind a false cornice, so that when the window is apparently securely shut an opening is left above. An ordinary venetian blind serves somewhat the same purpose if partly let down. An ornamental glass screen, fixed on the lower sill so as not to rise with the window, is more ornamental than a board, and prevents any direct draught.

With these simple contrivances no draught is possible; and the cold air, directed upwards, falls in a gentle shower all over the room.

Tobin's tubes, already alluded to, are flat tubes against the wall, opening into the outer air below and into the room at about the level of the mouth, in an upward direction.

The Door. The third and worst way of ventilating a room is through the door. It is a capital saying, and should be enforced, that doors are made to shut and windows to open, and not vice versâ. If a room is already sufficiently ventilated, there will be no draught rushing in at the keyhole, as can be seen by the flame of a candle held there. If there is insufficient fresh air in the room, it will do its best to get in by the door, carrying with it, of course, all the smells, poison and sewer gas that may exist in any part of the house.

Ventilation is really self-acting. The poisoned air does its best to escape out of the room and the fresh air to enter, and if we do not absolutely prevent this by ignorance, these beautiful laws will work harmoniously and without effort.

Sitting-rooms and bed-rooms must not, of course, be overcrowded. Each person must be allowed *at least* 50 sq. ft. of flooring in a room 10 ft. high, and gas should never be used unless the rooms be very spacious; lamps and candles consume far less oxygen, and of course electric light is better still, but one single gas jet requires as much fresh air as five persons.

A great objection to free ventilation in towns is made by careful housewives on the ground of dirt. The matter is important, for there is no doubt that town air is laden with dirt of all sorts, and requires as careful filtering as water. This can be done effectually by muslin or perforated zinc stretched across the open window.

We have now pointed out some of the benefits of proper ventilation, but we have yet to mention one of its greatest advantages.

Catching Cold. Let us remember that the most fatal disease in England is consumption; then come bronchitis and inflammation of the lungs; and mark that one of the commonest ways these begin is by our "catching cold" on going from close, unventilated rooms into the open air, and that the surest general preventative we can adopt against these diseases is to have our rooms (and especially our bed-rooms) fresh and well ventilated. Sitting in close rooms with sandbags on the tightly closed windows, list round the doors and the register down in the chimney to avoid cold, only ensures catching it; while letting the foul air freely out and the fresh freely in is the surest safeguard against it.

We must look a little further still into one or two points before the subject is dismissed. Theoretically, the cold air should enter at the floor level and the hot foul air leave at the top. In good houses the latter is frequently carried out not only by valves at the top of the chimney breast, but by holes in the central ornamentation, in the ceiling especially, when there is any gas burning, so that the fumes and bad air can be carried off directly. But the admission of fresh air at the level of the floor is a different matter, and is found in practice to cause such cold feet that it is seldom admitted lower than three or four feet from the ground. In cold weather natural ventilation is even more difficult on account of the draught.

Of course, if the air be warmed all the difficulty is solved. The opening can be larger, the current slower, and the air changed more frequently; but, as yet, warmed fresh air, which is the key to successful ventilation in this country, is almost unknown.

How Wind Aids Ventilation. The wind is a great ventilator both by perflation, or wind blowing in, and by aspiration, or wind sucking out. In the Sylvester system there are two cowls, the one facing the wind and blowing fresh air into the chamber, and the other with its back to the wind and drawing the foul air out.

Over a chimney the wind generally aspirates, or draws the foul air out; at a window it generally perflates, or blows fresh air in. Wind can change the air of a room 100 times an hour. You can tell if your room is ventilated from the house or open air by placing a candle flame at the keyhole. If the flame be blown into the room, your ventilation is wrong.

Of course, windows should be inlets and chimneys outlets; but their rôles are sometimes reversed. If there be no fire and the chimney be very cold, air may come down it into the warm room, or if the chimney top be lower than others surrounding it, the wind may strike them and be deflected down it.

A fire, however small, is a great ventilator. It draws 15,000 ft. an hour up the chimney. Of course, fires ventilate the room best below the level of the mantelpiece. The colder the room, and the hotter the external air, the more need is there for the open window.

In addition to the openings described, there are Ellison's bricks and Sheringham valves communicating directly through the wall with the open air. In both, the external opening should be smaller than the internal, thus modifying any draught. The Sheringham valve often acts as outlet as well as inlet; and so, of course, in certain conditions may the window itself, though normally it is an inlet at both top and bottom.

The entrance of air through the walls, too, must not be forgotten; all depends, of course, on the difference of temperature between the internal and external air. A closed room with 34 degrees difference between the air inside and outside will change its air twice as fast through the walls as in a room with the window open and seven degrees of difference of temperature within and without. With a difference of only four degrees between the internal and external air, it will pass through a sandstone wall at the rate of 4 cubic ft. per hour per square yard; through a brick wall, 7 cubic ft; and through a mud wall, at the rate of 14 cubic ft.

Forced Ventilation. In artificial or forced ventilation there is extraction or propulsion of air by heat, steam, fans, etc. In mines there is a large fire at the bottom of the upcast shaft, or an exhaust fan at the top. A large hall often ventilates a house in the same way. In crowded meetings and churches some such system is needed. The earliest illustration of artificial ventilation is in a bee-hive, where the air in the middle is kept remarkably pure. It is said that at the entrance some twenty bees keep up a steady hum with their wings, which they flap without stopping in successive relays, and this forces fresh air in.

Schools must have warmed air and artificial ventilation on account of the small cubic space allowed, and the air is often changed without draught ten times instead of three times an hour.

Of course, at present all ventilation is a voluntary matter, for air is the only food that man is allowed to adulterate to any extent at will. There is no doubt that all efficient ventilation for the public must be self-acting, give no trouble, and require no care in adjustment. On the whole, a window a little open at the top with, if possible, something to direct the air upwards, and an open fireplace, are the simplest and best methods at present; but it is quite possible that ere long, in flats, a central furnace in the basement, kept up at a small cost, will be arranged to supply through pipes fresh warmed air to each one, so that the rooms can be perfectly ventilated in the coldest weather. Ventilation in sick-rooms is touched on in Home Nursing in the section on Ill-Health.

THE NATURE OF ELECTRICITY

Matter, Energy, Ether, and Electricity. The Electrons. Electromagnetic Theory of Light

Group 10
ELECTRICITY
28

Continued from page 3898

By Professor SILVANUS P. THOMPSON

Matter and Energy. Often as it has been said that we are profoundly ignorant of the nature of electricity itself, there is yet a great deal that we know about it, and the attempt must now be made to explain briefly what is known.

Not many years ago it was supposed that the only kinds of things of themselves in the physical Universe were two—*matter* and *energy*. Matter, that which possesses the fundamental properties of mass (and therefore is heavy) and of inertia, and which, though its atoms are of some 80 different kinds, called "elements" by the chemist, is subject to a law of conservation—we can neither create it nor destroy it. The quantity of matter in the Universe appears to be a fixed amount. Energy, that which, acting on matter, manifests itself in the various physical forces; the kinetic energy of moving bodies, by virtue of which they can perform work; the potential energy of systems; bodies that have had their configuration altered by doing work upon them; the energy of heat, which is a mode of internal motion of the molecules in the mass, in whatever kind. Energy is likewise subject to a law of conservation—we can neither create nor destroy it; but we can transform it from one species to another, and we can dissipate it into forms that are no longer available for doing work.

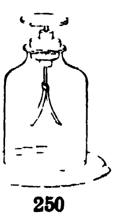
Early Theories regarding Electricity. At the time when the doctrines of energy were being developed, it was thought that electricity itself was merely another mode of motion or form of energy, just as heat is. Prior to that, electricity had been supposed to be a sort of imponderable fluid—a weightless gas; and magnetism had also been set down under similar categories. Both had been vaguely classed amongst the so-called "forces of Nature." But that term is unscientific, since the word force (unless qualified by some adjective, such as electromotive, to show that a non-mechanical effort is meant) in its precise signification is restricted to mean that which exerts either a mechanical push or a mechanical pull on matter. But electricity of itself is not a push or a pull on matter; it is therefore not a force, neither is magnetism. But just as matter can be acted upon by energy, and become the vehicle for the manifestations of energy, so electricity can also be acted upon and become the vehicle for the manifestations of energy. In this respect electricity itself resembles matter.

The Ether. There is, however, yet another thing-of-itself in the Universe, that mysterious medium which fills all space between the stars, and apparently permeates also through all solid bodies. It is called the luminiferous ether, because we cannot conceive of the waves of light coming to us from the sun or the stars unless they are waves of some medium that stretches throughout interstellar space. And because the speed of propagation of waves in any elastic medium depends only on the elasticity (stiffness) and density of that medium, and as the speed of light-waves is so enormous (186,000 miles per second), we know that the stiffness of the ether must be enormously great, for its density is marvellously small. It behaves in some respects like a jelly of extreme rigidity, yet of extreme tenuity also, being less dense than the very lightest gases. It used to be debated whether the ether were not a kind of matter, a sort of gas, lighter than hydrogen. It also appears to be subject to a law of conservation—we can neither create it nor destroy it. Moreover, like matter, it can act as the vehicle of energy. For light-waves are a form of energy, and they are conveyed by the ether.

The Electromagnetic Nature of Light. Wheatstone, in 1834, measured the velocity with which an electric impulse is propagated along a wire, and found it to be almost the same as the speed of light. This, and certain other relations between the electric units of measurement, caused Clerk-Maxwell, in 1864, to propound the theory that the waves of light are electromagnetic waves. He studied the laws of wave-motion as applied to electricity, and showed that they would account for many observed facts; for example, that glass and other transparent solids are non-conductors of electricity, and that the metals that possess electric conductivity are opaque to light. This theory was generally accepted by British physicists, who tested its truth in several ways; but on the Continent it was not accepted until 1888, when Hertz had shown how to set up electromagnetic waves by the sudden oscillatory discharge of condensers, as explained on page 3898. An electromagnetic wave is one in which there are electric displacements, which are propagated in space from one point to another, accompanied by magnetic displacements at right-angles to them. The main difference between them and ordinary light-waves is in their size, for the waves of visible light are very minute, from 15 to 30 millionths of an inch in length, while the Hertz waves may be from about half an inch up to several hundred feet in length.

This identity of species between light-waves and Hertz waves leads to the question whether the ether is itself of an electrical nature, since what the older physicists regarded as waves of actual motion in the ether are explainable as electromagnetic waves.

Dual Aspect of Electricity. From a very early date it was recognised that when electrification was produced, by friction or otherwise, there were two kinds produced—a *vitreous* charge and a *resinous* charge. The former was obtained on the surface of glass by rubbing it with silk ; the latter on resin or sealing-wax by rubbing it with flannel or fur. A charge of either of these kinds will attract bits of paper, or straw, or a feather, or other light thing. But each kind apparently repels itself. Thus, if a rubbed glass rod is hung up in a silk stirrup, and another rubbed glass rod is held near it, the suspended one is repelled. On the other hand, the two opposite kinds attract one another. Simple experiments about these relations are readily performed with the aid of a gold-leaf electroscope [**250**], which consists of two narrow strips of thinnest gold-leaf mounted on a brass stem, which is supported by being fixed in a glass tube which passes through a cork of paraffin wax in the top of a glass jar. It is usual to fix a brass plate on the top of the electroscope. Suppose the end of a warm glass tube to be rubbed on silk, and that the tube be then made to touch the plate. The two gold leaves immediately open out as though they repelled one another ; and when the glass rod is removed they will still remain slightly divergent, because part of the charge from the glass remains in the instrument. When once so charged, the difference between the two kinds of charge is readily observed, as follows. If the rubbed glass rod be again brought near without touching, the gold leaves are seen to open out more widely ; but if a rubbed stick of sealing-wax or other resinous body be brought near, the leaves are seen to close up toward one another. If the gold-leaf electroscope be dry and clean, so that the metal part is really well insulated, it will keep its charge for several hours, or even days.



250

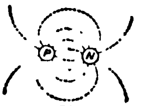
Positive and Negative. To account for these facts several theories were advanced. It was thought that there were two kinds of electricity, the vitreous being called *positive electricity* and the resinous *negative electricity.* It was, however, observed that when two things were rubbed together, if one became positive, the other always became negative ; also, that the amounts of the charges so produced were always equal to one another, so that if allowed to discharge into one another they re-combined and neutralised one another. This led to a tentative theory of the two fluids which could not be separated without doing some work to part them asunder. The two-fluid hypothesis in turn gave way to Franklin's one-fluid theory, according to which, though electricity itself was regarded as a single fluid, distributed everywhere, but neutral in its properties, whenever work was done by moving it, so as to produce a surplus at one place and leave a deficit at another, the surplus and deficit at once showed those properties of attraction that had first led to the discovery of the existence of electricity. The one doubt at the time was whether the vitreous or the resinous state was the surplus. Franklin concluded that the vitreous state was the surplus, and therefore called it *positive.* If the one-fluid theory be true at all, the resinous or negative state is, however, most probably the surplus. The main reason for this assertion is that a resinous charge is more readily dissipated than a vitreous of equal amount. According to the two-fluid theory, a current is a double flow of positive electricity one way, and of negative electricity the other way, along the wire. According to the Franklinian theory, the current flows only from positive to negative. The more probable theory is that if electricity is a fluid at all, the current consists of a flow of resinous electricity in the direction from negative to positive. It is certain that in electrolysis there are two sets of *ions*—that is, electrically-charged atoms—which are propelled by the action of the current in opposite directions, the anions (such as chlorine and oxygen) moving from negative to positive, or up-stream ; the kathions (such as hydrogen and the metals) moving from positive to negative, or down-stream.

Atomic Nature of Electricity. There is as much reason to regard electricity as atomic as to regard matter as atomic—that is, Nature appears to have ordained that electricity, whatever it is, exists in certain definite very minute quantities of the same magnitude, each of which cannot be subdivided into any smaller quantities. This is, indeed, an inevitable inference from Faraday's discovery of the laws of electrolysis. Thus, when hydrochloric acid, the molecules of which consist of an atom of hydrogen combined with an atom of chlorine, is electrolysed, each molecule splits up into two *ions*—namely, a hydrogen ion, consisting of a hydrogen atom charged with a positive atomic charge of electricity, and a chlorine ion, consisting of a chlorine atom carrying a negative atomic charge of electricity. Now, the electrochemical equivalents of the elements are known. To dissociate one gramme of hydrogen from chlorine requires 96,600 coulombs of electricity to be passed through the electrolyte. The physicist has further concluded, from various other experiments, that 1 gramme of hydrogen contains no less than 10^{25} (that is 10 quadrillions) of atoms. It follows that each atom of hydrogen carries a positive charge of $9{\cdot}66 \times 10^{-21}$ of a coulomb ; and each atom of chlorine an equal negative charge.

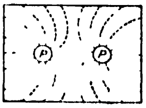
Electrons. This natural unit or atomic quantity of electricity has been called an *electron.* An ion is, therefore, an atom of matter combined or associated with an electron. Some atoms are, as the chemists say, divalent, and carry two electrons ; thus, the oxygen atom carries two negative electrons, and the zinc atom carries two positive electrons. When one atom of oxygen carrying two negative electrons combines with two atoms of hydrogen, each carrying one positive electron, there is produced one molecule of water. The electrons then are known to us as associated with matter. It is certain for quite other reasons that negative electrons can exist by themselves. It is not so certain that a positive electron can exist by itself. Indeed, one view is that there are no positive electrons; that a positive ion consists not of an atom of matter plus a positive electron, but of an atom of matter that has got one negative electron too few associated with it. According to this view, we can account for the production of electrification by friction as follows. When we rub two things together, if they are of different materials, one will part with its electrons more readily than the other, so that when we rub one surface over the other, and part them, one will lose some of its electrons and the other will gain them. Thus, if we rub celluloid with flannel, the flannel loses some of its (negative) electrons and becomes positive, while the celluloid gains the (negative) electrons and becomes negative. If two pieces of the same substance be rubbed together the gains and losses on each piece are, on the average, alike, and no electrification of either piece is observed. But this is no longer true if the two pieces are not in similar condition. Thus, rough glass becomes negative if rubbed on smooth glass; and non-conducting substances when hot generally become positive if rubbed on a cold piece of the same substance.

Electric Stresses. If we rub glass on silk there is no sign of electrification shown until we separate them one from the other, when we find the surface of the glass is positive and that of the silk negative. Now, since a positive and a negative charge attract one another, it is obvious that we cannot draw them asunder without expending some energy in the act. Where does this energy go to? It certainly remains in the "system"—meaning by that term the two charged bodies and the medium between them—for it can be given back as work done when the two charged bodies run together again. The case is analogous to that of two bullets tied together by a short spiral spring or a piece of elastic indiarubber. When we separate them they apparently attract one another back; but the energy given to them in pulling them apart resides not in the bullets, but in the strained medium that connects them. A closer analogy is afforded by the mutual attraction between two magnet poles of opposite kinds, one north, one south. Now, in that case, as explained on page 560, we can follow up these actions, and can show that the magnetic stresses follow certain curved lines through the medium. In a precisely similar way it is possible to explore experimentally the space between two electrified bodies.

Lines or Tubes of Electric Force. If we place a dry glass plate on a non-conducting table, and bring to touch it at two points two wires which are kept highly electrified by a suitable source, and then sprinkle between them certain powders, such as warm powdered tourmaline or crystallised quinine powder, we find that the powder arranges itself in more or less defined lines, just as iron filings do in a magnetic field. Fig. 251 gives diagrammatically the curves of the electric lines in an electric field of force between a positive body, P, and a negative body, N. The whole intervening part of the medium is, in fact, in a state of stress, as revealed by these curves. Along the lines there is a tension; transverse to them there is a pressure; with the result that these stresses in the medium tend to urge the two charges toward one another. But, considered from the electron point of view, each "charge" consists of electrons, as many positive electrons on one as negative on the other, if the charges be equal. The stresses then in the medium may be mapped out as curving lines—or, rather, as tubes—each of which terminates at one end at a positive electron, at the other end on a negative electron. Two similarly electrified bodies repel one another; or, rather, the stresses tend to urge them apart. Fig. 252 shows the tubes of electric force in the neighbourhood of two positively-charged bodies. In this case the tubes have each one end on one of the positive charges, and their other end on the negative charge on the walls or other surrounding or neighbouring conductor. Every atom, at any rate under ordinary conditions, has an electron associated with it, and therefore has an electric "tube" proceeding from it.



251



252

Electrons and Conduction. While in a non-conductor or dielectric medium, such as air or glass, we can have a permanent state of electric stress between two charges, this is not so in conductors; for if we impart to any part of a conductor a charge, that charge instantly spreads through the metal. When the whole conductor has come to the same potential the flow ceases. Apparently, then, electrons can move freely through the metals. According to this view, when we join a battery to a loop of wire positive electrons rush in at one end and negative at the other, and the tubes which extend across the space from a positive to a corresponding negative electron must rush along with the electrons, and finally collapse into the wire as the electrons meet. In the case of a telegraph wire stretched over the earth and connected down to earth at the distant point, the current, on this view, will consist of the two electrifications travelling along in company from the battery and toward the distant end, one travelling along the wire, the other travelling on the earth, with "tubes" stretching between them and also travelling along. The tubes which thus connect the positive and negative electrons sweep through the dielectric; and the energy path thus lies, not in the conductor, but in the intervening or surrounding medium.

NOTE. In the diagram on page 3088, instead of *charge* read *discharge*, and instead of *discharge* read *charge*.

WATER SUPPLY

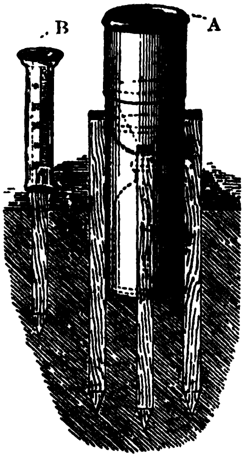
Rainfall and its Measurements. Sources of Public Water Supply. Types of Wells. Storage and Impounding Reservoirs

By Professor HENRY ROBINSON

PRELIMINARY to a study of the great subject of Water Supply we must make ourselves familiar with the approved methods of estimating rainfall. Evaporation from the sea and the surfaces of land causes air to become laden with water vapour. On cooling, the water vapour condenses and forms mists and clouds. Excessive condensation leads to rain. Variations of temperature and barometric pressure alter the capacity of the air for retaining water vapour and mists. Rainfall is measured and recorded in terms of the depth of water that would be caused if it were collected on a flat area, and assuming that no water could run on to it from an adjacent area, and no evaporation take place.

The late Mr. G. J. Symons may aptly be described as the pioneer of meteorology as far as rainfall is concerned. He was the originator of the British Rainfall Organisation, now carried on by Dr. Hugh Robert Mill, at the Camden Town Station in London. The records are published in a book called "British Rainfall," and deal with about 4,000 returns.

The mean annual rainfall in England varies from about 20 inches to about 160 inches—the latter in the Lake District. This, however, is far exceeded in places abroad, as, for instance, in Chena Pungi, in Assam, where, in 1861, the rainfall was 805 inches, of which 366 inches fell in July. The mean annual rainfall there is 559 inches.



1. SNOWDON RAIN GAUGE

Rain-gauges. The amount of rainfall is ascertained by rain-gauges, the most common being the Snowdon [1]. This consists of a brass cylinder, A, which is sunk into the ground, leaving the lip about one foot above the surface. Inside this is a funnel, which collects the rain and leads it into a bottle resting on the bottom of the cylinder, the amount being measured daily by means of the graduated glass, B. The bottle holds about three inches of rain. If the rainfall exceeds this the excess is collected in the inner can.

Various forms of self-recording rain-gauges have been invented, one of which is Negretti & Zambra's [2]. The rain enters a collecting funnel, A, and runs into a tilting-bucket, B, divided into two equal parts, tipping over when ·01 inch of rain has fallen. This advances an escapement wheel one tooth, and by means of a perfect helix attached to this wheel, the long lever carrying a pen, as shown, is raised until an inch of rain has fallen. When this point is reached, the lever falls to the other end of the helix, and the recording pen runs back to zero, and begins to record a second inch. The recording drum is worked by clockwork, the chart being divided into ·05 inch, and lasting a week. The escapement wheel is also divided into ·01 inch of rainfall.

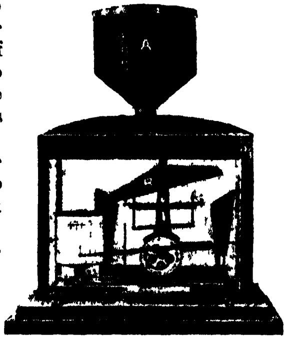
A later pattern of the machine is the Electrical Self-Recording Rain-gauge, which is very similar to the above, and another gauge is Richard's Self-Recording Rain-gauge [3]. In the latter a funnel leads the rain into a tilting bucket divided into two equal parts. One of these compartments being under the funnel, when rain falls the balance descends, a writing pen recording this motion on the revolving drum. The tipping of the first compartment causes the second to place itself under the funnel. The filling and emptying of each compartment are alternately and automatically produced, and to each of these double operations corresponds a rise and a fall of the writing pen.

In Halliwell's Standard Self-Recording Rain-gauge, the rain from a receiver passes through a wide pipe to a cylinder, in which is a float, bearing a vertical rod, that raises or lowers a sliding pen arrangement. As the water accumulates, the float and pen rise, the latter recording continuously the rate of rainfall. Shortly before the pen arrives at the top of the chart, the cylinder is emptied by a syphon arrangement, the pen returning to zero and starting registering again.

The diameter of a rain-gauge should never be less than five inches. The late Mr. Symons experimented with gauges from one inch diameter up to six feet square, and found them all agree within 5 per cent., and (excluding the very large ones, which cause an excessive deposit of dew) the differences are generally within 2 per cent. Rain-gauges placed high above the ground collect less rain owing to the high velocity of the wind causing an eddy over the opening, an instance of this being a gauge which collected 12 inches on one of the towers of Westminster Abbey, 18 inches on a roof close by, and 23 inches on the ground.

Rules for Rain-gauging. It will be helpful to give the following abbreviated list of the rules issued by Dr. Hugh Robert Mill for the use of the observers all over the country who are taking records for him.

SELECTION OF SITE.—A rain-gauge should be placed on a level piece of ground, and clear of all objects higher than itself. If an open site cannot be obtained, the exposure to the south-west and north-east should always be free. The height above sea-level should be determined.



2. NEGRETTI & ZAMBRA'S RAIN GAUGE

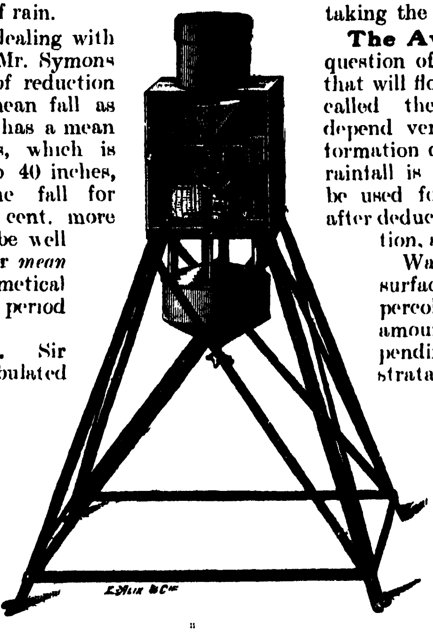
MOUNTAIN AND MOORLAND SITES.—Gauges should not be unduly exposed to the sweep of the wind. A turf wall about two feet high, surrounding the gauge at from 6 to 10 feet distant, is recommended.

PLACING THE GAUGE.—The gauge should be firmly fixed so as to prevent tilting, and should be surrounded with short grass.

HEIGHT ABOVE GROUND.—The funnel should be set exactly level and one foot above ground, but never more than 1 ft. 6 in.

SMALL AMOUNTS.—If the gauge contains less than ·01 of an inch, but more than half that amount, it is entered as ·01. If less, it is not counted.

SNOW.—To measure snow in a Snowdon gauge all that is necessary is to melt the snow in the funnel in front of a fire and measure the resulting water. To estimate by depth, take the average depth over a considerable area, when one-twelfth is the equivalent amount of rain.



3. RICHARD'S RAIN GAUGE

Mean Rainfall. In dealing with rainfall records, the late Mr. Symons established the method of reduction to a percentage of the mean fall as follows. Suppose a place has a mean annual fall of 30 inches, which is increased for one year to 40 inches, 40 ÷ 30 = 1·33, or the fall for that year was 33⅓ per cent. more than the mean. It may be well to explain that by *mean* or *mean fall* is meant the arithmetical average fall of any whole period or record.

Rainfall Data. Sir Alexander Binnie has tabulated statistics [see table on next page] to show the probable maximum error in an estimate of mean annual rainfall (taken from a large number of records all over the world) for periods of from one to thirty-five years.

The Mean Annual Rainfall. Thus, if records are available over a period of ten years, the error in estimating the mean annual rainfall is not likely to exceed 8·22 per cent.

Engineers generally agree that the three driest years would yield one-sixth less than the mean. The late Mr. Symons, after careful investigation, made it one-fifth or 80 per cent. of the mean. For the British Isles Dr. Mill anticipated that the wettest year would exceed the average by 43 per cent., and that the driest would fall below it by 29 per cent. Sir Alexander Binnie made these figures 45 per cent. and 24 per cent. respectively.

Gauging for Waterworks. When, however, an engineer has to deal with watersheds for waterworks purposes, where the area is limited, more accurate information than the above is required, and the question of the flow off the area for very much shorter periods must be taken into consideration on account of the fact that the rainfall relied on for filling storage reservoirs falls chiefly in the winter months. This being the case, it is obvious that the season of the year plays a very important part, and, together with the falls over short periods, requires careful study. Also a greater number of gauges are necessary in order to get accuracy, as it has been found that in small areas gauges placed in different positions in a valley gave quite different results.

The rate at which rain falls and flows off the ground is a point which should always be kept in mind when taking rainfall figures into consideration, as this affects the question of waste weirs for reservoirs, and does not appear when taking the average of a whole year.

The Available Rainfall. The question of the amount of the rainfall that will flow off a catchment area—called the *available rainfall*—will depend very largely on the geological formation of that area. The available rainfall is that quantity which could be used for water supply purposes after deducting the loss due to evaporation, absorption, and percolation.

Water, after falling on the surface of the ground, tends to percolate into the soil, the amount of this percolation depending on the character of the strata, or its capacity to absorb moisture, and on the natural slope of the ground. The greater the slope the larger the quantity that will run off to feed the watercourses to which all surface water ultimately arrives. The rain passes through the soil for a certain depth until it comes to the natural surface of saturation; from thence it will follow the line of underground flow, this line depending on the resistance of the strata The percolation may be permanent, in which case it is entirely lost as far as that particular watershed area is concerned, or it may be temporary, when it will sink below, and, after travelling underground, will issue in the form of springs at a lower level, and join

Period of records—in years.	Percentage of deviation of the mean annual rainfall of the period from the true mean annual rainfall.	
	Above	Below
	Per cent.	Per cent.
1	51	40
2	35	31
3	27	25
5	14·93	14·93
10	8·22	8·22
15	4·75	4·75
20	3·24	3·24
25	2·75	2·75
30	2·26	2·26
35	1·78	1·78

the same stream that is fed from the surface water. An illustration of this occurred in a case in which the writer was engaged, where a fault in the strata compelled the water to issue in the form of a spring about half a mile below where it had been intended to place a dam for impounding purposes, whereby only about half the estimated available rainfall would have been available.

The most accurate way to arrive at the available quantity is to gauge the stream, and then, by directly comparing the quantity flowing with the quantity that has fallen and been collected in rain gauges, the amount of the loss by the before-mentioned causes can be estimated. Some close approximation can be made to the amount by a comparatively short period of gauging, if a long record of rainfall gaugings be available; but it must always be borne in mind that the heavy falls over short periods are more important than averages for this purpose, and also that the condition of the ground when the rainfall takes place, whether after a drought or not, materially affects the percolation.

Percolation. The question of percolation has received considerable attention at different times, and experiments have been made with what are called *percolation gauges* to see the results with various soils. Percolation at one period may have an influence on springs for months.

A wet winter will give abundant springs in the following autumn, but if that be followed by a dry winter the latter will obliterate the effect of the previous wet winter.

In summer there is no percolation as a rule. The records from percolating gauges are usually divided up in half-yearly periods of summer and winter. The figures given in the table in next column for percolating gauges were given in "British Rainfall."

An examination of these figures shows that the percolation varies considerably with the two sets of gauges, indicating that percolation gauges do not give so reliable results as river gaugings, which afford the data required by engineers, and are far more useful, although more difficult to observe.

Absorption. If the watershed be hilly and the surface only slightly absorbent, there is the minimum absorption, and, the area having a sloping surface, the rainfall passes to the streams with the least evaporation. If the area be flat, with a pervious soil, the bulk of the rainfall passes underground. If the soil be clayey instead of absorbent, the maximum loss by evaporation takes place. If the surface of the gathering ground be wooded, it affects the amount lost by evaporation, and the rate at which the rainfall passes off to the streams, as large quantities are retained by the trees which shelter the surface from the sun's rays. If such an area were cleared of timber, the rainfall would pass more rapidly to the streams. In Humboldt's "Cosmos" the author describes an interesting case bearing on this, of the effect of clearing forests in one of the countries that he visited.

Evaporation. The evaporation in this country is generally taken at between 12 and 16 inches. At Nagpur, in India, the evaporation was found to be 4 feet in 272 days of dry weather, while from the large reservoirs supplying Manchester it has been found to reach one-tenth of an inch per day in times of drought. The following are some figures on evaporation from open reservoirs in America:

At Ogdensburg (New York)	49·4"	per annum
„ Syracuse (U.S.A.)	50·2"	„
„ Salem „	56·0"	„
„ Cambridge „	56·0"	„

Dew Ponds. Under certain conditions evaporation ceases, and water is condensed on the surface of reservoirs. On Salisbury Plain, and other elevated districts on the chalk formation, small ponds called "dew ponds" are constructed on the tops of the hills where little or no surface water can run into them, yet a small supply of water is obtained, owing to the very heavy dew arising from the condensation of the vapour which is evaporated from the surface of the chalk.

AT APSLEY MILLS, HEMEL HEMPSTEAD.

	Summer	Winter.	Year.
Rain	12·55"	13·51"	26·06"
Percolation (3 ft. sand). .	3·91	12·55	16·46
Evaporation	8·64	0·96	9·60
3'-3" of chalk Percolation .	1·83	10·42	12·25
Evaporation	10·72	3·09	13·81
3'-3" of earth Percolation .	1·54	11·21	12·75
Evaporation	11·01	2·30	13·31

The Nash Mills gauges gave as follows:

3 ft. of chalk Percolation. .	10·65
Evaporation	17·19
Rainfall	27·84
3 ft. of earth Percolation . .	6·52
Evaporation	21·32
Rainfall	27·84

In all schemes for the utilisation of the rainfall it is necessary to take into consideration the periods of drought; and in estimating the yield from a gathering ground the quantity to be relied on is based on the available rainfall over the three consecutive driest years. The term *drought* can be regarded only as a relative term. The late Mr. Symons has suggested these definitions:

ABSOLUTE DROUGHTS.—Periods of 14 or more consecutive days absolutely without rain.

PARTIAL DROUGHTS.—Periods of 28 or more consecutive days in which the total rainfall does not exceed 0·25 in.

LONG DROUGHTS.—Periods of not less than 60 days with a total rainfall of less than 2 in.

Storage. The yield from gathering grounds in times of drought is of extreme importance, as the question of providing storage directly depends on it.

Some engineers provide storage for 200 to 250 days' supply, and rely on one-third or one-fourth of a cubic foot per second during the drought from each 1,000 acres of gathering ground.

The following formula for finding the number of days' drought to be provided for was employed by the late Mr. T. Hawksley:

$$\text{Number of days drought} = \sqrt[8]{\frac{500}{\text{available rainfall of 3 dry years.}}}$$

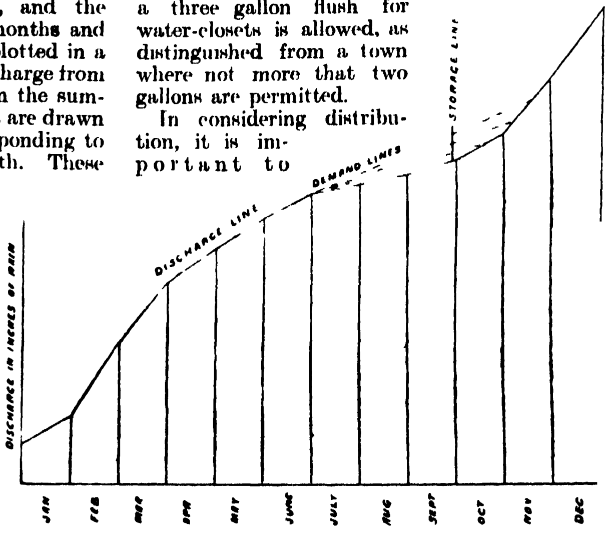
The relation between the size of the gathering ground and the amount of storage required is one of the first considerations. If the demand is small compared with the average yield of the gathering ground, the amount of storage may be small, or nothing at all. The exact amount of storage that is required to maintain a certain supply from any river can be best determined graphically, if gaugings are available throughout the period of greatest drought. Fig. 4 shows how this can be done.

The vertical scale represents the discharge of the river expressed (preferably) in inches of rain over the whole gathering ground, and the horizontal scale represents time in months and years. The results of gaugings are plotted in a cumulative line, showing the total discharge from the beginning up to any date. From the summits of the *discharge line* straight lines are drawn (dotted in diagram) at a slope corresponding to the demand in inches of rain per month. These *demand lines* will bridge over the depressions (representing droughts) and cut the discharge line again if it rises rapidly enough after a drought. The greatest vertical distance between the discharge line and the demand line gives the exact measure of the storage capacity that is required to meet the demand throughout the drought in question. If the demand line is on the same, or on a flatter slope than the flattest part of the discharge line, no storage is necessary. If a second diagram is plotted with a vertical scale representing inches of storage required, and a horizontal scale representing inches of demand per annum, a curved line can be drawn, giving the storage required for any rate of demand.

Water Supply in Towns. The amount of water required for the supply of a town depends on several considerations, one important factor being the extent to which it is wanted for manufacturing or trade purposes. For ordinary domestic use about 10 gallons per head per day will suffice provided there be no avoidable waste. Provision has to be made for gardens, stables, manufactories, public baths and washhouses, street watering, sewer flushing, fire extinction, etc. For these requirements another 10 gallons per head per day has to be provided. Where the town does not require water for trade purposes, 25 gallons per head per day should be a safe calculation. The following data may be given to illustrate this. Bristol has a consumption of about 22 gallons per head per day, which is ample, whereas Glasgow has about 50 gallons per head per day, of which 19 gallons are for trade purposes, the remaining 31 gallons being for domestic supply and for public purposes. The Glasgow water being soft (having only one degree of hardness), the minimum of soap and the maximum of water are used, while the charge for water for non-domestic purposes is only 4d. per 1,000 gallons.

At Bristol, on the other hand, the water has 22 degrees of hardness, which means much soap and little water for washing purposes, and the cost for non-domestic water is from 6d. to 1s. 6d. per 1,000 gallons. Residential cities like London, Edinburgh, and Dublin take about 33 gallons per head in the first-named to 38 gallons in the other two. Of the manufacturing towns, Liverpool takes about 30 gallons, Manchester 28 gallons, Belfast 35 gallons, Dundee 48 gallons, and Aberdeen 43 gallons. The consumption for domestic purposes is increased in a town where a three gallon flush for water-closets is allowed, as distinguished from a town where not more that two gallons are permitted.

In considering distribution, it is important to



4. DIAGRAM SHOWING PERIODS OF DROUGHT

remember that the consumption of water is not uniform throughout the day, as great fluctuations occur at different hours of the day and at different times of the year.

Sources of Water Supply. An urban or rural district having to be supplied with water, the first thing to consider is the possible sources, having regard to the quantity required and the cost of the works involved. These can be defined as consisting of either gravitation or pumping works, the former enabling the water to be collected from surface sources (such as streams receiving the rainfall flowing off what are known as *gathering grounds, catchment areas*, or *watersheds*), the last mentioned including water raised by pumps from a stream to a reservoir at a higher level, or water raised from an underground source to a similar storage reservoir, or to a water tower enabling the necessary head or pressure to be obtained in the distributing pipes throughout the area of supply to reach the highest buildings.

Underground Sources. If the water from an underground source has to be utilised by sinking a well, it must be remembered that the lowest water-level in a deep well in this country usually occurs in the autumn, and the most rapid rise occurs in February. In selecting the spot for sinking a well, it is necessary to examine carefully the surrounding district, and to form a clear idea of the physical and geological conditions, so that the well may be sunk at a point where the dip of the strata which are water-bearing will bring the water towards the well. The depth to which a well has to be sunk to ensure the requisite supply involves a study of the area of the underground water that can be drawn to the pumps at the bottom of the level. At the bottom of a well a chamber can be made or adits driven to store water. This enables the pumps to be at work only during ordinary hours, as they are made powerful enough to deal both with the regular flow to the well and with the increased volume due to storage.

Inverted Cone. The effect of pumping is to produce what is known as a curved *cone of depression*, or *inverted cone*, due to the resistance of the water passing through the strata from the higher water-level around to the lower level of the pumps. To assist the passage of the surrounding water to the pumps, adits are often driven from the bottom of the well. These intercept fissures in the strata, thus tapping large volumes of water.

The effect of withdrawing water from its underground stores by pumping from deep wells is often attended with the lowering of the water-level over large areas, thus involving the loss of water in wells which had hitherto afforded the supply needed for domestic or trade purposes. Where water flows in a defined channel, as in a stream, or from a spring, its abstraction involves compensation to those who are entitled to utilise it. If, however, water flows through underground strata, the Courts have held that there is no legal title to it, as it cannot be identified. The inhabitants of a district may, therefore, be deprived of their water supply if their wells are on the before-mentioned cone of depression. By adding lithia to water, a very definite and well recognised effect is produced in the spectroscope, by which water *can* be identified, and the writer succeeded in doing so in a case where water was abstracted from a stream by laying drain-pipes in a field adjoining, and thus *enticing* (as it is termed) the water from the stream without compensating the riparian owners.

Temperature of Well Water. The temperature of water from wells and boreholes is 52° F., at a depth of 100 ft.; 59° F. at a depth of 500 ft.; 68° F. at a depth of 1,000 ft.; 76° F. at a depth of 1,500 ft., and so increasing with the depth. For the supply of a town, a temperature of from 52° F. to 55° F. is desirable.

Classification of Wells. Wells are classed as (1) shallow wells, (2) subsoil wells, and (3) deep wells. The first, intended to supply adjoining wants, are always liable to pollution from surface water, derived from the houses, farms, or cultivated land. The second derive their supply from a greater depth, and pollution can be avoided if the well is built with brickwork in cement, surrounded by a layer of clay puddle, until it has been carried through the pervious surface soil, to prevent polluted water percolating to the level whence the supply is drawn. The top of the well should be carried a few feet above the ground, and covered. The third is sunk to reach water-bearing strata at a depth from the surface where the water would be free from organic pollution, unless, in very exceptional cases, a fissure in the strata brings polluted surface water to the deep-level water.

Artesian Well. An *artesian* well is one that is sunk to a source of supply which is fed by water flowing from a higher level than the top of the well, so that when the source is reached the water flows from the top of the well at a greater or less height, according to the head of water acting on the column. The size of the tube in this case governs the supply of water, as the quantity that can be discharged depends upon well-known hydraulic rules, the factors being the diameter, length, and roughness of the tube, and the head or pressure of water.

Tubbing. Cast-iron cylinders bolted up in segments and called *tubbing* are often employed as the lining of a large well. The first part of the cylinder has a cutting edge at the bottom of it, so that as the ground is excavated the cylinder sinks by the weight of the ironwork alone, aided, if necessary, by a temporary weight. A timber framing is used during the execution of the first 20 ft. of the work, to keep the cylinders vertical. If the work be in water-bearing strata, compressed air can be used to prevent the water rising and interfering with the men excavating, the well being made airtight for that purpose.

Wells Through Rock. In sinking large wells through rock, blasting has to be resorted to, on the *small shot* system, the object being to remove as much stuff with the fewest shots, the holes for which are generally not drilled nearer to the side than about 12 in. As the air gets fouled at about 30 ft. below the surface, a change of air is necessary, and this is effected by carrying a tube down the side, attached to a fan on the surface.

Boring large wells through rock can be done by employing rods to which is attached a wrought-iron crosshead, with wrought-iron chisels, having steel points. This tool is raised by a cable, which is coiled round a drum on the surface, and which enables the tool to be lifted and dropped quickly. During the operation its position is changed by a rotary motion. If the boring be a small one, only a single chisel is used. The diamond drill [*see* page 2669] enables a solid core to be extracted.

Tube Wells. Tube wells are a convenient and cheap way of sinking through ground that is not rocky, to ascertain the level of underground water, and to obtain either a temporary supply (as for a camp), or a permanent supply. The method of carrying out the work is by driving tubes screwed together in lengths, the screwed joints keeping out surface water. As one length is driven, another is screwed to the top of it and the sinking proceeds, the driving power being obtained by dropping a weight from shear legs on the top, as in pile-driving. The material inside the tube is removed by a *shell pump*, or cylinder, divided into compartments, each having a valve through which the débris passes into the pump, which is smaller than the hole, and is lowered by a rope, and after being lifted and dropped a few times, it gets filled, when it is raised and emptied.

Storage and Impounding Reservoirs. We shall now consider the question of providing the water supply of a town by storing it in a reservoir of sufficient capacity to provide for the possible contingency of droughts. The supply may be either from a stream or from a river at a low level, involving the pumping of the water to a storage reservoir situated high enough to afford the necessary pressure to reach the highest parts of the district, or it may be by impounding the water in a river supplied from an adjoining watershed by the construction of a dam of earthwork, masonry, or concrete across the valley in which the river flows. To meet the requirements of the district it is essential that the capacity of the reservoir, governed by the height of the dam, and by the amount of water that can be impounded, should be sufficient to meet the exceptional needs of periods of drought. It is also necessary to make trial borings over the whole site of the proposed reservoir to ascertain that there are no strata through which the water can percolate and be lost underground. Levels must be taken across the valley and trial holes, or trial shafts, made along the line of the proposed embankment or dam, the line being settled upon these results.

Capacity for Reservoirs. In determining the capacity required for an impounding reservoir, the engineer has to consider what compensation has to be provided for those who have the legal right to the use of the water flowing in the stream either for agricultural or other riparian purposes, or for power in working mills by waterwheels or turbines. Although the users of streams are often benefited by the conservation of water in a storage reservoir, by which occasional floods lower down the river are prevented or mitigated, yet, in practice, the engineer has to deal with compensation water. To solve all the problems that have been indicated requires careful observation, skill, and experience.

In dealing with the conservation of water from gathering grounds the question of quality and purity, as well as of quantity, is a factor. These will be touched on later.

The better conservation of the rainfall of this country is a national question, and demands at this time careful consideration. The population increases, but the water which is available for their requirements does not increase, and every year there arises a struggle for watersheds from which to obtain the supply for the needs of the great communities centred in our towns, while the populations in villages too often depend upon shallow wells, which are liable to pollution. An ideal state of things would be realised had the whole country been mapped out into watershed districts under a Department of State, by which a careful study of the physical geography and of the hydrogeological conditions of the country would have led to a more equitable and systematic utilisation of the rainfall than has hitherto obtained. The rivers and watersheds could then have been utilised on some definite system to ensure the conservation of the water, and to avoid the appropriation of important gathering grounds for small purposes.

Storage of Flood Water. The utilisation of the excess water in wet seasons to meet the deficiencies in dry seasons can be accomplished only by the construction of impounding reservoirs, in which flood waters may be stored, with the double advantages of mitigating the effects of floods and of better adjusting the balance between supply and demand

In considering the question of conserving flood water for town supply, flood water was, until recently, objected to, as it was under the ban of being polluted. The report of Lord Llandaff's Commission, in 1899, on London water removed this ban as it stated that "no restriction need be placed on taking flood waters," and also, "it would present a double advantage—the cost of pumping to store would be saved, and it would be possible to take much more water into the reservoir when the river is full, as the intake would not be limited by the capacity of the pumps, which cannot deal with more than a fraction of the water passing down at times of flood."

NON-COMMISSIONED OFFICERS

Channels to Promotion from the Ranks. Examinations for the Private. Technical Branches of the Service. Pay, Discharge, Pensions

continued from

By C. DUNCAN CROSS

LANCE-CORPORAL or acting bombardier is perhaps the most difficult position of any man in the Army, and for this reason. He is promoted from among his fellows, and exercises a certain limited authority over them. He must live among them, mess with them, and be one of them; yet all the time he must keep his authority intact. A very good use for his leisure hours will be attendance at the regimental school or private study to improve his education, for to-day war is a complicated thing, in which book knowledge has its place quite as much as physical strength. In any case, before being promoted to corporal or bombardier, the aspirant will have to gain a third-class certificate of education, if he does not already possess one. This is an easy examination which any intelligent boy should be able to pass. It consists of:

ARITHMETIC. Compound rules and reduction, simple vulgar fractions, and the ability to make up a messing account.

COMPOSITION of a letter to a friend..

WRITING FROM DICTATION. Extracts from Regimental Orders.

In this he must gain 120 marks out of a possible 200. As a corporal he will have to wait some time for his third stripe. The interval may very well be occupied in gaining a second-class certificate for:

ARITHMETIC. Reduction, practice, proportion, fractions, decimals, military percentages, averages and proportion, superficial and cube measures, ability to make up a pay and messing account for three, etc.

COMPOSITION. Ability to describe clearly any simple object, incident, or place in the candidate's acquaintance.

WRITING FROM DICTATION. Extracts from Regimental, Command, or Army Orders.

Sergeants. With a second-class certificate a man may be promoted to sergeant when a vacancy occurs. In addition he will have to pass a practical examination in the intricacies of drill and the interior economy of a company, squadron, or battery.

.At the present time it is possible to rise to colour-sergeant, or the equivalent positions of troop sergeant-major and battery sergeant-major in Cavalry and Artillery, merely by waiting for seniority. But all signs point to the fact that in future a first-class certificate will be necessary; and this is a more serious affair.

ARITHMETIC. The whole subject (except present worth and discount, stocks and cube root). Prominence is given to problems.

COMPOSITION. The ability to write out in clear language the substance of a passage of English prose read out by the examiner.

MAP READING. A knowledge of the four cardinal and the four intermediate points of the compass; a knowledge of plain scales sufficient to measure distances on a map; a knowledge of the meaning of contour lines and coloured shadings on maps; and ability to draw the conventional signs used in field sketching.

ENGLISH HISTORY. From the year 1688, and a campaign or a biography.

GEOGRAPHY. Including a general knowledge of the size and position of the continents, oceans, and the countries of the world; detailed knowledge of the British Empire; a general knowledge of the movements of the earth, the variations of time, season, and climate.

A soldier holding a first-class certificate can be examined, at his desire, in any foreign language, in shorthand, or in typewriting (these two last being particularly useful to those engaged in clerical work), or in any of the following military subjects: (1) Military engineering, tactics, and topography; (2) military law; (3) administration, organisation, and equipment; (4) military history. The holding of the certificate is valuable, not only for the increase of pay which it carries, but also as a proof to his superior officers that he intends to succeed in his profession. For promotion to warrant rank it is essential.

Quartermasters. A post much sought after is that of quartermaster, which carries with it the rank of honorary lieutenant. To attain this the soldier must have branched off earlier in his career and have had something to do with the quartermaster's department—have become in time quartermaster-sergeant. Then, if he holds a first-class certificate and is not over forty years of age, his colonel may recommend him, on the occurrence of a vacancy, for quartermaster. In the Cavalry the post of ridingmaster bears an honorary commission and is obtained by corporals and sergeants after a course at Canterbury.

Another post of honour is that of sergeant major. Our sergeant having been promoted to colour-sergeant, or its equivalent, must then wait with what patience he can for promotion, which, other things being equal, goes by seniority among the senior N.C.O.'s. To a good many men this appointment is the summit of their ambition, and they are content to serve on as warrant officers to complete their twenty-one years for a pension. To a few of those who desire it, comes the appointment of quartermaster, carrying with it the rank of honorary lieutenant.

Technical Branches. Of the technical branches the Royal Engineers is the most popular. Men of the following trades are enlisted as sappers, and approximate in rank to infantry privates: Balloonists, blacksmiths, boatbuilders, boatmen, boilermakers, bricklayers, cabinetmakers, carpenters, coppersmiths, coopers, divers, electricians, engine drivers and makers, farriers and shoeingsmiths, fitters, gasfitters, harness makers, instrument repairers, joiners, masons, metal turners, moulders, painters, paperhangers, pattern makers, plasterers, plumbers, riveters, sawyers, shipwrights, slaters, tinsmiths, wheelwrights, whitesmiths, wood turners, and a few men of other trades such as architects, clerks, photographers, printers, tailors, telegraphists. Any man who is a good craftsman in these trades will find a niche in the Engineers. A few drivers are also required. Telegraphists and men conversant with railway work are welcomed in the Reserve.

Before being accepted the recruit has to satisfy the authorities that he is a good workman. This may be done either by producing a certificate from his employer or by trial in a military workshop. Men are rated and paid according to their abilities, and those whose trade qualifications do not come up to standard are classed as "labourers." On improvement they are promoted to a higher class of pay.

Pay for Engineers. It may be well to state briefly the system of payment in the Engineers. There are seven rates of Engineer pay, as follows:

	s.	d.	
1st Rate	2	0	per day
2nd ,, ...	1	8	,,
3rd	1	4	
4th	1	0	
5th	0	8	
6th	0	6	
7th	0	4	

Every recruit on being dismissed from instruction in field works, or whatever branch of the Service he may be attached to, begins to earn Engineer pay at one of these rates in addition to his daily pay. Before he can be promoted the Engineer must be proficient at his trade, whether it be bridging, survey, telegraphy, or what not. He will find in this self-contained corps instructors of all sorts to assist him, and the smart man is soon picked out for promotion to acting corporal. From acting corporal he rises through second corporal to corporal, just as does the infantryman, and his work will increase in importance and interest as he goes on; till, on passing the educational examination outlined previously, and on giving proof of efficiency in his trade he reaches the rank first of sergeant, then of company sergeant-major, or of quartermaster-sergeant. He will find as he gets on that there are billets for warrant officers, such as instructorships at the depots, on the staffs of the regimental districts, and at the Record and Survey Department at the War Office, at home and abroad, that carry with them excellent pay. At the end of his service, too, he is nearly sure of obtaining employment in a civilian capacity, thanks to the admirable training he has received in the corps.

Army Service Corps. The Army Service Corps is another skilled corps to which tradesmen will naturally turn. Its duties are the supply of the Army with necessaries, and it therefore invites workmen belonging to the following trades: Bakers and confectioners, butchers, carpenters, clerks, coopers, farriers, saddlers and collar and harness makers, shoeing and jobbing smiths, tailors, engine drivers and makers, fitters, gasfitters, metal turners, moulders, plumbers, riveters, metal shipwrights, tinsmiths, and whitesmiths. When the men are accepted they must show their knowledge of their trade, and when they have completed their military training they are employed at their special trade as far as possible. Promotion is rapid, owing to the large proportion of N.C.O.'s required for responsible positions in the corps, and at the end of their period of service employment is generally not far to seek.

Army Ordnance Corps. In the Army Ordnance Corps there are wanted carriage smiths, clerks, collar makers, coopers, fitters, labourers, saddlers, sail makers, smiths, and wheelers. After three months' drill and instruction those who pass the trade test are employed at their particular calling. The corps is a small one, whose duties are the provision of arms and ammunition, equipment, stores for barracks, etc., and the repair of articles returned to store. Since over 40 per cent. are warrant or non-commissioned officers, it will be seen that the opportunities to the skilled man are very great. The armourer section forms a notable feature of the corps. To enter it a man must be a qualified gunsmith, and after undergoing a course at the small arms factory he is promoted at a bound to armourer-sergeant, and generally attached to a body of troops to take charge of the arms and their repair. The machinery artificer section consists of qualified fitters and watchmakers, whose duties are the examination and repair of gun mountings and instruments. Candidates for this section on giving proof of their expertness are promoted immediately on enlistment.

There is no prospect of rising beyond the rank of warrant officer, but the pay of the corps is so good that it attracts many skilled men who prefer the certainty of the Army to the uncertainties of civil life.

Medical Corps. The Royal Army Medical Corps is for the care of the wounded in the field and for the care of the sick in peace time. For men who have a liking for the work there are good openings, inasmuch as there is a very large proportion of N.C.O.'s to privates—about one in four. After being dismissed from the preliminary instruction recruits are posted to the various branches of the corps—to the nursing, clerical, cooking, or general staff, where they learn the duties they will have to carry out in the field. In addition to the regimental pay there is corps pay, corresponding to the "Engineer pay." On being reported qualified in their duties recruits begin to draw their corps pay, ranging from 5th rate for third-class orderlies of the nursing section and privates of the general duty section (4d. per day) to 1st rate for sergeants and lance-sergeants of the nursing and cooking sections (1s. per day). The work in peace time is light but unexciting, and since promotion is rapid, there is a steady flow of recruits to the corps. On retirement there is a good chance of obtaining employment in hospitals, asylums, prisons, and other public institutions. There is, however, no chance of rising above warrant rank. The regimental pay is slightly better than that of the Infantry of the Line, ranging from 1s. 2d. per day for a private on enlistment to 2s. 8d. per day for a sergeant. Quartermaster-sergeants get 4s. 6d. per day.

Boys. A small number of boys are required in the Army for service as buglers, trumpeters, drummers or musicians. They must be between 14 and 16 (unless from the Gordon Boys' Home, where they have been trained as musicians or in some trade; or boys for the Royal Artillery, when the age limit is extended to 17), and the consent of a parent or guardian is necessary. At the age of 18 they become available for service in the ranks, and proceed as do other soldiers.

Discharge and Pensions. Should a soldier within three months of his joining the Army desire to leave the Army, he may purchase his discharge for a payment of £10. After that time it will cost him £18. Should he have served three years and have been transferred to the Army Reserve the sum increases to £25.

At the end of 12 years' service with the Army and the Reserve a man is given a free discharge with a gratuity of £1 for every year served, with a maximum gratuity of £12. But the soldier whom we have been advising will re-engage after 12 years for another nine years to complete his time for a pension, and on leaving he receives a pension according to his rank and the length of time he held it before discharge. Warrant officers and non-commissioned officers are divided into classes according to the time served in their rank and their qualifications: Warrant officers, 3s. to 5s. a day; non-commissioned officers, 1s. 3d. to 3s. 6d. per day; and privates, 8d. to 1s. 6d. per day. Service beyond 21 years brings with it 1d. a day for the higher classes and ½d. a day for the lower classes, with a maximum addition of 9d. and 5d. respectively. For wounds or injuries contracted in the country's service pensions are given on the man's discharge, varying between 6d. and 3s. 6d. a day, according to rank and the extent of the injury. Good conduct medals carry with them a gratuity of £5 on discharge, and the Victoria Cross a pension of £10 a year. An important question before a man nearing the end of his service is: "What can I do when I return to civil life?" For a really good man who has been popular with his officers there is often some position of trust to be obtained by his commanding officer's influence. Should this privileged avenue fail, Government employment is offered to discharged soldiers in the Post Office, the Royal Arsenal, Army Clothing and other Government departments. The police force, the Commissionaires, and the staff of Park Rangers are also favourite outlets for ex-soldiers. There is a National Association for the Employment of Reserve and Discharged Soldiers, where men may register their names for civil employment, and it is evident that the matter will shortly be taken in hand by the Government by teaching men a useful trade during their period of service in the Army, and by ear-marking certain Government appointments for ex-soldiers and sailors. In any case a thrifty man should be able to save, after he begins to draw service pay, not less than 6s. a week, which, with interest at the rate of 2½ per cent., will amount at the end of his 21 years to nearly £400—a very useful asset with which to purchase a business or set himself up in trade.

Pensions for Widows. Lastly, pensions are granted to widows and children of N.C.O.'s and men who have died of wounds or injuries received in the execution of their duty. These vary between 5s. and 10s. a week for the wife, and 1s. 6d. to 2s. for each child, according to the rank of the husband. For the orphans of soldiers and a few other deserving cases there exist the Duke of York's Military School and the Royal Hibernian Military School, where boys are educated free of charge. The future of these boys is provided for by the authorities, who at the expiration of their school life will either apprentice them to trades or allow them to join the Army. Among the best men in the Army are to be found boys who were brought up at these admirable institutions.

DAIRY FARMING

continued from page 3893

By Professor JAMES LONG

NO article of food has been subjected to so much criticism or to such searching examination as milk; and yet we have much more to learn about it, especially as to its behaviour in relation to fermentation, to the manufacture of cheese and butter, and to digestibility. Although a fluid, it contains food in the form of fat, which is the chief constituent of butter, sugar, casein (a most important albuminoid), and various mineral matters. Its average composition is as follows:

Constituent.	Average Quality.	Low Quality.	High Quality.
*Fat	3·35	2·50	6·91
Casein and Albumin	3·45	3·04	3·48
Sugar	4·83	4·90	5·02
Mineral matter	·72	·66	·72
Water	87·65	88·90	83·87
	100·00	100·00	100·00

* This and subsequent tables are from "Elements of Dairy Farming," by James Long.

If, however, we take the estimates and average analyses of various British and foreign authorities, the average fat percentage reaches 3·7, and the solids other than fat, 9 per cent.

Colour. Milk varies in *colour* in accordance with the breed or individuality of the cows producing it. The Jerseys and Guernseys of the Channel Islands, the South Devon cows, and cattle of similar types in France and Denmark produce milk of richer colour than the majority of native breeds, this colour being due to the globules of fat which are held in suspension, and which, when removed, leave the fluid white. If, however, the casein or curdy matter be also removed, as in the cheese dairy, the whey, which is the liquid remaining, is of a greenish yellow colour, containing nothing but sugar and the mineral matter.

Solids. The solid matter in milk is held partly in suspension and partly in solution, the proportions, as defined by the eminent French chemist Duclaux, being as follow in milk of very poor quality:

Solids.	In Suspension.	In Solution.
	Per cent.	Per cent.
Fat	2·75	—
Sugar	—	5·38
*Casein (and albumin)	2·72	·55
Phosphate of Lime	·21	·14
Soluble Salts	—	·35

* Duclaux includes all nitrogenous matter under this term.

We have stated that the colour of milk varies with the breed; the remark equally applies to its quality. It varies also in accordance with the length of time which divides each milking, with the date which has elapsed since the cow calved, with the condition of her health, and whether or not she be in a state of excitement. The first milk drawn, too, is much poorer in quality than the last milk, hence the importance of thoroughness in milking. It is for this reason that the owners of many herds cause each cow to be stripped after the milker has completed his work, thus:

	Fat.	Solids.	Water.
	Per cent.	Per cent.	Per cent.
First milk	1·82	11·83	88·17
Strippings	9·63	19·18	80·82
First quart	1·22	10·82	89·18
Last quart	8·48	17·24	82·76

Colostrum. Whatever may be the quality of the milk of the individual cow, or the difference between the various cows in a herd, the composition of the milk of mixed herds is very similar, owing to the fact that the milk of each cow is mixed before it is despatched to the purchaser. The first milk yielded by a cow after she has produced her calf, and known as *colostrum*, is poor in fat but extremely rich in casein and albumin, which is present in all milk but usually included under the term casein.

COMPOSITION OF COLOSTRUM (WARINGTON)

	Per cent.
Water	71·7
Fat	3·4
Casein and other albuminoids	20·7
Sugar	3·2
Mineral matter	1·1
	100·1

Morning and Evening Milk Compared. As the cow, however, progresses and becomes stale—namely, as she approaches the time of drying—her yield diminishes in quantity but sensibly increases in quality. It is believed, too, that with the increase in age, especially after a cow has reached six years, her milk increases in quality, but facts do not fully warrant any statement being made as to its general application. When a cow is milked every twelve hours the milk she produces is practically identical in quality; but where the afternoon or evening milking is—as is the case in this country—from seven to nine hours after the morning milking, the quality is sensibly increased in the evening, and as sensibly diminished in the morning. The evening milk is, therefore, weight for weight, much more valuable than the morning milk.

Influence of Food. The influence of food on the quality and value of milk is not fully recognised. Producers, as a rule, believe that they can improve the fat contents by high while it is distinctly in opposition to scientific teaching. Farmers have observed that in changing a herd from one pasture to another there is an almost immediate and beneficial result. But that result is chiefly in the direction of an increased quantity, and the reason is obvious: the cows are removed from grass which has been practically eaten close to the soil on to a field which is fresh, sweet, and perhaps carrying abundant herbage.

Value of Fresh Pastures. Apart from this, however, the mere *change* from a stale to a fresh pasture encourages secretion. And so it is, where the cows are stalled, when they receive an increase in their ration of cake, meal, grains, bran, or some similarly palatable food. When a cow is receiving a full ration—that is, as much as she can properly assimilate—no addition, either of quantity or quality of food, will enable her to produce milk of superior quality; but when she is under-fed there is every reason to believe that any addition to her ration is followed not only by an increase in the quantity but an increase in the quality.

Again, it is obvious that much depends on the health of the cow. If her system be disturbed, not only is the quantity diminished, but the quality suffers, and so far as has been observed a diminution in quantity means a diminution in the fat percentage. The following instances of two cows suffering from pleuro-pneumonia may be quoted to emphasise this:

	Per cent.	Per cent.
Water	89 60	89·18
Fat	1·18	1·30
Sugar	4·40	4·50
Casein	4·16	4 38
Mineral matter .	0 66	0·64
	100 00	100·00

Cooling and Aerating. It is important that milk should be *aerated*, and if intended for sale, *cooled* as soon as it is drawn. The modern system of cooling, by means of either the *horizontal* or the *lenticular cooler*, figured and described in the next lesson, provides complete aeration by which the cow-like odour of the milk is removed. Where milk is placed in a vessel, and especially if it be covered with a lid, without cooling or aerating, its disagreeable odour is largely retained. The exposure of milk to any pungent smell should always be avoided, as it possesses a property of absorption which may render it almost unfit for use, or even for conversion into butter.

Specific Gravity. The density or *specific gravity* of milk varies in accordance with its quality; but to ascertain its density by direct weighing is impossible except in skilled hands and by the aid of the delicate instruments of the laboratory. Specific gravity is taken for all ordinary purposes by the aid of an instrument known as the *lactometer*, but it is important that the temperature should be observed, inasmuch as milk expands with heat. A gallon of pure water weighs 10 lb. at 60 degrees F., when the barometer stands at 30 in. Under similar conditions milk may weigh from 10·27 to 10·34 lb. per gallon, its specific gravity, by altering the decimal point, thus being 1·027 to 1·034, figures which may be regarded as the limits. Although it is quite possible that while pure milk may possess a density represented by either of these extremes, yet the probability is that it is watered or skimmed. Obviously the fat globules of milk are lighter than the water of milk which, as we have seen, forms some 87·5 per cent. of its composition; but the remaining constituents—the minerals, the casein and the sugar—are heavier. If, therefore, we remove the cream, which contains practically all the fat, the density of the milk is raised; whereas, if we add cream to pure milk it is reduced. The reason why milk is slightly heavier than water is due to the fact that the sugar, casein and mineral matter, owing to their larger quantity, influence it more than the fat. Again, if water be added to milk, its specific gravity is reduced; thus, milk with a low specific gravity is usually regarded as watered milk. If we take a pure sample and assume that its specific gravity is 1·031, the figure will be increased by the removal of the cream. If we add 10 per cent. of water, the density will be reduced to 1·029, and still further reduced point by point until, when 50 per cent. of water is added, its density stands at 1·016.

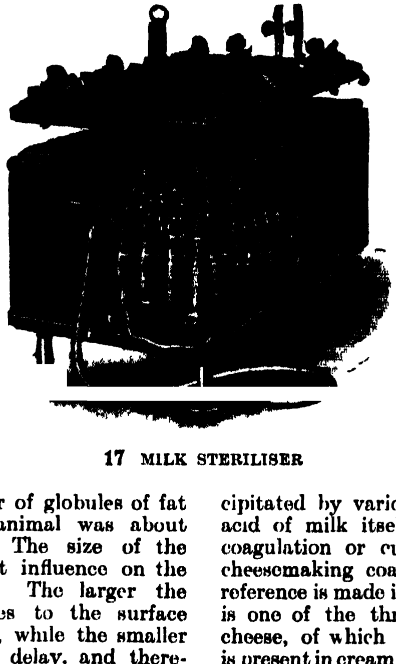
Testing for Adulteration. One of the common practices of the day is the addition of separated or skimmed milk to new or whole milk. As by the Government standard milk offered for sale must contain 3 per cent. of fat, it follows that a vendor can dilute a rich sample—one which, for example, contains 3·7 per cent. of fat—with separated milk and still remain on the right side of the law, although the practice, if known, would subject him to prosecution. If we assume that pure milk of good quality varies from 1·029 to 1·032, neither of which figures are extreme, there is reason to suspect its purity if it falls below the former or is raised higher than the latter figure. A high specific gravity—1·034, for example—suggests the addition of separated milk. It is important in testing with the lactometer to obtain a table which is frequently sold with the instrument in order that whatever its temperature when tested, its actual specific gravity may be recognised by reference to the figures. Just as milk expands with a rising temperature, so it contracts as the temperature falls; but this contraction ceases at about 4° C., below which expansion again begins.

The German expert Fleischman has shown how the constituents of milk are divided in the process of butter and cheese making. His figures are extremely valuable and are as follows:

Substance.	Water.	Fat.	Casein, etc.	Sugar	Ash.
Whey	78·9	3·2	22·3	76·6	60·3
Buttermilk ..	14·0	2·3	13·8	11·2	12·5
Skim Cheese ..	3 6	11·5	61·5	4·2	26·7
Butter ..	·6	81·5	·6	·2	·5
The Loss ..	2·9	1·5	1·8	7·8	—
	100	100	100	100	100

It should be pointed out, however, that in the manufacture of skim cheese a larger quantity of fat is left in the skimmed milk than under other conditions.

The Fat in Milk. If a drop of milk be placed beneath the microscope, the field will be covered with a large number of tiny globules somewhat evenly distributed, although somewhat irregular in size, especially in the milk of Channel Islands cattle. A drop of the last milk drawn from the cow at milking time will contain a much larger number of these globules than a drop of the first, or *fore* milk, while the latter will contain still more than are seen to be present in a drop of *skimmed* milk. Fat globules of average size measure about $\frac{1}{5000}$ of an inch in diameter, but the largest globules are about $\frac{1}{1500}$, and the smallest $\frac{1}{12000}$ of an inch The number of globules present in a cubic millimetre ($\frac{1}{1000}$ of an inch) has been estimated at from a million to 3¾ millions. The fat of milk, which is represented by these globules, chiefly consists of *olein*, *stearin*, *palmitin*, *butyrin*, *caproin*, and *caprylin*, palmitin and stearin being regarded as solid fats, and the remainder as liquid fats or oils. The constituents butyrin, caproin, and caprylin in their corresponding form of fatty acids are volatile. If we take the average size of the fat globule of the Guernsey and Jersey cow at 100, and its diameter at $\frac{1}{8000}$ of an inch, the size of the globule in other milks will be found to vary from 110 to 133, and the diameter from $\frac{1}{10000}$ to $\frac{1}{12000}$ of an inch.



17 MILK STERILISER

Size and Number of Globules of Fat. In an investigation in which the milk of 15 cows of six different breeds was submitted to 150 examinations it was found that the number of globules of fat produced by the average animal was about 136,000,000 per second. The size of the globule exerts an important influence on the success of a butter dairy. The larger the globule the quicker it rises to the surface where milk is set for cream, while the smaller the globule the longer the delay, and therefore the greater the difficulty in reaching the surface—a difficulty which becomes impossible when, owing to such delay in warm weather, acidity commences, the milk is coagulated, and the passage upwards blocked. The fats of which the globule is composed are in no case constant in quantity—especially varying with the temperature and probably with the food consumed. In winter the solid fats are larger in proportion, and the food smaller, while the volatile fatty acids frequently vary as winter approaches to such an extent that pure butter has, upon analysis, frequently been condemned as margarine owing to the similarity in its composition to that imitation in this particular aspect. Agreeable as milk fat is to the palate, its odour and flavour are rapidly changed by exposure to light and air. This change is believed to be due to the decomposition of the glycerides of the volatile fatty acids, which is retarded by the aid of salt and various chemical preservatives—which, however, should never be used. Decomposition is retarded by the skilful removal of all foreign matter in the manufacture of butter, especially of the sugar and casein, which, present in the cream, find their way into imperfectly made butter.

The Sugar of Milk. This is one of its most constant solids, and the one which, in the process of cheesemaking almost entirely remains in the whey. It is composed of carbon and the elements of water as follows:

Carbon	40 00
Hydrogen	6 66
Oxygen	53 34
Total	100·00

Sugar of milk does not ferment so easily as cane sugar. It can be obtained from milk by the evaporation of the fluid in which it is in solution after the extraction of the casein and fat. In its pure state it keeps well, and is soluble in hot water or in five to six parts of cold water. [See the lessons on Sugar in FOOD SUPPLY.]

The Casein of Milk. The albuminoid matter of milk, which includes albumin, is usually described by this term. The following figures represent the composition of casein:

Carbon	53·83
Oxygen	22 52
Hydrogen . ..	7 15
Nitrogen	15 65
Sulphur	A trace

Although casein can be precipitated by various acids, including the lactic acid of milk itself, which causes spontaneous coagulation or curdling, it is in the process of cheesemaking coagulated by rennet, to which reference is made in a subsequent lesson. Casein is one of the three important constituents of cheese, of which it forms about one-third. It is present in cream in small quantities, but should be entirely absent from butter, in which, as it decomposes, it causes a disagreeable flavour and odour. The albumin of milk, unlike the casein, is not precipitated by rennet, but by heat; hence the practice of many cheesemakers of *cooking* the curd, as it is termed—that is, heating it to an unusually high temperature. The albumin of milk is believed to form about one-sixth part of its albuminoid matter.

The Mineral Matter or Ash of Milk. This is utilised in the animal economy in building up the body and other structures of the body of which minerals form part. It is extracted from the soil by plants, and conveyed by them in the form of food to the cow. Average milk contains about 0·7 per cent. of mineral matter, usually described as ash, for the reason that when the solid matter of milk is burnt the minerals remain in that form. The chief mineral constituents of milk are *potash, lime, phosphoric anhydride,* which forms about one-third of its total weight, *chlorine, soda, and magnesia.* Where milk is sold the loss of fertile matter to the soil from which the cows are fed in the course of a year is considerable, owing to the removal of the nitrogen in the casein, and the potash and phosphate of lime in the ash. These three materials, as we have shown in dealing with the science of manuring [pages 433–4], form the three cardinal constituents of the soil, and those which are essential for the growth of crops. Where, however, cows are fed upon purchased cake or corn, and especially where, in addition, artificial manures are employed, the loss through the medium of the milk may be ignored, that loss being variously placed at from 20s. to 25s. per cow per annum.

Bacteria in Milk. The maintenance of the sweetness of milk is almost as important as its purity. Milk changes with great rapidity during hot weather, and at all times acidity is induced by the presence of organisms known as *bacteria.* The organism chiefly concerned in the production of acidity in milk is known as *Bacterium lactis,* which is chiefly derived from air, and which is abundant in dairies, milk shops, cow-houses, and other apartments in which milk is produced or handled. The organism chiefly feeds upon the albuminoids of milk, and by its action converts the sugar of milk into lactic acid. The lactic bacterium, however, is not the only organism found in milk; there are others which are equally responsible for fermentation or chemical changes, not only in the milk itself but in the butter and cheese produced from it, and among these may be mentioned the butyric ferment (*Bacillus butyricus*) which is the cause of rancidity in butter. Other forms of bacteria are occasionally found, including the organisms responsible for tuberculosis and other serious diseases; but where ordinary care is taken, or where milk is boiled or sterilised, the presence of these germs need not be feared.

Why Cheese Ripens. Milk also contains a variety of unorganised ferments, some of which are responsible for the ripening and flavour of cheese, and of moulds. Among the former may be mentioned *galactose,* an enzyme and digestive ferment, which was discovered by Drs. Badcock and Russell, said to resemble a secretion of the pancreas of animals. To this enzyme the discoverers largely attribute the ripening of cheese, which they contend may now be cured by its aid at a low temperature, thus rendering the old-fashioned cheese-rooms and the maintenance of a high temperature unnecessary. In Great Britain, however, the old system is still in force, and is likely to remain so until more is known of the new discovery.

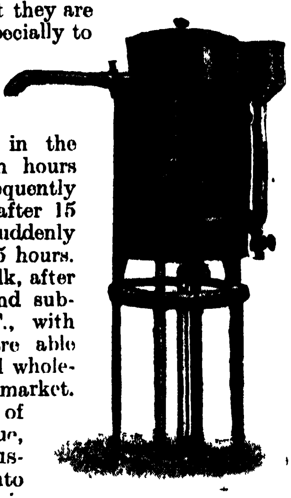
Multiplication of Bacteria. The bacteria of which we have spoken are single-celled members of the vegetable world, seldom exceeding 10 μ. (μ. = ·001 millimetre in diameter). The multiplication of these organisms is extraordinarily rapid; in a humid atmosphere, and at a temperature of from 86° F. to 104° F., the cells divide in from 15 minutes to an hour, so that at the latter temperature a single cell may become millions in a day of 24 hours. Before its extraction from the udder of the cow, milk is germ free, but immediately it is exposed to the atmosphere it is attacked by bacteria, especially in the cattle-house, where they abound—hence the importance of milking, if possible, in the open air. Harwood records that in a test made at the Maryland Station 7,000 bacteria were found in a cubic centimetre of milk (about a quarter of a spoonful); while after standing in water for 15 hours at 60° F., 2½ millions were found. When 24 hours had elapsed, the number had reached 69 millions, while at the end of 39 hours there were no less than 300 millions.

Bacteria are Good Servants but Bad Masters. Although there are bacteria which are useful to man, it is incontestable that where, owing to imperfect conditions, these increase rapidly, they become extremely deleterious in their turn, and render milk unfit for food. When the temperature of milk is reduced, the rapidity of reproduction diminishes, and it is for this reason that dairymen require the farmer to cool the milk down to 50° F., when reproduction is practically checked, to be increased, however, immediately the temperature rises. Facts similar to those recorded by Harwood have been laid down by experimenters like Knopf, Miguel, and Freudenreich, in whose laboratory in Berne we have been enabled to see something of this particular work. The researches of Dr. Newman, who has repeatedly taken samples in London boroughs, many of which were unfit for human food, entirely confirm the results in the laboratory. When milk is coagulated, the growth of bacteria is checked; this is believed to be in large measure owing to the acid which they produce—in a word, their multiplication is stopped by the accumulation of the products of their own growth. While bacteria are harmful when allowed to obtain the mastery, they are the valued servants of the butter and cheese maker who keeps them under control.

Sterilisation. The lactic bacterium is from 1·3 μ. to 1·6 μ in width, while in length it is about 1½ times its breadth. It is destroyed when the milk is boiled, but its spores or seeds, which are believed to resist heat up to 245° F., are practically killed when submitted to boiling point for half an hour. This, at all events, appears to be the result of the practice called milk sterilisation. Lister has demonstrated that where sterile milk is drawn from the cow into a sterilised bottle, and contact with air prevented, and if the bottle be hermetically sealed, it will keep. Milk, however, is now in daily practice sterilised by submission to heat at 212° F. for half an hour. The milk is first cleaned in the centrifugal separator, from which the cream tube is removed; as it revolves, the dirt, the bacteria and other impurities are thrown to the sides of the vessel, where they form a somewhat disgusting scum. It is subsequently passed into bottles, placed in the steriliser, with the stoppers loose, submitted to the required heat, when the stoppers are closed by a gloved hand in the live steam, so that the entrance of fresh germs from the air is prevented [17]. Milk prepared in this way may be delivered to customers by the dozen, or by a week's or fortnight's supply according to arrangement.

Pasteurisation. Pasteurisation [18] differs from sterilisation inasmuch as the milk is submitted to a lower temperature—175° F.—by which the bacteria are destroyed but not the spores. Coagulation of milk does not take place until from 7 per cent. to 8 per cent. of lactic acid has been produced. If before this quantity be present the acid is neutralised by the addition of an alkali, coagulation is postponed; but neither alkaline nor other so-called milk preservatives should in any case be used. Although the opinions of experts differ as to the influence of these materials, the majority of medical opinions is to the effect that they are deleterious to health, and especially to children and invalids. Pasteurised milk will keep longer than raw milk. When Fjord heated separated milk (a portion of which was boiled in the month of June after seven hours of exposure) to 158° F., subsequently cooling it slowly, it boiled after 15 hours' exposure; when suddenly cooled to 77° F., it kept for 35 hours. In factories, the separated milk, after skimming, is Pasteurised, and subsequently cooled to 50° F., with such results that farmers are able to take it home for use, and wholesale buyers to place it on the market.

If the lactic fermentation of milk be permitted to continue, *butyric acid* is formed [see CHEMISTRY, page 3273]. *Lactic acid*, into which the sugar of milk is changed during fermentation, and as the result of the activity of the lactic bacteria, is composed of the same elements as the sugar itself, but the value of the milk as a food is entirely changed.



18. MILK PASTEURISER

Cream. Cream is a milk product which possesses no definite standard. It may be thin or thick when removed from the milk; its thickness depends partly upon temperature, partly upon the presence of acid, and partly upon the quality of the milk and the system of skimming or setting adopted. By the aid of the *separator*, it can be removed as thin cream—which means that it contains more of the milk serum. If set at a low temperature, and if the milk be cooled before it is set, the cream will be thin. Cream cooled on ice, or slightly heated, will become thicker. In the latter case its apparently more substantial character is owing to the presence of acid and the slight coagulation of the casein. Very rich cream may contain only one-third of its weight of water, while very thin cream may contain two-thirds.

Devonshire Cream. Clotted cream, as made in the West of England, contains some 60 per cent. of fat and 33 per cent. of water, with approximately 5 per cent. of casein. Commercial cream is frequently preserved by the aid of chemical preservatives, for which reason it is a less desirable food. If milk be set in open vessels with a depth of 5 in. to 6 in. for 12 to 24 hours for the cream to rise, and the whole be then scalded to 170° F., there is slight coagulation—in such a case the cream becomes *clotted*. In this form it is not only highly appreciated on the table, but keeps longer. The remark applies equally to the milk serum remaining, and to the butter produced from the cream itself.

The Separator. If cream of 10 per cent. quality be removed by separation, that quality should be high. At wholesale price, 100 lb. of milk, or 10 gallons, would cost during the six months April to October, 6s. 3d.; so that one gallon of cream costs 1s. 6¾d. per quart plus the cost of separation. Such cream, however, is commonly sold by retailers at 4s. a quart, or 6d. a reputed quarter pint jar, which is equal to 4s. a reputed quart. Naturally, thick cream is frequently purchased, however, and thinned by the addition of milk before retailing. Where cream is removed by the separator, the quantity of fat left in the milk seldom exceeds 0·2 per cent.; but where it is skimmed from the milk which has been set in open vessels the fat remaining may reach one third of its total contents.

Why Cream Rises. The rising of cream is due to its lower density, that density varying from 1·000 to 1·016, so that, while it is lighter than milk, it is heavier than water. The practice of estimating the quality of milk by the aid of a *creamometer* is fallacious; this is owing in part to the temperature of the atmosphere, and in part to the individuality of the cows producing it. A tube in which milk is set may throw up cream of a high percentage, while the milk itself may be actually poor in fat. On the other hand, the percentage of cream may be low, and the fat yield high. Many examples may be taken from tests in the Government laboratories, and in our own practice, but we select two; in one case the cream percentage was 17·5, and the fat percentage only 2·5; in another the cream percentage was 4·5, and the fat percentage 4·57. Cream may be *pasteurised* for the improvement of its keeping properties, or it may be *separated* for the improvement of its quality.

Separated or Skimmed Milk. Separated or skimmed milk is that from which the cream has been removed, the first-named by the machine, the second by hand skimming. Its food value is practically maintained as equal to full milk by the addition of digestible fats or oils equivalent to the fat removed in the cream.

Skimmed milk of average quality is composed as follows:

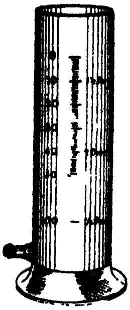
	Per cent.
Water	90·10
Fat	·75
Casein	3·50
Sugar	4·85
Ash	·80
	100·00

The density of skimmed milk varies between 1·033 and 1·037. If 10 per cent of water be added the gravity is reduced to 1·032, so that it then compares on this basis very closely with full milk. Separated milk possesses a slightly higher specific gravity than whole milk, containing as we have seen less fat. If skilfully mixed with rich full milk of low specific gravity it may be passed for whole milk without detection.

Butter Milk. Butter milk is the by-product left after churning cream or milk from which butter fat has been removed. The quantity of butter milk produced depends upon the quality of the cream. As cream is churned in a mature, ripe or acid condition, buttermilk is acid, but it is a sound and wholesome food. The composition of an average sample is as follows:

	Per cent.
Water	91·2
Fat	·6
Casein	3 5
Sugar	4 0
Ash	7
	100·0

Whey. Whey is the liquid by-product of cheese-making. In skilful hands it contains but little fat, although large cheesemakers remove this fat by skimming for the manufacture of whey butter. Whey, however, is chiefly supplied to pigs, its value depending upon the large quantity of sugar which it contains. In an average sample the sugar present reaches 5 per cent., the curdy matter 1 per cent., the fat ·35 per cent., and the mineral matter ·76 per cent.



19. CREAMOMETER

Milk Testing. The quality of milk is tested in various ways; by chemical analysis, by the Babcock and Gerber machines, the lactometer and the creamometer. There are other methods which require technical skill, but in practice the amateur now depends chiefly upon the two first named. By *chemical analysis* the water is driven from the milk by heat, the dry matter remaining being the milk solids, which are separately determined. The method of determination, however, belongs to the department of chemistry [see the course on CHEMISTRY, page 3820]. The *creamometer* [19] is a glass tubular or cylindrical vessel 10 in. high by 1½ in. in diameter, although smaller and consequently less reliable tubes are sometimes used. There should be a scale on the upper portion of the vessel divided into 100 parts, commencing with zero near the top. The milk is poured up to this mark when quite fresh, and kept for 24 hours at an even temperature, as near 60° F. as possible; in due course the cream will rise, and the percentage can be read upon the scale. This test, however, as we have already shown, is not of a thoroughly reliable character.

The Lactometer. The *lactometer* should always be used in conjunction with the creamometer where that vessel is employed. This instrument is usually adjusted for use at 60° F. If gently introduced into milk at this temperature the specific gravity will be shown. Thus, if the scale on the stem be level with the surface of the milk at the figure 30, the specific gravity is 1·030; but if the temperature be higher or lower, the specific gravity indicated will be higher or lower; the indication, however, will not be correct, and therefore a correction scale is necessary, in order that the exact gravity may be ascertained by referring to it. The best lactometers are fragile, the stem not exceeding ¼ in. in diameter, and the bulb 1¼ in. by 3 in. in length. The most perfect lactometer is that invented by Quevenne.

The Babcock and Gerber Machines. The instruments invented by Babcock and Gerber are intended to determine the quality of milk by the extraction of its fat. The Babcock machine is a disc which revolves at great rapidity. Carefully measured quantities of milk are passed from a pipette into small bottles, the necks of which are graduated. These bottles are submitted to centrifugal force, when, by the aid of sulphuric acid, the casein of the milk being held in solution, the fat is driven into the neck of the bottle, and its percentage there read off. These machines are now generally used by advanced dairymen, and are of great value to the milk industry. The method of making the test, if the instructions sent with each machine be followed, is easily mastered. A number of samples of milk can be tested at one and the same time. Cream, buttermilk, skimmed milk, and whey may be tested by the same method. In some instances, especially in factories, samples of milk are daily kept and mixed with an appropriate antiseptic, the mixed or composite sample being tested weekly. As it is necessary, in order to avoid prosecution, that all milk sold should contain 3 per cent. of fat, it is not only important to dairymen but to farmers that milk should be frequently tested.

CARPENTRY
continued from
page 3848

By WILLIAM J. HORNER

The Half-lap Joint. This joint is also called the *halved* joint and *lap* joint, though the latter term applies equally to pieces which merely cross each other and are screwed or bolted together [192]. Examples of half-lap joints are shown in **143** to **150**. One-half the thickness of each piece is cut away, so that the timbers join in the same plane, the combined thickness at the lapping joint being the same as that of each separate timber. This joint is used chiefly for uniting narrow pieces either when they cross, or meet each other at right or other angles, or for joining them end to end. It is neater and stronger than a joint which is merely lapped, like **192**, but it is neither neat enough nor strong enough for all purposes. It would never do, for instance, to make a half-lap joint in the middle of a beam or post, thereby diminishing its strength by one half; but, where only the ends of timbers are halved, their strength is not diminished much, and for many purposes there is no objection on the score of loss of strength to halving intermediate parts.

These joints are marked with square and gauge, sawn nearly to the lines, and finished exactly to the lines with rebate plane and chisel, the rebate plane being used because its iron cuts right out to the sides of the plane, and so can remove shavings up to the shoulder of the halving.

Modifications of Plain Half-lap. These consist in cutting one or both sides in the form of a dovetail, or V-shaped [**147** to **150**] bevelling, or dovetailing the face [**149**], mitring a corner [**189**], or making notches, tusks, or other variations calculated to enable the joint to withstand better the particular stresses of the structure. Strictly speaking, a half-lap joint is one in which both timbers are of the same thickness, and exactly half of each is cut away to bring their faces flush at the joint. There are many cases, however, where, though the lap is of the same character, it is not halved. Sometimes it is found best to cut less than half from either or both timbers, or only one may be cut for some portion of its thickness and the other left whole. Often, also, the thickness of the two timbers is dissimilar, and they may or may not have to be made flush with each other on one face. Halved joints are usually screwed together. In rough work they might be nailed, and in large work bolted.

Tenoned, or Mortise & Tenon Joint. This is the joint most commonly employed in framed work. It can be used in much the same circumstances as the half-lap, but being both stronger and neater than the latter it is generally preferred, except in cases where the extra work involved in making it is objectionable, or where the members could not be put together without cutting chase mortises—that is, mortises which permit the tenon to be slipped in sideways [**167**].

In the mortise and tenon joint the tenon is the projecting tongue, and the mortise the slot which receives it. Examples of these joints are shown in **151**, **152**, **154**, **156**, and others. There are two main varieties: those in which the mortise is cut entirely through the member, the tenon on the other member coming through flush with the outside, so that its end is always visible [**151**, **152**, **154** and **156**]; and the stub or stump tenon which does not go through, but fits into a correspondingly short mortise [**155** and **183**], and consequently does not show anywhere on the outer faces of the work when the members are put together. Both of these types are popular, circumstances deciding which is the more suitable.

Fixing Tenoned Joints. Tenoned joints are held together by being glued and wedged, or by driving wood pins or pegs through from one side, thus holding the parts together. Screws or nails are sometimes used instead of wood pins; and in heavy work, bolts. Gluing and wedging is generally more suitable for light and neat work. When pins are used, drawboring is practised to help to keep the parts together. In large joints held in this way, glue is not always used.

When a through mortise and tenon joint is to be wedged, the mortise is increased in width at the outer face to allow for the thickness of the wedges [**151** and **152**]. This, provided the glue holds the wedges to the tenon, really makes a dovetailed joint which cannot be pulled apart. Generally, two wedges are used, one on each side of the tenon, as shown in **151**; but sometimes wedges are driven into the tenon itself, splitting and spreading it, saw cuts, or a nick with a chisel being first made to start the wedges into. Fig. **154** shows what is considered the most substantial method of wedging, but it is not always employed, because of the trouble of making saw cuts the entire length of the tenon, as shown. Wedges inserted at an angle in this way never come out. Stub tenons also are often wedged, but in their case the wedges cannot be driven from the outside after the tenon is in place, and so their thin ends have to be inserted in the tenon, and then the latter must be forced into the mortise, the wedges thus becoming driven home by the pressure of their heads against the bottom of the mortise. This is called *fox wedging* or *foxtail wedging*.

When stub tenoned members are of minor character, coming between others, fox wedging is not necessary. In light work glue alone is relied on, and in heavy work the parts are held together by exterior attachments independently of the stub tenon joints.

In putting a tenoned frame together, cramps are used to pull the joints up tightly, and these are left on for a time until the glue has set.

Drawboring. Drawboring with pins is done on the same principle as that in which a cottar draws two parts together. That is, the tapering side of the cottar acts as a wedge against the side of the hole in one of the parts, while it exerts pressure in the opposite direction in the other part. This is done by making the holes slightly out of centre with each other, so that when the pin is driven through, it exercises an inward pull on the tenon. The same principle is often put into practice in the insertion of screws into half-lap joints, and into any places where the piece of wood which is being screwed down has at the same time to fit closely against a shoulder or other part, which makes a side pull as well as a downward one desirable when screwing it down. The screw holes are bored through the first piece in the ordinary way, as described in our remarks about the insertion of screws, but in continuing the smaller hole on into the second piece the gimlet or bradawl is kept out of the centre relatively to the large hole, toward the side to which it is desired the screw shall pull the upper piece of wood. When the screw is put in it tends to bring the holes concentric with each other, and so exercises a side pull on the wood. The pins for drawboring tenoned joints are generally made by paring them with a chisel against the bench hook or stop, first making them square with a slight amount of taper in their length, and then removing the corners to make them octagonal.

Marking Out and Cutting Mortises and Tenons. Tenoned joints are so commonly employed, and they have such special features of their own, that there are several tools which are used almost exclusively in making them. One of these is the *mortise gauge*. An ordinary gauge might be used for marking out mortises and tenons, but it would involve two operations, where one with the mortise gauge suffices. The latter has two nickers instead of one, and marks two lines representing the width of the mortise. This width, of course, can be adjusted to whatever is required, and the block of the gauge can be set in the same way as that of a single marking gauge to fix the distance of the lines from the edge of the wood. Another important tool, little used except for mortises, is the mortise chisel. It is an exceptionally stout chisel, suitable for withstanding the heavy malleting and prising necessary in cutting and clearing out mortise slots.

The mortise gauge and an ordinary square are the tools used in marking out mortises and tenons. It is essential that the wood should first be planed square and true before either square or gauge can be used with accuracy. In marking out tenons, the entire length of the wood from shoulder to shoulder is usually the important thing to look after, and generally, if the tenon goes through, some allowance is left on its end for trimming off after the work is put together [152]. The extreme ends of the wood, therefore, do not need squaring, but care must be taken to scribe the shoulder lines square. The lines for these are squared completely round the wood. Then the lines of the tenon are gauged with the mortise gauge, which is used also without alteration for the mortise lines. It is generally set direct from the chisel that is to be used to cut the mortise slot [158]. If the mortise is to go right through, it is marked out on both sides of the wood, and allowance made on the outer side for the wedges [151 and 152]. If it be for a stub tenon, it is marked on the one face, and greater care taken to cut it square from that face, undercutting the correct amount for wedges if wedges are to be inserted. When mortises are cut near the ends of wood, as at the tops and bottoms of doors, a little extra length is left on the ends for sawing off after the work is together [152]. This gives more strength for wedging, and is simpler and better than squaring the pieces exactly to length before putting together. The tenon is sawn nearly to the lines, and finished with a chisel, or in large tenons it may be sawn practically to a fit, and eased, if necessary, with a rebate plane. To facilitate insertion, the sharp corners at the ends of tenons are chamfered off with a chisel, but in the case of through tenons, the chamfered part must be trimmed off after. Usually, most of the mortise slot is first cleared out by boring a series of holes with a centre-bit, and then it is cut to the lines with a mortise chisel, which, except in cutting small amounts at the finish, is driven by a mallet [160]. The mortise chisel used should always be of the same width as the mortise, and if care be taken to hold it upright, this ensures the sides of the mortise being parallel, and of the correct width. Mortises for stub tenons should be cut slightly deeper than the length of the tenon, to ensure a close bearing at the shoulder. Wedges are sawn of the same thickness as their tenons, and glued and driven in, either at the sides [152] or into the saw cuts [154 and 155]. Stub or stump tenons [155] are used when the tenoned member has merely to withstand side thrust, and is not required to have a strong tensile hold on the mortised member. It has the further advantage of weakening the mortised member less than would be the case if a through mortise were cut; and also, being concealed, it is sometimes preferred for the sake of appearance. In some cases also, the width of the mortised member is so great that there would be no gain in strength if a tenon was carried through.

Proportions of Tenons. In ordinary framed work, mortises and tenons are usually made one-third the thickness of the stuff, and unless the width of the tenoned member is more than about six times the thickness of the tenon, the latter is made the full width of the former; except, of course, in mortises cut at ends, where the width must be reduced to leave material beyond [152 and 156]. If the tenoned

Dovetail tenons 167 Chase mortise

piece exceeds this proportion of width, the tenon is reduced, generally with a haunch, of which we shall speak immediately; or if the piece be very wide, more than one tenon is cut on its end. Fig. 161 shows what are called a *pair of tenons* cut on a wide piece. This is usually done in the middle and bottom rails of ordinary house doors. If a single tenon the full width were made, it would necessitate a mortise so large that the mortised member would be weakened very much, and there would be a risk of so wide a tenon becoming loose through shrinkage. In thick stuff, tenons are sometimes divided in the direction of the thickness, forming two thin tenons side by side, with a space between instead of one thicker one. These are called *double tenons* [163]. Mortises and tenons must always be arranged so that the long way of the mortise runs with the grain of the wood. Tenons are always formed on end grain, and mortises in side grain.

Haunching. When tenons do not extend the entire width of the member they are cut on, a short *haunch*, *stump*, or *tusk* [161 and 162] is often formed extending the full width of the member, and of the same thickness as the tenon. A shallow mortise is cut to receive the haunch, and when in place the tenoned member is thus prevented from warping as effectually as if the tenon itself was of full width. In fact, the haunch makes it equivalent to a tongued and grooved joint, and the tenon may be considered as an extension of the tongue. Haunched tenons are always employed in panelled doors, the haunches fitting in the same grooves as the panels, and extending the same distance in as the latter.

Tusk Tenon. A tenoned joint somewhat similar in principle is shown in 164. It is called a *tusk tenon*, and in this case the prevention of the member from warping is, of course, not the idea, because it is not of a section that could warp. It is the joint generally used in fitting the ends of floor joists into framing where openings have to be left for fireplaces, stairs, etc., but it is suitable for any cases where the end of one horizontal timber has to be tenoned into another. The tenon which goes through and is kept in place by a pin or wedge on the far side is of comparatively small section in order to avoid weakening the timber in which the mortise is cut, but, to enable the joist to support as heavy a weight as possible, a short tusk is made which relieves the slender tenon from a great deal of shearing stress and yet weakens the mortised timber very little. Sometimes, when the latter is very wide, the tenon does not go through, but the pin which holds it in place is driven down through a hole bored from the top. The proportions adopted for a tusk tenon are shown to scale in 164, and it is always intended of course to be used in the position shown, with the square shoulder downward and the bevelled part at the top. The haunches of tenons like 152 and 162 are sometimes tapered similarly so that they may not show when the parts are together.

Dovetail Mortise and Tenon. This is shown in 165 and 166. It is used chiefly for temporary work. As the illustration shows, it is inserted loosely, and tightened by wedges. Fig. 165 shows the end of a single rail inserted in this way, and 166 shows two rails meeting in a post. It can also, if necessary, be used for stub tenons.

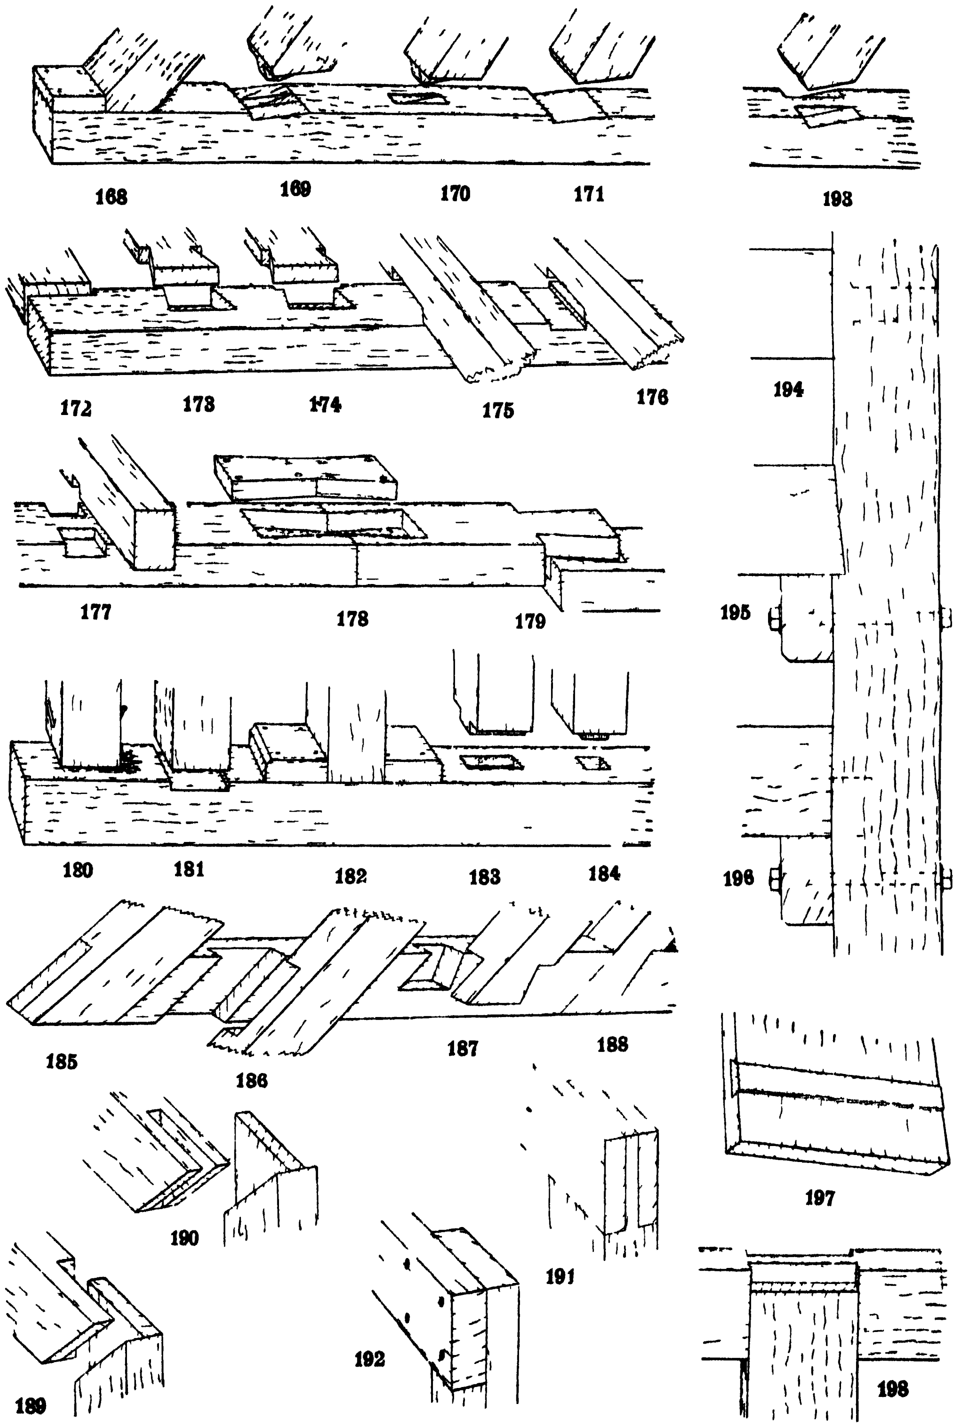
Open Mortise and Tenon, or Slot Mortise. This [153] is a slight improvement on a halved joint, and it permits of a wider, and consequently stronger, tenon than could be employed if it were enclosed in the ordinary way. Such a joint can be held together only by pins or screws, in the same way as a halved joint.

Barefaced Mortise and Tenon. This [157] is employed when the members are of unequal thickness, but are flush with each other on one face. The tenon is then shouldered back from the flush face only, and on the other face of the thin member the tenon is continuous with the surface.

Chase Mortise. The chase mortise [167] is employed in cases where a tenoned member has to be inserted after a frame has been put together, and as it is impossible to insert the tenoned ends endwise in the usual way, one of the mortises is cut away at the side for some distance, and the tenoned member inserted in the frame diagonally, with one tenon at the entrance of the ordinary mortise and the other at the end of the chase mortise. It can then be pushed sideways along the chase mortise until both tenons are in their proper place. The chase mortise is then generally filled up by inserting a strip of wood.

Oblique Mortise and Tenon. Examples of this are shown in 169 and 170. Other slight modifications of their form are possible, and sometimes employed. In 169 the end of the member itself is recessed a little way into the mortised timber, the tenon extending further still. In 170 the tenon only enters the surface of the mortised member. In another form frequently employed, the tenon is shouldered or notched back slightly from the front, and sometimes also, instead of tapering to nothing at the back, some amount of depth is given to it there. Occasionally the tenon is notched, giving it the appearance of two saw teeth, one behind the other. Sometimes a joint the exact reverse of a mortise and tenon, known as a *bridle joint* [193], is made. It has no particular advantage of its own, except that it is then possible to see from the outside whether it is in close contact everywhere. Figs. 168 and 171 show two simpler forms of joint which might be used under the same circumstances. In 168 a block is nailed on the surface of one member to take the thrust of the other. In 171 the member is notched out to provide a shoulder for taking the thrust.

Miscellaneous Joints. There are a number of joints commonly employed, some of which are closely allied to the tenoned joint or to the simpler forms already described. Figs. 172 to 177 show methods of connecting timbers which meet, or cross at right angles. Fig. 172 is a rebated joint which is employed to resist pressure inwards on either member; 173 is a dovetailed joint to resist tension; 174 is a similar joint, except that its end is housed to enable it to withstand



TIMBER JOINTS

168 Oblique butt joint in which thrust is taken by a block 169 End of member recessed and stub tenoned into the surface 170 Stub tenoned only 171 Recessed only 172 Rebated joint 173 Dovetailed joint 174 Dovetailed and housed joint 175 Notched joint 176 Double notched joint 177 Cogged joint 178 Dovetail key uniting pieces end to end 179 Dovetail formed on the end of one piece 180 Skew nailed butt joint 181 Rebated or housed joint 182 Stepped joint 183 Stub tenon 184 Joggle 185 Halved oblique joint between two ends 186 Halved joint between pieces crossing obliquely 187 Halved dovetail joint not going completely through 188 Similar dovetail which does go through 189 Half lap mitred on one face and square on the other 190 Open mortise and tenon with mitred shoulders 191 Open mortise and tenon dovetailed 192 Plain lap 193 Bridle joint 194 Housed and tenoned joint 195 Notched joint with cleat 196 Stub-tenoned joint with cleat 197 Dovetailed key 198 Forked tenon

downward pressure; **175** is a notched joint to prevent the notched timber from moving endwise; and **176** shows a double notched joint to prevent either timber from moving endwise. If the timbers were sunk flush with each other, it would be a halved joint. Fig. **177** is a cogged joint used for preventing end movement between timbers which cross. The lower one is thus not weakened so much as it would be if notched entirely through, while another advantage is that, even if the end of the upper one be flush with the outer face of the lower, there is still some amount of end grain to prevent the upper from moving back. Fig. **178** illustrates a separate dovetailed key uniting timbers end to end; **179** is an end joint in which the key is formed on the end of one of the timbers; **180** to **184** show joints adopted for connecting verticals with horizontals, the horizontals being either above or below; **180** is a simple butt joint, skew-nailed, or in large joints, spiked, not possessing, of course, very much strength except to resist direct downward pressure; and **181** has its end let into a shallow recess or rebate, and would be called a *housed joint*, though, strictly speaking, a housed joint is one in which the end of the member is enclosed on all sides. In **182** the vertical is held in practically the same way, the only difference being that, instead of a recess being cut in the horizontal, two blocks or steps are nailed on each side to enclose the end of the vertical. Fig. **183** is a simple stub tenon, and **184** a joggle. Another good method for a wide post would be double tenons as in **136**.

Some More Complicated Joints. In addition to these, there are other more complicated joints, mostly without any corresponding advantage, which might be employed. Figs. **185** to **188** are oblique halved joints, which otherwise do not differ from forms already described. Fig. **189** is a corner joint which is simply a half-lap mitred on one face and square on the other, the mitre being made for neat appearance, and at considerable sacrifice of strength. Fig. **190** is an open mortise and tenon with mitred shoulders; not so strong as square shoulders, but even with its double mitre rather stronger than **189**; **191** is a dovetail, a very substantial joint, superior to a mortise and tenon for resisting tension. In **191** the dovetail is formed to resist outward pressure on the vertical member, but it could, if necessary, be tapered the other way to prevent the horizontal from being forced upwards. Fig. **192** is a plain lap joint, which would have to be screwed or bolted together; **197** shows a tapered and V-edged key fitted in a corresponding groove across a wide piece of wood to strengthen and prevent the latter from curving or warping. It may be planed flush with the surface, or allowed to stand a little above it, as in the illustration, the advantage of the latter method being that it is thicker, and therefore less likely to get bent itself by the large piece. On the other hand, the flush surfaces are neater, and sometimes essential. When there is no objection to a thick key standing above the surface, it is often a question whether a simple batten screwed on instead would be preferable.

Heavy Timber Joints. Figs. **194** to **196** show some methods of connecting beams with posts in heavy timbering; **194** very much resembles the tusk tenon in **164**, but it is stronger than the latter, because the entire depth of the horizontal is housed, which in **164** is impossible. The entire depth and width of the horizontal is supported in the housing, and therefore could not shear off, except under a weight that the beam itself was too small in section to sustain. Housing is often practised in jointing horizontal members when they happen to be of smaller section than the members that support them. Fig. **195** is another example which, although it is open at the sides, has its entire section supported. In this case, a shallow notch is cut in the vertical, and the support increased by bolting a cleat beneath. The notch may be either parallel in the form of a rebate, or tapering to nothing at the top, the latter method not weakening the post quite so much, but the difference is hardly worth considering.

In **196** the end of the beam is tenoned into the post and supported also by a cleat. A stub tenon formed on the lower half of the end is used so that the beam is supported from the bottom. The cleat in both cases is shown bolted to the surface, but it might be made more secure by notching it in the same way as the end of the beam in **195**. Fig. **198** is called a *forked tenon*, but it is practically the same thing as the open mortise and tenon [**153** and **190**], except that it occurs at an intermediate position instead of at an end. It is sometimes used in framed work when the forked end has to support the other in a horizontal position, as in the illustration. It holds it more securely than if it was tenoned into it in the ordinary way; but, on the other hand, the horizontal is very much weakened by cutting so much material from its body. The edges of this joint are generally slightly veed or undercut in order to keep the main surfaces of the joint in close contact.

PERMUTATIONS AND COMBINATIONS

Number of Ways of Arranging Things when Some are Alike.
The Binomial Theorem. Proof for a Positive Integral Index

Group 21
MATHEMATICS
28
ALGEBRA

continued from page 3915

By HERBERT J. ALLPORT, M.A.

PERMUTATIONS

161. The number of *arrangements* of r things which can be formed from n things is called the number of *permutations* of n things r at a time. This number is denoted by ${}^nP_r$.

For example, if we have three letters, a, b, c, the number of permutations which can be formed by choosing the letters two at a time is six. The permutations are

ab, *ac*, *bc*, *ba*, *ca*, *cb*.

162. To Find ${}^nP_r$. Since there are n different things, one thing can be chosen in n ways. Having chosen one thing, there will be $(n-1)$ things left, so that a second can be chosen in $(n-1)$ ways. Now, when a second thing is chosen, it can be placed with any one of the n ways of choosing the first; hence, from *each* way of choosing the second thing we get n ways of choosing *two* things. Therefore, since there are $(n-1)$ ways of choosing the second, we get $n\,(n-1)$ ways of choosing two things.

Again, when two things have been chosen in any one of these ways, a third thing can be chosen in $(n-2)$ ways; thus, since two things can be chosen in $n\,(n-1)$ ways, and a third in $(n-2)$ ways, the number of ways of choosing three things is $n\,(n-1)\,(n-2)$.

Proceeding in this manner, we see that the number of ways of choosing r things is

$$n\,(n-1)\,(n-2)\ldots\text{to } r \text{ factors}.$$

Now the rth factor is evidently $n-(r-1)$, or $n-r+1$. Hence we get

$$-{}^nP_r = n\,(n-1)\,(n-2)\ldots(n-r+1).$$

163. If we put $r=n$ in the result of Article **162**, we obtain the number of ways of arranging n different things amongst themselves.

Thus $\quad {}^nP_n = n\,(n-1)\,(n-2)\ldots3\,.\,2\,.\,1\,.$

This expression, consisting of the product of the first n natural numbers, is denoted by the symbol $|\underline{n}$ or $n\,!$ and is called "factorial n."

164. *To find the number of permutations of n things taken all together, when the things are not all different.*

Suppose the n things are letters, p of them being a's, q of them b's, r of them c's, and the rest all different. Let x be the required number of permutations. Now each permutation contains the whole of the n letters, so that each contains p letter a's. Suppose that instead of these a's we put in p letters which are different from one another and from all the rest. Then, by arranging these p letters we get $|\underline{p}$ permutations [Art. **163**] instead of a single permutation. Treating each of the x permutations in the same way, we should obtain $x\times|\underline{p}$ permutations.

Again, each of these $x\times|\underline{p}$ permutations contains q letter b's, and, exactly as before, if we change these q letters into letters which are different from one another and from all the rest, we should obtain $|\underline{q}$ permutations from each of the $x\times|\underline{p}$ permutations. Hence the number of permutations will now be $x\times|\underline{p}\times|\underline{q}$.

Similarly, by changing the r letter c's, we get

$$x\times|\underline{p}\times|\underline{q}\times|\underline{r}\ \text{permutations.}$$

But the n letters are now all different, and, therefore, the number of ways of arranging them is $|\underline{n}$ [Art. **163**].

$$\therefore\ x\times|\underline{p}\times|\underline{q}\times|\underline{r} = |\underline{n},$$

and $$x = \frac{|\underline{n}}{|\underline{p}\ |\underline{q}\ |\underline{r}}.$$

COMBINATIONS

165. The number of *groups* of r things which can be chosen from n things, without regard to the *arrangement* of the r things in each group, is called the number of *combinations* of n things r at a time. This number is denoted by ${}^nC_r$.

166. To Find ${}^nC_r$. Each combination contains r different things, and, by Art. **163**, these r things can be arranged in $|\underline{r}$ ways. Hence, each combination gives rise to $|\underline{r}$ permutations, so that

$$|\underline{r}\times{}^nC_r = {}^nP_r.$$

Therefore,

$${}^nC_r = \frac{{}^nP_r}{|\underline{r}} = \frac{n\,(n-1)\,(n-2)\ldots(n-r+1)}{|\underline{r}}.$$

By multiplying numerator and denominator of the expression on the right by $|\underline{n-r}$ we get another form of the result, *viz.*,

$${}^nC_r = \frac{n\,(n-1)\,(n-2)\ldots(n-r+1)\,|\underline{n-r}}{|\underline{r}\ |\underline{n-r}} = \frac{|\underline{n}}{|\underline{r}\ |\underline{n-r}}.$$

167. *The number of combinations of n things taken r at a time is equal to the number of combinations of n things taken $(n-r)$ at a time.*

For, in taking r things away from n, we leave $(n-r)$ things behind. Hence the number of ways of choosing $(n-r)$ things is the same as the number of ways of choosing r things; that is $\quad {}^nC_r = {}^nC_{n-r}$.

EXAMPLES 35

1. How many different numbers can be formed by using one or more of the numbers 1, 2, 3, 4?

2. How many permutations can be formed by taking all the letters of the word *Philadelphia*?

3. In how many ways can six people sit at a round table?

4. In how many ways can three boys and two girls be chosen from six boys and three girls?

5. If ${}^nC_7 = {}^nC_8$, find ${}^nC_3$.

6. Of the permutations formed by using all the letters of the word *successes*, how many have *s* at each end?

THE BINOMIAL THEOREM

168. In Article **27** it was shown that the product of two compound expressions is obtained by taking the sum of the products formed by multiplying every term of the one expression by every term of the other. In the same way we obtain the continued product of any number of expressions by taking the sum of all the products formed by multiplying together any term of the first, any term of the second, etc.

Suppose we have n factors, each of which is $(a+b)$, and that we wish to form their product. If we take a letter from each factor and multiply these letters together we obtain a term of the product. By doing this in every possible way we obtain every term of the product.

We can take the letter a from each factor, and this can only be done in one way. Hence a^n is a term of the product. Again, b can be taken from one factor and a from the remaining $(n-1)$ factors; the number of ways in which one b can be chosen is the number of ways of choosing one thing out of n things, or ${}^nC_1$. Thus the product $a^{n-1}b$ can be formed in ${}^nC_1$ ways, so that ${}^nC_1a^{n-1}b$ is a term of the continued product. Similarly, b can be taken from 2 factors and a from the remaining $(n-2)$; the number of ways of choosing two b's is ${}^nC_2$, so that ${}^nC_2a^{n-2}b^2$ is a term of the continued product.

Proceeding in this way, we obtain

$$(a+b)^n = a^n + {}^nC_1a^{n-1}b + {}^nC_2a^{n-2}b^2 + \dots + {}^nC_{n-1}ab^{n-1} + {}^nC_nb^n;$$

or, using the values of ${}^nC_1$, ${}^nC_2$, etc. [Art. **166.**],

$$(a+b)^n = a^n + na^{n-1}b + \frac{n(n-1)}{1.2}.\ a^{n-2}b^2 + \dots + nab^{n-1} + b^n.$$

This formula is the *Binomial Theorem*, and the expression on the right is called the *expansion* of $(a+b)^n$.

Example. Expand $(2x-y)^4$.

By putting $a=2x$, $b=-y$, $n=4$, in the above formula, we obtain

$$(2x-y)^4 = (2x)^4 + 4\,(2x)^3\,(-y) + \frac{4.3}{1.2}(2x)^2\,(-y)^2 + 4\,(2x)\,(-y)^3 + (-y)^4$$

$$= 16x^4 - 32x^3y + 24x^2y^2 - 8xy^3 + y^4 \quad \underline{Ans.}$$

169. General Term. In the expansion of $(a+b)^n$ a term of the continued product is formed by taking b from r of the factors and a from the remaining $(n-r)$ factors. Now r b's can be chosen from n in ${}^nC_r$ ways, so that

${}^nC_ra^{n-r}b^r$ is a term of the expansion.

By giving a suitable value to r we obtain any term in the expansion; ${}^nC_ra^{n-r}b^r$ is therefore called the *general* term.

Note that in Art. **168** the index of b in the second term is 1, in the third term is 2, and so on; hence the term containing b^r is the $(r+1)$th term, not the rth.

Example. Find the 7th term of $(3a-1)^{11}$.

$$\text{7th term} = {}^{11}C_6\,(3a)^{11-6}\,(-1)^6$$

$$= \frac{11.10.9.8.7}{2.3.4.5}.\ 3^5.\ a^5$$

$$= 112266a^5 \quad \underline{Ans.}$$

170. In the expansion of $(a+b)^n$ the coefficient of the $(r+1)$th term from the beginning is ${}^nC_r$.

The coefficient of the $(r+1)$th from the end, *i.e.*, the $\{(n+1)-r\}$ or $(n-r+1)$th from the beginning, is ${}^nC_{n-r}$.

But ${}^nC_r = {}^nC_{n-r}$ [Art. **167**], hence, *in the expansion of* $(a+b)^n$ *the coefficients of any two terms equidistant from the beginning and end are the same.*

171. The most useful form of the Binomial Theorem is obtained from the result of Article **168** by putting $a=1$ and $b=x$. This gives

$$(1+x)^n = 1 + nx + \frac{n(n-1)}{1.2}x^2 + \dots + x^n.$$

Example.

$$(2x+3a)^5 = (2x)^5\left(1+\frac{3a}{2x}\right)^5$$

$$= 32x^5\left\{1 + 5.\frac{3a}{2x} + \frac{5.4}{1.2}.\frac{9a^2}{4x^2} + \text{etc.}\right\}$$

$$= 32x^5 + 240x^4a + \text{etc.}$$

172. The formula of Article **171** has only been proved for the case where n is a positive integer, but the result is true for *all* values of n, provided x is less than 1. We shall not give a proof of this, but an example will show the application of the formula to cases in which n is not a positive integer.

Notice that, if n is not a *positive* integer, no one of the factors n, $n-1$, $n-2$, etc., can be zero, so that the expansion is endless.

Example. Expand $(1+x)^{-\frac{1}{2}}$

The formula gives

$$(1+x)^{-\frac{1}{2}} = 1 + \left(-\frac{1}{2}\right)x + \frac{\left(-\frac{1}{2}\right)\left(-\frac{1}{2}-1\right)}{1.2}x^2 + \frac{\left(-\frac{1}{2}\right)\left(-\frac{1}{2}-1\right)\left(-\frac{1}{2}-2\right)}{1.2.3}x^3 + \dots$$

$$= 1 - \frac{1}{2}x + \frac{1.3}{2.4}x^2 - \frac{1.3.5}{2.4.6}x^3 + \dots \quad \underline{Ans.}$$

Answers to Algebra

EXAMPLES 34

1. 86.
2. 5, 8, 11, 14.
3. 512.
4. (i.) 360, (ii.) 25, (iii.) $4\frac{19}{48}$, (iv.) $\frac{3+\sqrt{3}}{2}$.

EXAMPLES 35

1. ${}^4P_1 + {}^4P_2 + {}^4P_3 + {}^4P_4 = 4+12+24+24 = 64.$

2. $\dfrac{\lfloor 12}{(\lfloor 2)^6} = 14968800.$

3. $\lfloor 5 = 120.$

4. ${}^6C_3 \times {}^3C_2 = 20 \times 3 = 60.$

5. ${}^nC_7 = {}^nC_8 = {}^nC_{n-8}$ [Art. **167**]. Therefore, $n-8=7$, and $n=15$. Hence, ${}^nC_3 = 455$.

6. Taking away two s's first, we can arrange the remaining letters in $\dfrac{\lfloor 7}{\lfloor 2\ \lfloor 2\ \lfloor 2}$, or 630 ways. The letters taken away can be put one at each end of any arrangement. Hence the required number is 630.

Algebra concluded

SUGAR-BEET GROWING

Propagation, Selection, and Characteristics of Beetroots. Sowing, Hoeing, and Harvesting. Manures. Beet-growing in the United Kingdom

continued from page 3881

SUGAR beet is grown in all the countries of Europe from Sweden in the north to Spain, Italy, and Greece in the south. It is cultivated in Canada and the United States, Australia, South Africa, Persia, and Siberia. The plant (*Beta vulgaris*) is indigenous to the South of Europe.

Propagation. Beet is propagated from seed. The original beet has been improved by a careful selection of the best sugar bearers, and judicious and scientific fertilising have evolved beets which contain as much as 18 per cent. of sugar. Vilmorin, of Paris, was the pioneer in this work of selection, and his successors, Vilmorin, Andrieux & Co., are still recognised as the premier house for beet seed. In England the houses of Sutton and Carter have paid considerable attention to the production of a good sugar-bearing beet, and both sell a good seed suitable for growing in England.

Selection. The method of selection is as follows: The beetroots which show least root above ground are pulled and stored, and in the spring those richest in sugar are planted out for seed. Richness in sugar is found by putting the roots into a solution of salt or sugar of the specific gravity of 1·065 to 1·070. Roots rich in sugar sink, and these are selected for planting, those floating being rejected. This test is a rough one, but answers well, a more scientific method being to test small quantities of the juice by the *polariscope.* The beets selected are placed in the ground and long seed stalks spring from them. The stalks are supported by sticks, and when the seeds are nearly ripe the stalks are cut and the ripening finished by hanging in sheds in a current of air. The yield of seed is about 15 cwt. per acre. Beet giving a large sugar yield costs no more to grow than beet with a small yield, so that the selection of seed is an important matter to the grower. Illustrations are given of the Vilmorin Improved, the White Silesian, from which the former is descended and sometimes regarded as a distinct species, and the Imperial [9]. Other well-known kinds are the Klein-Wanzleben, and Heine's Vilmorin [see Plate facing page 3649].

Characteristics of Good Beet. The shape and manner of growing of the beet are important. The most desired characteristics are thus summed up by Lock:

1. Beets should have a regular pear-shaped form and smooth skin.

2. They should not have a tendency to throw out forks or fingers and toes.

3. The flesh should be firm and white, the structure uniform, and the flavour "clean." Thin-skinned beets are preferable, as the thick-skinned varieties are frequently spongy and always more watery.

4. The beets should weigh 1½ lb. to 2½ lb. each, as neither very large nor very small roots are profitable to the manufacturer.

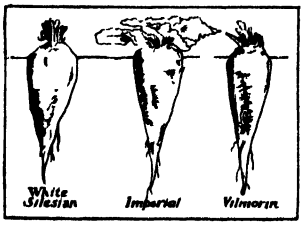
5. Good beets have no tendency to become necky, and their tops are always smaller than those of inferior beets. The large-leaved are preferable to the small-leaved varieties.

6. Good beets are denser than water. The quantity of sugar is roughly estimated as stated above. If the beets sink in a liquid of 1·07 sp. gr. the percentage of sugar is about 14.

7. The roots should grow entirely in the ground in properly prepared soil.

Range of Temperature. Authorities are agreed that temperature has to be considered in beet cultivation rather than the rainfall. Sugar formation is favourably influenced by dry weather in the autumn. A mean summer temperature of 70° F. for 90 days is sufficient to mature beetroot; if the temperature be much above this the amount of sugar is diminished. The crop must be matured and safely harvested before the frosts set in.

Soil. Any good soil that will grow wheat and has an arable depth of 12 in. to 15 in. is well suited for beet culture; it must be well drained. Where a large proportion of chalk is present in the soil the juice yield of the beet is small but of good quality. In the United States, Dr. H. C. Meyers devoted much time to the study of the growth of beet in alkaline soil such as exists in Utah. The locality in which the experiments were made was at Hooper, slightly above the mud flats of Great Salt Lake. Dr. Meyers found that moderate irrigation tends to carry the salts in the soil down to below the plant roots, and that by deep tillage, maintained throughout the season, evaporation and rising of the alkali may be largely prevented. Alkali soils have a great advantage over other soils in case of drought, in that the hygroscopic salts present take up and retain moisture which is available for plants. The tendency of the beet is to purify the soil by taking up alkali constituents ruinous to common crops. The importance of these observations is that arid regions unsuitable for any other crop may be utilised for beet.



9. SUGAR BEETS

Sowing. In Great Britain April is the time for sowing beet seed. The frosts should be over, because if the sowing be done too early and the plants become frost-bitten it will be necessary to plough up the first sowing and sow afresh. Some sow the seeds in continuous lines along ridges which have been thrown up from 14 in. to 18 in. apart. The ground should have been stirred up to a depth of 12 in. by the cultivator or subsoil plough, and if manured, the manure is ploughed in 5 in. deep. A better way than the continuous line is to dibble the seeds, three in each hole. To keep the beets down to the limits of size—½ lb. to 2½ lb.—they are planted with about 8 in. between the roots, bearing in mind that some of the new kinds of beet with strong foliage require the rows to be up to 20 in. apart instead of the 18 in. limit just referred to. The seedlings are allowed to grow until 3 in. to 4 in. high, and where more than one plant has come up from each hole, the weakest are pulled up, and any misses filled up with these plants. The quantity of seed required, if sown in continuous line, is 10 lb. to 15 lb. an acre; if dibbled in, 5 lb. to 7 lb.

Hoeing. As soon as the plants appear above the ground the soil should be kept loose and free from weeds by hand hoeing. After thinning and until the plants have grown too large, the horse hoe may be used two or three times, its work being finished off each time with a hand hoe. The soil should be earthed up so as to cover the roots. If any plants begin to send up stalks, the stalks should be at once broken off.

Harvesting. The crop must not be harvested until it is ripe, but at the same time it should not be left to be injured by the frost. In from three to seven months the leaves begin to droop and turn yellow, leaving exposed on the top of the root a crown of young green sprouts. As soon as this takes place, the roots are ready to be pulled. If the autumn be cold and dry, the roots may be left without injury for a week or ten days later, but if the weather be mild and moist, new growth would be encouraged, which is undesirable. The roots are pulled by hand labour, but more economically by special harvesters, consisting of a fork on wheels, drawn by horse power. The roots are caught by the prongs of the fork, which pulls them out of the ground and drops them. Care is taken not to puncture or bruise the roots, as this means loss of sugar. The earth is shaken off the roots, the leaves and crown cut off, and the beets carted to the factory. If the roots are to be stored in silos, only the leaves are removed, and they are stored as soon as possible in well-ventilated underground trenches covered with soil, or in properly constructed silos [see AGRICULTURE, page 1970], the object in storing being protection from the consequences of overheating, frost, and too rapid sprouting.

Use of Manures. The use of manure depends on the nature of the soil. It is generally recommended not to manure the beet crop directly, but to heavily manure a preceding cereal crop, and let the residue of manure serve for the beet. With modern artificial manures, however, the amount of manure can be adjusted to actual requirements, making it advantageous to manure the crop directly instead of indirectly. Nitrogenous compounds have a tendency to extend the period of growth and delay the time of ripening. This tendency must be corrected by phosphates. The Victorian Department of Agriculture recommend for light dressing 2 cwt. of sulphate of ammonia and ⅘ cwt. of superphosphate, and for heavy dressing 4 cwt. of sulphate of ammonia and 1⅗ cwt. of superphosphate per acre. Where potash is needed, ⅔ cwt. to 1⅓ cwt. of kainite may be used.

Sugar Factory Refuse as Manure. The cost is heaviest the first year, because subsequently the refuse of the sugar factory is returned to the land, and goes a good way in keeping the soil manured. Stable manures must be used either on the preceding cereal crop, or worked into the soil in the autumn ploughing. Chili saltpetre or nitrate of soda can be used in place of sulphate of ammonia, and the calcium nitrate produced electrolytically in Norway is equally efficient. The United States Government have carried out a large number of experiments on the effect of manures on beet crops. The fertiliser was found to increase the yield of beets but not the percentage or the purity of sugar. The use of 500 lb. of fertiliser per acre decreased the cost of the beets 11d. per ton; the application of larger quantities did not produce any further decrease in the cost of beets, so that 500 lb. is the most economical quantity to use. When 20 tons of stable manure per acre were applied instead of artificial fertiliser, an increase of yield was found in every case as compared with unmanured plots, the average increase being 8,720 lb. per acre. The percentage of sugar was increased by an average of 1·5. In growing beets at different distances apart in the rows, it was found that the nearer the beets were to each other the smaller was the yield per acre, and the size of the roots was also less.

Diseases. Beet is sometimes attacked by grubs of the beet canon-beetle (*Sulpha opaca*), the beet or mangold fly (*Anthomyia betæ*), and the silver moth (*Plusia gamma*). These are overcome by spraying the upper and under sides of the leaves with Paris green solution. A disease known as "jaundice" is prevalent in the northern parts of France, and generally makes its appearance during the first fortnight in July. When the plant is first attacked the leaves begin to droop and become mottled with white translucent spots. It has been found that this is due to bacteria, and as the sugar yield is reduced by a half in diseased roots, the refuse from the crop should be burnt before being returned to the land. When stored in silos, a slight loss of sugar takes place, and "greying" of sugar has been traced to dry-rot which sometimes sets in during storage.

Yield of Beet. An acre of roots weighing 2 lb. each, and growing 10 in. apart in rows 15 in. apart, would, if there were no misses, yield 40½ tons of dressed roots. The heaviest yield has been 65 tons, but 25 to 35 tons may be reckoned as the average. At 15s. a ton, this would yield from £18 15s. to £26 5s. per acre, the estimated cost being about £8 per acre, leaving a direct profit of £10 to £18 per acre. This question has been dealt with by Mr. Sigmund Stein, who is a persistent advocate of beet-growing in England. His figures come out at £7 15s. 5d., made up as follows

	Per acre. £	s.	d.		Per acre. £	s.	d.
Rent and taxes ..	1	0	0	Brought forward	3	1	0
Cleaning and forking weed stubble	0	1	0	Cultivating . ..	0	6	0
Ten loads farmyard manure and carting	1	11	0	Artificial manure..	1	10	0
Spreading manure	0	1	0	Seed	0	6	8
Ploughing 8 in. to 10 in. deep	0	8	0	Sowing	0	2	6
				Drilling, hoeing, and thinning ..	0	11	0
				Harvesting ..	0	10	0
				Carting	1	8	3
Carried forward	3	1	0		£7	15	5

Mr. Stein, reckoning on a minimum crop of 15 tons per acre, obtained on the balance-sheet a profit of £7 4s. 7d., as follows :

Dr.	£	s.	d.	Cr.	£	s.	d.
Cost per acre to cultivate	7	15	5	15 tons beet at 18s. per ton..	13	10	0
Extra carting to the factory	1	10	0	Value of 5 tons leaves and heads from roots	1	5	0
Profit per acre ..	7	4	7	3 tons spent slices at 10s.	1	10	0
				Value of saturation lime (free from factory)	0	5	0
	£16	10	0		£16	10	0

Yield of Sugar. The mean sugar content of 1,200 samples of beet analysed by Graftian, a Belgian chemist, in 1898, was 16·4 per cent., the extremes being 20·2 and 12·5 per cent. About half the sugar is obtained as *first* sugars, the rest being divided between *second* sugars, *third* sugars, molasses, and losses. The average percentage of water in the beetroot is 77·69, and in the juice extracted 81·51, the average specific gravity of the juice being 1·077.

In 1879, a Select Committee of the House of Commons was appointed to inquire into the effect produced upon the home and colonial sugar industries of Great Britain by the bounty system in those countries which manufacture sugar for export. One of the witnesses, Mr. James Duncan, stated that Great Britain was adapted for beet cultivation, but that the bounty system of foreign countries, averaging £2 a ton, acted as a preventive of successful production of beet sugar in the British Isles. Dr. Voelcker, chemist to the Royal Agricultural Society, stated that he found 12 per cent. of sugar in roots grown in Suffolk; 12·5 to 13 per cent. in roots from Berkshire; 11·75 in roots from Surrey; 10·5 to 13·25 in roots from Yorkshire, and 10, 12, and 13, up to 15 per cent. in roots from Killarney. Mr. Martineau had roots grown in Lincolnshire and the Isle of Thanet, and obtained 15 per cent. of sugar, compared with the average (at that time) of 10·5 per cent. in France.

Experiments in Great Britain. The factory which Mr. Duncan started was at Lavenham, but the venture was not a success. The quality of the beets improved year by year, but the farmers did not properly modify their rotations to secure a sufficient supply of beets for working at a profit. Sir J. B. Lawes and Sir J. H. Gilbert published, in 1898, a valuable summary on the conclusions they had arrived at as to the growth and manufacture of sugar in the United Kingdom. On the whole, the authors were rather sceptical as to the suitability of England as a beet-growing country, and although satisfactory crops could be obtained in certain districts, the results on the whole country, and on an average of seasons, were not, they said, likely to be profitable.

England too Cold. The perfected beetroot grown abroad is supposed to require an average temperature of 70° F., while statistics show that the mean temperature for July, the hottest month in the year is, in England, only 62·5° F., and for September and October, 50° F. and 43·2° F. respectively. These latter are the critical months during which the beet matures and ripens, and in England, October is nearly always rainy, and often frosty. Nevertheless, in favourable districts, it is probable that in the majority of seasons, a fair quality of beet for the manufacture of sugar could be grown if proper care were taken to gather the harvest before the early frosts appeared. These investigators strongly recommended the planting of the roots close together whereby the luxuriance of the foliage is limited, the purity of the juice increased and earlier ripening secured. Norfolk or Suffolk they considered most suitable for beet cultivation, the climate being appropriate, and the soil neither too light nor too heavy. They added that even if the Continental sugar bounties were reduced or abolished, beet growing could never be commercially profitable for the agricultural districts of Great Britain as a whole.

Why England should Grow Beet. Mr. Sigmund Stein, of Liverpool, has for years advocated beet-growing in England, and in December, 1905, he discussed the subject in a paper read before the Society of Arts. He enumerated the advantages which Great Britain possesses over Continental competitors. (1) We can grow more roots per acre; (2) we can grow richer roots than on the Continent (3) we have the consumption at hand, since we are the greatest sugar consumers in the world; (4) we save freight; (5) we save commission, as the factory sells direct to the consumer; (6) we can make use of the latest improvements in cultivation and manufacture by having at our disposal the best implements and machinery; (7) we can manufacture refined sugar direct at a very low price; (8) we can employ the plant of our works in the summer months after the campaign is over much better than the factories can do on the Continent, as we have many other industries in this country which could be well carried out in this factory.

The growing of beetroot is to be this year (1906) introduced in Essex for the manufacture of sugar on the spot, the Ipswich Chamber of Agriculture taking a great interest in the experiment.

CHILDREN'S CLOTHING
continued from page 3856

A CHILD'S WARDROBE

Day and Night Wear: Cutting, Drafting and Making. Frocks. The Sailor Blouse. Kilted and "French" Frocks

By AZÉLINE LEWIS

HAVING provided garments for the infant, we will proceed with those required from the toddling stage till three to four years old.

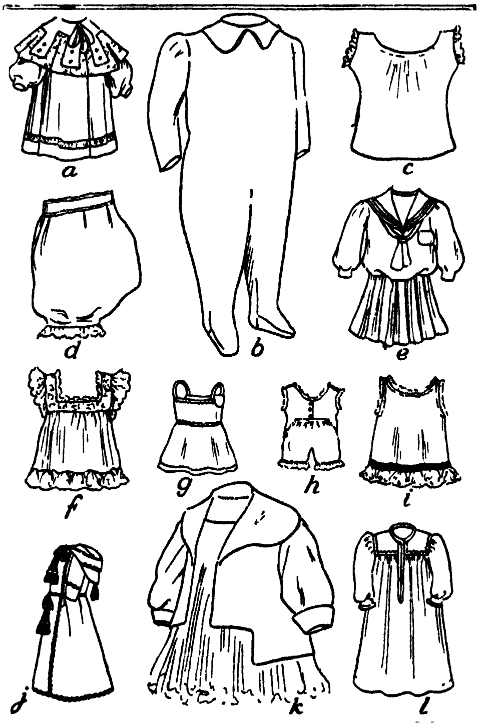
The remarks already made as to allowance for growing must be observed in these, as, indeed, in all children's garments, but more particularly in the very early stages of existence when growth is very rapid. All neck, waist, and wrist bands should be large enough, but not exaggerated, which remark applies also to the size, as over-much fulness means added weight and consequent discomfort to the child.

This brings us to another important point. As the infant grows so its activity increases, and it is then able to keep up the circulation and the warmth of the body by movements. The clothing, therefore, should be light and sufficiently warm, but not too warm, as this induces perspiration and fatigue. The flannel for the underwear should not be of a heavy or close kind, whilst the material selected for the petticoats and frocks should also be of a light make.

Fussy or starched frilling round the neck should be avoided, and, from the point of view of the child's health and comfort, the simpler the garment the better.

Day and Night Wear. The little woolly vest is still worn under the little chemise of finest cambric or longcloth. The latter, however, in a woollen-clad baby's wardrobe, would be of the finest wool or nuns' veiling, when the vest would be dispensed with.

For the first year, the pilch No. 1 is required, also the stork pants, which may be needed a little longer. After this the little drawers shown in 21*d* are better. A little stay bodice of cambric, or soft woollen material, is worn over the chemise, made to flap over somewhat after the style of the bodice for the long flannel in 1. A knitted one, however, is preferable, as it is so much more elastic.



21. CHILD'S OUTFIT

The little flannel petticoat is attached to this, whilst the upper one is better made all in one, or buttoned on to a bodice of the same material. In America a little suspender bodice for the diapers finds much favour. This is made like a little chest protector—back and front—with elastic at the lower edge.

Over the second petticoat comes the frock, and indoors a dainty cambric pinafore would be worn.

A small dressing-gown is a welcome addition to the wardrobe after the first year, and the Dominican shape in the sketch is a very comfortable little model [21*j*].

With respect to night attire, the sleeping suit is undoubtedly the best for the active little mite, and, as a baby will kick, even at night, the footed shape is the best from one to two and three years of age. This covers the entire body, and may prevent chills. It is, of course, made of flannel.

As the child is now able to sit up, there is not the same objection to passing the clothes over the head as in the case of a tiny infant, but it is advisable that they should be easily and quickly put on, with as little twisting and turning as possible.

The necessary and most usual garments for a child from one to four years are shown in **21**: (c) shows the small chemise which can be worn at this age, though many mothers prefer the little combination garment shown at (*h*); (*g*) gives a flannel petticoat with shaped skirt part and little bodice to match, feather-stitched round the edges; (*i*) is the most usual shape of over petticoat cut in one, princess fashion, and trimmed with tucks, feather-stitching and embroidery; (*l*) is a small nightgown, with square yoke, made of longcloth, flannel, nun's veiling, or Scotch wincey, which both washes and wears admirably, and is equally useful for frocks as well as underwear. In (*b*) we have the footed sleeping suit already referred to, whilst (*j*) shows the dressing gown—of Dominican form—which makes a very cosy little wrap for a tiny tot.

Yoked frocks are the same as those for the first stage, so at (*e*) we have only selected a little sailor frock as a model; (*k*) shows a little matinée coat, and (*a*) a long sacque coat with cape, whilst (*f*) depicts a simple little pinafore with square embroidery yoke; (*d*), of course, shows the little drawers.

Various alterations and modifications arise from time to time, but in the main the patterns remain the same, and those selected are the usual shapes. As far as the coats are concerned, the alteration usually affects the collar or neck portion, and the trimming generally.

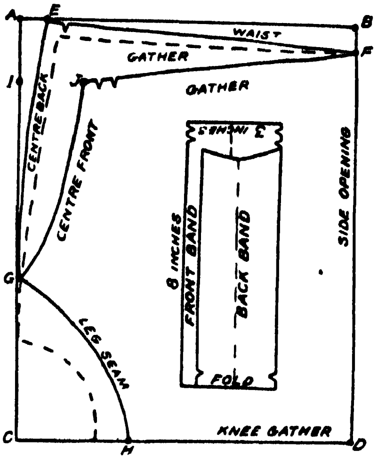
For the hygienic "second-stage set" the same principle should be followed as in the first, and the same models may be used with the necessary abbreviations of skirt and enlargement of bodice. The garments should fasten alternately, as already mentioned.

The Drafting. We will now consider the diagrams for the clothes mentioned. The chest measurement may be from 22 in. to 26 in. Neck, 10 in. to 12 in.; wrist, 6 in. to 8 in. Length from neck to hem, 20 in. to 24 in.—depending on the style of frock. If the Dutch style be selected, this, of course, would be longer.

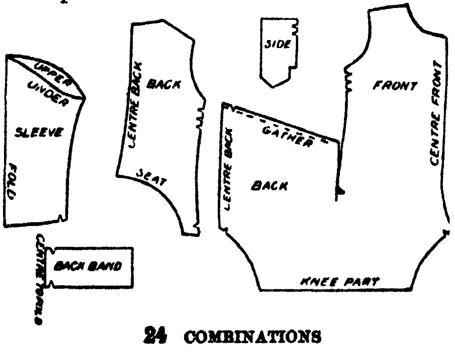
Diagram 22 shows the first chemise, which will require ½ yd. of 36-in. material to make two, folded over with selvedges in centre and fold on each side.

A to B and C to D are 8 in.; A to C and B to D are 13 in.; A to E, 2 in.; A to F, 3 in.; A to G, 5½ in.; B to I, 4 in.; I to H, 1½ in.; D to J, 1½ in. Curve from F to E, G to H, and H to J and C.

This little chemise may be fastened on the shoulder, or down the front, as preferred; in the latter case, the centre would be slit down and hemmed. If preferred gathered round the neck, add on one or two more inches to centre, and carry the slopes of E and C to meet this.

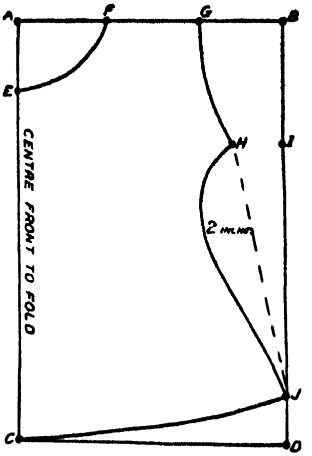


23. FIRST KNICKERS



24 COMBINATIONS

In 23, we have the second stage drawers, the pilch illustrated in No. 20 being considered the first. For these, ½ yd. of 36-in. material will be required for one pair, if tiny pieces be joined on at front leg. A to B and C to D, 10½ in.; A to C and B to D, 13 in.; A to E, 1 in.; B to F, ¾ in.; A to G, 8 in.; C to H, 3½ in.; A to I, 2 in.; I to J, the same. Curve from E and J to G and G to H, and from F to G. As these two patterns are quite easily enlarged, they are not given again.



22. CHEMISE

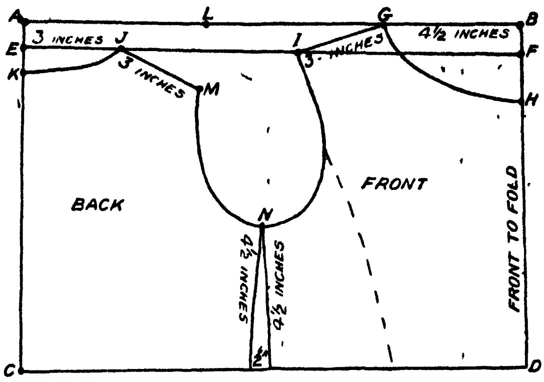
The broken lines indicate the direction to be taken for the divided skirt [see later], which is advisable for some, if not for all children, either of flannel to replace the ordinary shape of flannel petticoat, or cambric. If prettily festooned or tucked, and trimmed with lace at the bottom, it has all the appearance of a petticoat, with the extra advantage of warmth to the lower portion of the body.

The combined garment is now preferred to the chemise and drawers, though one of woven material is usually worn under this. The small garments, however, are rather expensive for their size, as children so rapidly grow out of them. For the very first size, an ordinary vest does excellently, cut to form short leg pieces, then joined up, with the neck either drawn in by a ribbon, or cut at the side to form the head opening, and bound with washing ribbon.

Diagram 24 shows a very comfortable pattern for combinations, which should not present much difficulty in cutting out with the aid of the preceding diagram and instructions.

They are 23 in. from shoulder front to knee, and 20 in. from centre-back to point of leg in front, and will take 1 yd. of 36-in. goods.

The curved lower portion of back, it may be pointed out, is to give room and as a protection for the sides, and must be joined to the front exactly as the notches indicate. These are made of flannel or longcloth, and trimmed according to taste, the opening being back or front as preferred, and may be made with or without sleeves, either long or short.

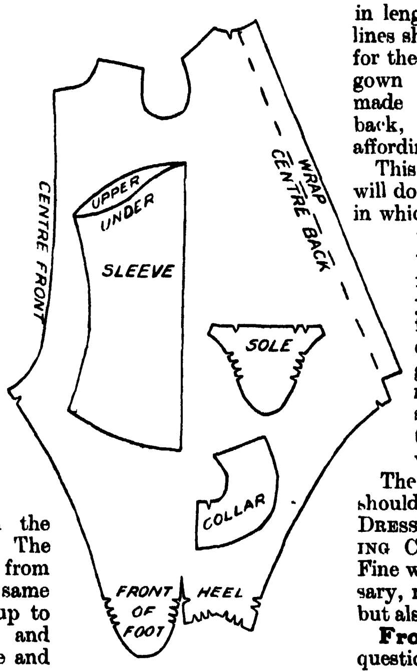


25. DRAFTING BODICE

Diagram **25** gives the drafting of a bodice for the second stage, which will form the foundation for bodice of petticoat, yoke for frock, etc. A to B and C to D, 16 in.; B to D and A to C, 11 in.; A to E, E to K, and B to F, 1 in.; B to H, 2½ in.; A to L, 5½ in.; L to M, 2 in. The remaining measures are marked on the diagram.

Diagram **27** is the princess petticoat shown at (i) in **21**.

This shape requires ⅝ yd. of 36-in. material, and, as will be seen by the broken line, is cut from the bodice just drafted [**25**]. If the banded style be preferred, the lower portion is quite easily added on, either in the gathered or circular form. The lower edge may measure from 1¼ yd. to 1½ yd. round. The same model will do for children up to four and six years of age, and can easily be increased in size and length. The trimming, of course, is a matter of taste.



26. FOOTED SLEEPING SUIT

A Child's Sleeping Suit. We now come to the night attire of the little people, from one year old and upwards. As already remarked, for children up to two years of age at least, the footed sleeping suit, made in a soft, light flannel, is the safest form of night wear. Diagram **26** shows the shape of the garment, which is 14½ in. half-chest, and 24 in. across the widest part of leg, the length from shoulder to point of front foot being 36 in. This will take 2¼ yd. of 36-in. flannel.

The foot portion is somewhat complicated, but if the notches be very carefully followed, and those which correspond with each other put together, the making is not difficult.

No. **28** shows at A the foot portion, and at B the foot, heel and sole put together, and the relative position of the notches. The seams are herring-boned with very fine cotton.

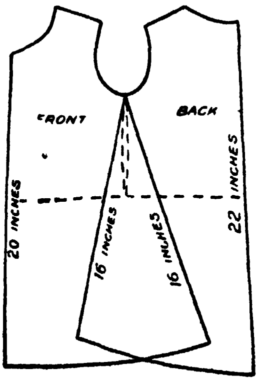
If more protection is required at back and front, a yoke can be added, cut the same shape, and stitched or feather-stitched to the suit, which can be worn by either boy or girl. As for obvious reasons it must be cut somewhat long and large, the foot portion should be drawn in to the ankles by a ribbon or elastic passed through fancy stitching.

After the age mentioned, a nightgown may be preferred, though the male infant will keep to the sleeping suit without feet. Diagram **29** gives a model of a simple sacque affair which, like the princess petticoat [**27**], can be easily evolved from the bodice shown in **25** by increasing it in length and width. The broken lines show the direction to be taken for the skirt part if a yoke nightgown be required. It is better made to fasten either at centre-back, or left side of front, thus affording protection to the chest.

This pattern, it may be noted, will do for the small dressing-gown, in which case, of course, the front would be left open the whole way down. By curving the front neck, if made with a yoke, and adding a wide fold of material round neck, down yoke, and fronts of gown, we shall have a very nice copy of the kimono style. For either shape 1½ yd. to 2 yd. of 36-in. material will be needed.

The making of these garments should present no difficulty if the DRESSMAKING and UNDERCLOTHING Courses have been followed. Fine work, however, is very necessary, not only for the appearance, but also for the comfort of the child.

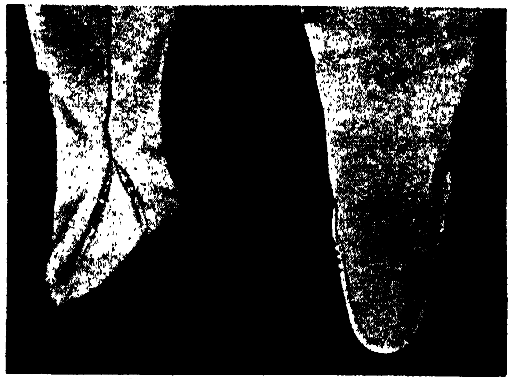
Frocks. We now come to the question of frocks, and here we have a wide selection as far as make and trimming are concerned, although for the first year or so the choice in cut is chiefly limited to the yoke and smocked styles. The yoke may be at the shoulder only, or may extend below the armpit in the Empire style, both of which are easily cut from our drafting, and the preceding instructions.



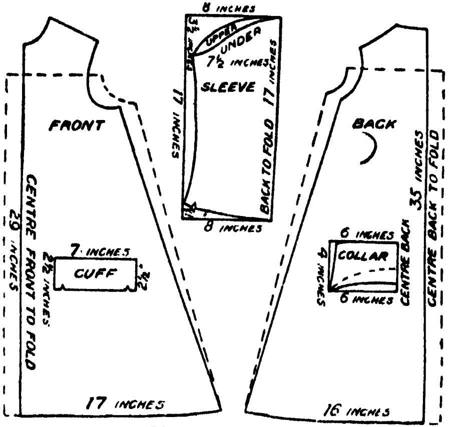
27. PETTICOAT

For a rapidly growing child the yokeless smocked frock is decidedly the best, as it expands so readily, but it should be cut with the sleeves carried up to the neck, as in the drafting of the long flannel of diagram 2 [p. 3744], and not with a round armhole. This is an important matter, as the armhole does not expand with the growth, and it is likely to irritate and even hurt the child, besides being more difficult to smock than the other shape, and less effective when done.

A point to be remembered in smocking is that ample material should be allowed for the purpose, as skimpiness detracts very much from the beauty of the work.



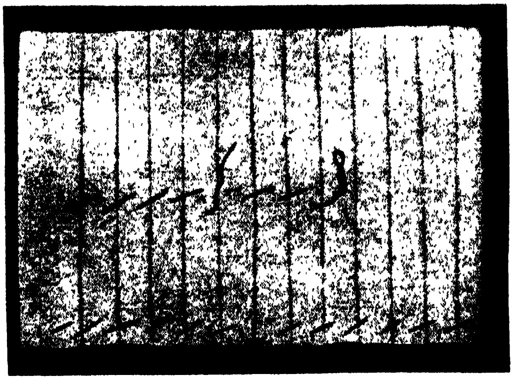
28. FOOT OF SLEEPING SUIT



29. NIGHTDRESS

From four to six years of age the yoke and smocked style is usually worn, but may be varied by the long-waisted French variety, or the kilted style, with a sailor or American blouse, equally suited to girl or boy from two and a half years of age.

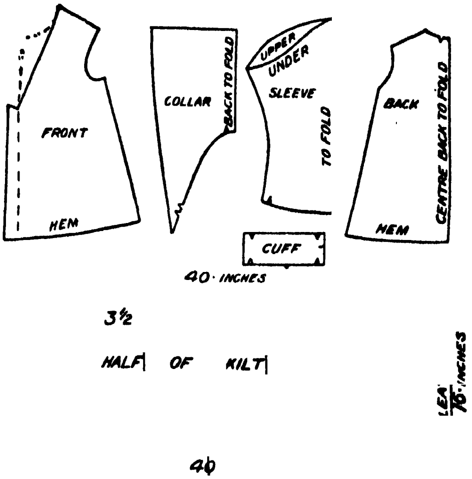
Diagram 30 depicts a drafting of the latter style, the bodice of which can also be evolved from 25, either high-necked or open, sailor fashion, the former shown by the broken line. Without the collar and with a box-pleat in the centre, it forms an American blouse. The sleeve can either be put in a cuff, or pleated at the wrist-part to form one.



31. KILT TACKED FOR PRESSING

For a sailor blouse, the collar would be of double material, the edge turned in and stitched once or twice, the first row quite close to the edge, the second ¼ in. to ⅜ in. from this. The under part is secured to the edge of blouse, which should have a linen stay to prevent stretching, whilst care should be taken not to stretch either edge.

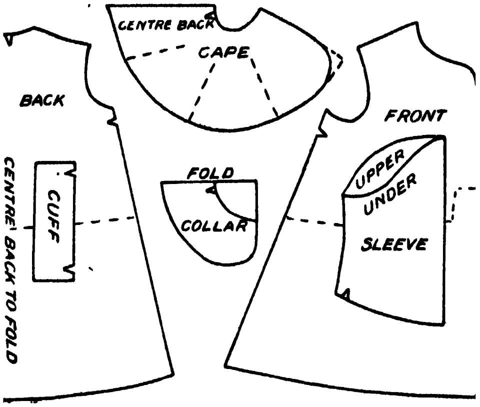
The seam must be well pressed, when the upper portion can be hemmed over the turnings and again pressed, care being taken with the points of the collar to keep them neat and to prevent them having a thick appearance.



30. SAILOR FROCK

A Kilted Frock. The kilt fastens at the back, and is hemmed before being pleated. It must be very carefully marked and spaced as shown, so that the pleats are quite even. When tacking, care must be taken to keep the first pleat at the lower edge in a line with the upper one, and with the thread of the material, otherwise each succeeding one will get more on the bias, and the appearance will be spoilt [see 31]. With respect to the material required, this frock will take about 2 yd. of 44-in. goods.

Diagram 31 shows half of kilt tacked and ready for pressing, which should be done on a hard surface; it will take a little time to get the pleats perfectly flat, especially if the cloth be thick. It is best, when doing this, first to put the iron on the bottom edge whilst holding the other taut with the left hand. This will keep the pleat edges straight, which, if the material be at all wiry or thick, may not always be an easy task. When this is so, a second row of basting in the middle is advisable. The kilt is arranged at the waist into a band, which buttons on to a little under-bodice of lining.



32. CHILDS FIRST COAT

This frock is capable of various modifications. If the blouse portion be made a little narrower at the lower edge, and left loose here and at the fronts, it forms the little Quartermaster frock illustrated later, and is worn over the vest bodice depicted with it.

In the long-waisted, or French, frock the bodice portion is carried down a few inches below the waist line, but should not be too low, as this impedes the movements of the child. The making of this style varies considerably, but can be easily accomplished by means of the foregoing diagrams and an approved sketch, and is more fully explained later on. The skirt should never extend below the knee and should also be made a little shorter at the back than the front. Long-skirted frocks are only suited to yoke and banded styles, but whilst extremely picturesque and quaint, are not very practical.

For children of two to four and six years this style will require 2¼ yd. to 2½ yd. of 44-in. material, much, of course, depending upon the style and "frilliness" of the frock.

For out-of-door wear after the pelisse is abandoned, the little matinée coat shown at (*k*) in 21 is a very great favourite with most mothers, and is adapted to boys and girls from 1½ to two and three years of age. Many mothers make dainty little slip skirts to wear with these coats out of doors, as recommended for the infant.

For boys, though, a severer style is more suitable. These slip skirts measure 1¾ yd. to 2 yd. round, and are just gathered into bands 1 in. or so wide, and fasten on like the ordinary old-fashioned petticoat; or they may be fastened by means of ribbons over the shoulder, as in the baby's slip skirt shown in diagram 1, which, if crossed over at back and front make a pretty finish. For winter, if the long sacque shown in 32 is preferred, it can be made with a cape and worn with a lace or silk frilled collar according to taste. It will take 2¼ yd. of 44-in. material, and, as will be easily seen, the above-named matinée coat is merely a shorter edition, with the corners cut.

Headgear. For the first few months, baby boy and girl wear the same kind of headgear; but after then the boys wear hats and the girls hoods or bonnets. These should at first be of such a make and material that they do not cause any inconvenience to the small head, and of the soft, close kind which the French aptly term a "dormeuse."

For boys, hats with or without brims, with a soft ruched cap inside, are worn at first, the cap being omitted as the child grows. After this, cloth tams, "jelly-bags," and Turkish caps, "man-o'-war" and sailor hats are added to the list.

For girls there is a wide choice in styles, which, however, resolve themselves into modifications and varieties of the Dutch or Puritan, and the Directoire, or poke, bonnet. In summer, frilled or floppy-brimmed hats, and dainty, modified poke or sun bonnets are best for small girls, and mushroom shapes as they grow older. In winter, of course, the quaintly pretty Dutch bonnet may be advisable if preferred. [See MILLINERY]

OIL AND COLOURMEN. Shop and Fitting. Stock and Staff. Licenses. Proprietary Goods

NATURALISTS

The business which, for want of a better title, is called that of a "naturalist," is usually combined with another branch of shopkeeping. The most suitable businesses upon which may be grafted that of a naturalist are those of a furrier and of a dealer in live animals and birds. Sometimes gunsmiths, fishing tackle dealers, antique dealers, and even barbers, house furnishers, and tobacconists, take up the department. The man who adopts it must have a personal taste for it, and a knowledge of and liking for natural history in its various departments.

The trade has depreciated recently from two causes—first, the flooding of the market with cheap, gaudy, and badly-prepared glass shades of foreign birds, whose appearance repels people of taste; and, secondly, the Wild Birds' Protection Act, which protects so many of the species—and rightly so—that the city sportsman has now a great difficulty in pursuing his sport.

Stock. To make a side line in this trade, a shopkeeper must, of course, show specimens of many kinds, and the taxidermist is usually willing to let him have these on terms of sale or return. In exhibiting them, care should be taken to put them in a position so that direct sunlight does not reach them, as the bleaching effect of light will soon spoil both fur and feathers, and ruin butterflies. Glass cases will steam inside from the effect of direct sunlight. Stuffed heads of animals, not in glass cases, and rugs, will require to be carefully freed from dust, which induces the attacks of moths. If the presence of moths be suspected, a brushing with benzoline will prevent trouble. Benzoline must be applied in the open air, on account of its explosiveness, and should be allowed to evaporate well before bringing the specimens indoors.

In towns where there is a good college in the vicinity, some trade may be done in implements and in cabinets for insects and eggs. Insects' eggs themselves had best be avoided, except by those who are able to identify the specimens and their varieties.

Mounting Specimens. The mounting of horns and heads on shields (usually made of polished oak), foxes' heads and hares' heads and feet, as sporting trophies, will be the principal trade in a country town; but care should be taken to ascertain if the specimens brought for preservation are in a fresh condition, especially when the weather is hot or damp. A good test is the brightness and fulness of the eyes. Specimens sent by post or rail should be packed securely in a box, with dry hay or straw, all risk of crushing being avoided.

It is usual to obtain a deposit of 25 per cent., especially from a new and unknown customer. This will be found necessary, as the preparation of the specimens take a considerable time, and the customer's interest in the interval wanes, and there is the risk of having goods left on hand unless the deposit be insisted on. This is particularly so in the case of pet animals and birds, the owner's grief in many instances being assuaged by the acquisition of a living duplicate.

In the event of specimens being received from abroad, especially the tropics, they must be carefully examined, and if there are any live insects, they must be treated with preservatives [see Taxidermy] and stored in a dry place off the floor, away from risk of rats and mice. As a customer very often does not require his collection mounted at once, a charge for warehousing may be made.

Precautions in Packing. All finished work is best delivered without being packed; but if the distance be too great, and a packing case necessary, a charge is made for this. The box for a glass case should be only a few inches larger than the case, and only straight dry straw should be used in packing, care being taken that the pressure is only on the woodwork, and the glass free. Large heads and horns may be packed in crates and fixed by large screws through the backs of the shields, and the horns supported by crossbars of wood.

It will be seen from the foregoing that a certain amount of trade can be done with a very small outlay. The taxidermist will require cash payment for work done, but probably the dealer will be compelled in some instances to give credit, but he must arrange his price to cover that; he will also assume some risk in having work left on hand, but he can dispose of such work after giving due notice to the owner of his intention. A great advantage is that finished work is not perishable if proper care be taken.

It will seldom pay to dispose of goods by auction, unless they can be included in a sale of similar goods—that is, natural history specimens. This can be done by including them in one of the periodical sales, such as are held periodically near Covent Garden, London, W.C., where large quantities of natural history, entomological, and geological specimens are offered, and the dealer can often pick up a small stock of saleable articles and specimens suitable to his district and trade. In buying, he must remember that the return may not be immediate, and that second-hand articles nearly always require a little outlay for renovation.

Freaks and Curiosities. Curiosities in the way of freaks, such as animals and birds with an abnormal number of heads or limbs, can seldom be sold to any advantage. Goods which sell most quickly are those of the ornamental type, such as mounted horns and heads. The larger and more mature command the best price and the quickest sale. The dealer must be able to detect the species at a glance, and so to judge its proper value.

Dressed skin rugs and feather screens soon show signs of wear, and should be carefully examined for probable spots which moths have attacked.

The sale of native arms, implements, dress, and ornaments, is frequently combined with this trade, but it is difficult to judge if one is buying an imitation made in this country or not. Sometimes a known customer has a surplus lot of curios to dispose of, collected by himself, and authentic; an opportunity of this sort should not be neglected by the dealer.

Prices. The subjoined list of prices may be a guide for general work, but the variation in the requirements of each customer and individual specimens makes it impossible to publish a complete list of charges. The best way would be for the dealer to get an estimate from the taxidermist as the practical man before giving a binding price. The prices quoted are those below which it is impossible to expect good and reliable work.

BIRDS.

	s.	d.
Stuffing small birds, without case, up to the size of a linnet, goldfinch, or canary	2	0
Size up to pigeon	4	0
Size up to grouse	6	0
Size up to pheasant	8	0

Double this for the cost of the bird mounted in plain case.

FRESH WATER FISH.

,, ,, tiger or lion	1	0	0
Tiger or lion, with head stuffed and eyes inserted, lined and bordered with felt	3	0	0

Aids to Selling. A photographic album of finished specimens is of great value to convey an idea of the best way of treating them, and will save room, etc., the dealer not requiring to have the objects themselves at hand. This is especially valuable with respect to the mounting of horses', rhinoceros' and hippopotamus' hoofs and feet, which are sometimes mounted in silver, copper, and brass, as inkstands, cigar, cigarette and tobacco boxes, candlesticks, trinket boxes, paperweights and doorstops. Elephants' feet are also made into workboxes, flower-stands, footstools, umbrella-stands, and liqueur stands.

Foxes', hares', and otters' feet (or pads, as they are called in the trade) are mounted as paper-knives, letter clips, whip handles. Deer's hoofs, with part of the leg included, can be mounted as whip handles and hat pegs; a set of four makes a handsome candelabrum. Various animals' tails are utilised as whisks and brushes.

Opening Business. Established in a town, a port in preference, the beginner would, by judicious advertisement, get into touch with the sporting community, with whom his business mostly lies.

The naturalist should be able to use rod, rifle, and shot-gun; and if required to accompany his customers on an expedition for big game, etc., the opportunities for observation, making notes and sketches on the spot, sometimes from life or at all times from fresh-killed specimens, are invaluable. It is quite exceptional for sportsmen to take an experienced man with them, and consequently many a valuable specimen is spoilt by having the skin literally torn off by the natives and roughly dried, taking its chance of hundreds of destructive insects and risks of injudicious packing making it valueless for scientific purposes, as, if mounted, it must be repaired and faked to make it presentable. For a business of this description premises with a shopfront are not necessary.

Workshop. A lofty, well-ventilated workshop with a large stove, water supply and a large sink is necessary. The shop should be big enough to accommodate the largest animals and leave room to manipulate them. A convenient size is about 50 ft. long by 20 ft. wide, with doors 15 ft. high by 8 ft. wide.

The tools required are described in the article on practical taxidermy. To learn the trade a start must be made very young. The boy must show a decided interest in natural history, and have grit to endure the many unpleasant processes and difficulties connected with it.

Apprenticeship is not universal in the trade, the boy usually starting at the bottom of the ladder, making himself generally useful (or perhaps otherwise) for a small wage, and working up.

The salary for a first-class man is not likely to exceed £3 per week, but if thoroughly scientific and well versed in the requirements of museums, a more lucrative appointment may be obtained.

NEWSAGENTS

In the present state of society the newsagent is as essentially a part of modern life as the printer and the reporter, and there should be no difficulty in anyone with the ambition of becoming a disseminator of news finding a suitable sphere for his activities.

The amount of capital required to start depends entirely on the ideas of the beginner. For instance, he may select a stand in a busy thoroughfare, or a pitch near a railway station, where a constant stream of men passes morning and evening, and, with the expenditure of a few shillings, obtain and dispose of a supply of the morning and evening papers. Or he may ally himself with one particular newspaper, and obtain from the manager a district, which he is expected to work for all that it is worth. The latter class are familiarly known as "hawkers," and some people are squeamish about venturing on such a course. A good wage, however, is usually made right away, and there are no expenses to come off. We have known many a splendid business built up from just such beginnings, the initiative and alertness demanded in this line being an excellent training for future and more extended operations.

The ShopKeeper Newsagent. Presuming, however, that the aspirant wishes to blossom forth at once as a shopkeeper, one of two courses is open to him: first, to acquire a business which, for some reason or other, has come into the market; or, secondly, to select a shop, preferably in some busy thoroughfare. With regard to the former course, that of acquiring a business as a going concern, the utmost caution must be exercised by the buyer, as frequently, despite the specious reasons given by the seller, those businesses which come into the market are either suffering from "dry rot," or have got into the sere and yellow leaf. Assuming that the business is acquired, the first thing to do is to notify the change to the customers and wholesale merchants of your predecessor. This is generally done by joint circular and advertisement. Then call a clearing sale, and get rid, at any cost, of the old stock.

The New Business. In regard to the opening of an entirely new business, the choice of a line to be run along with the news agency will lie entirely with the beginner. We are concerned at present with the newspaper trade only. An advertisement should be inserted in the newspapers circulating in the vicinity, and a neat circular drawn up and addressed to likely parties in the neighbourhood. Do not grudge expense in advertising; money judiciously spent thus is a good investment. It is a wise thing to make a systematic canvass of the district in which the shop is situated and, if possible, to obtain orders for the permanent delivery of the morning and evening newspapers, magazines, etc.

Buying Terms. Where possible, it is always well to deal direct; but any good wholesale house will be pleased to quote terms. As a rule, 25 per cent. is allowed off the ordinary penny and halfpenny papers. On some the dealer may get a little more, while on others he will be allowed less. Of course, he will not get those terms for the sixpenny weeklies, and some of them will cost him 5½d. plus the carriage. It is obvious, therefore, that these are not a source of profit directly. In fact, when carriage is considered, to say nothing of delivery, the balance is decidedly on the wrong side of the ledger. As a rule, newsagents who know their business supply the sixpenny weeklies only to customers for other newspapers or magazines. Pending better terms, it might be wise policy to leave them severely alone. The same remark applies to special editions of "trade" papers, which are issued at certain seasons. It is a good maxim in business to "Let every herring hang by its own head."

Accounts have usually to be paid monthly; but unless good security is given, the beginner must pay cash in advance. As to the class of newspapers wanted, that will depend to a large extent on the locality in which the shop has been opened, and the common-sense of the newsagent must here, as always, come into play. For instance, if the shop be in the vicinity of a school, a good trade may be done in the excellent juvenile literature which is now so plentiful.

The Shop. In order to attract, and what is of equal importance, to retain, customers, the shop should have a neat and tidy appearance. The papers should be arranged neatly on the counter, so that the visitor may easily read their titles. A judicious display of show-bills and neat cards may be used with advantage. The windows should be an index of the shop, and have an attractive and inviting appearance. They should be frequently changed, and on no account should the announcement of a Christmas publication be allowed to hang till Easter, nor the advertisement of a Summer Number stare one in the face at Christmas. There is nothing more repellent and detrimental to business than badly-dressed windows. They give one the idea of untidiness and unpunctuality on the part of the shopkeeper —two fatal defects in any business.

The newsagent who is alive will take advantage of the plentiful supply of literature which is freely offered to push the sale of forthcoming newspapers and periodicals, or to give a fillip to those already in the market.

What to Sell. Quite a good trade may be done in the sale of cheap reprints of standard works, and in magazines and periodicals. This is considered a perfectly legitimate part of the newsagent's business. An excellent feature of this class of literature is the increasing number of publications which are now being issued at net prices, and which, as a rule, yield a profit of 15 per cent. This is fair alike to the public and to those who handle the goods. The purchaser knows that he is paying the market price, while under the discount system he may pay ninepence in one place, tenpence in another, and if he buys at a railway bookstall, the full price of a shilling.

Special editions of the illustrated papers, issued in connection with great national events and at Christmas, are now recognised institutions, as are also the double numbers of magazines and other periodicals. In these the alert newsagent may usually do a good stroke of business. If he is wise, however, he will take full advantage of the advertising matter issued by the publishers and book his orders beforehand. This, of course, means the expenditure of a good deal of time, and also money; but it will pay. He will do well to limit his supply as nearly as possible to the orders which he has received. That is until he knows his district thoroughly, and even then he should be guided to a large extent by this rule; because even old and experienced dealers have again and again been bitten by laying in a heavy stock of "special" numbers in anticipation of the big rush which never came off.

Returns. The question of "returns" should be very carefully considered by the newsagent. On a number of newspapers and magazines a certain percentage of "returns" is allowed. This enables the shopkeeper to stock these publications without running the risk of heavy loss. Of course, it is not fair to abuse the privilege which is thus given by the publishers of these periodicals, etc. The newspaper list should be carefully gone over every week, and scrutinised, and "returns" reduced to a minimum. All non-returnable newspapers left over should be relentlessly cut off, and no papers kept except those for which there are definite orders. The same remark applies with equal force to the magazine list. This must be kept steadily in view unless profits are to be reduced altogether to the vanishing point. An old newspaper or magazine is generally of as much value as, say, last year's almanac. The newsagent must pay the carriage on his "returns." Some publishers are now accepting the headings of old news, papers in lieu of the newspapers themselves thus saving the newsvendor the carriage charge.

Profits. The question "What profit can be made?" is the most important of all. In arriving at a satisfactory answer there are a good many points which must be considered. Of course, the first is the price at which goods may be obtained. As already indicated, 25 per cent. is allowed off the ordinary penny and halfpenny newspapers; some publishers allow a little more, while a considerable number allow only about 15 per cent., and in the case of the sixpenny weeklies, most of the publishers allow only 7½ per cent. Put it down at say 20 per cent. on newspapers over all. Taking net and non-net magazines together, say 10 per cent. Now, let us take a business turning over, say, £600 a year, £500 of which is newspapers and £100 magazines and other periodicals. We have thus a gross profit of £110. Let us see what expenses have to come off.

Delivery. Take first the cost of delivery; and with the advent of the halfpenny paper, the question of delivery has come to be a serious matter, because the newsagent has to pay the same for delivering a halfpenny paper as he has for delivering a penny one, while his profit is only one-half. Then, as districts are often widely scattered, and distances at which the papers have to be delivered considerable, this necessitates a number of errand boys. If 10s. a week—that is, £26 a year—be allowed for these, the estimate is moderate; a girl to attend the shop and look after the books, say another £26 a year.

Then carriage is a very heavy item. On a business such as we have supposed, it would amount to no less than £12 a year. There is thus left the sum of £46 to pay the newsagent's own wages, rent, taxes, light, and fuel, to say nothing of postages, advertising, and leakages. Not much prospect there of soon amassing a princely fortune. It may be pointed out that in the large towns, where there is a wholesale house, the newsagent is in a much better position than his brother in the country, in respect that he has no carriage to pay; and the bigger the town the better prospect there is of a larger cash trade being done. On the other hand, however, to balance this, the rent in the metropolis and other large cities is much higher than in provincial towns.

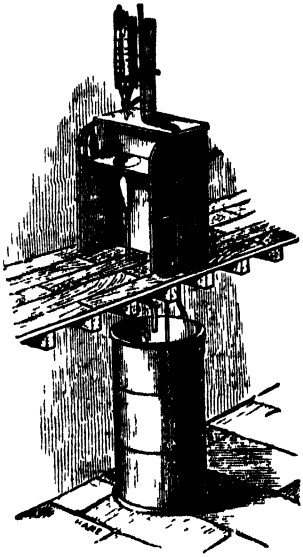
Charges for Delivery. In the good old days when the customer was content to wait the pleasure of the newsagent in delivering his paper, something might have been, and no doubt was, made at the business. Now, when every customer wants his morning or evening paper as soon as it is published, or immediately after the arrival of the train, it comes to be a question, unless delivery is charged for, whether the game is worth the candle.

A good many towns in England, and a number of Scottish towns have adopted the charge for delivery, and the arrangement has worked well. It might, therefore, be advisable for the newsagents throughout the country to take the matter up and devise means by which concerted action might be taken. It is more than likely that the public would at once fall in with the suggestion. Men like and expect to be paid for their own work, and do not, as a rule, object to those who work for them receiving a fair wage.

Work of the Newsagent. Anyone going in for the newsvendor business must make up his mind for a life of hard work and strenuous endeavour. It is not the line for the Tired Tims and Weary Willies. To do the work thoroughly he must be up early and work late. He must go to the publishing offices or attend the arrival of the early morning trains himself and see that his army of boys are all forward and supplied with the papers for their various districts; and, in the event of one or more not turning up, he must arrange for others to take their places—a rather difficult matter. The morning papers must all be delivered before breakfast, or before business men go to their offices.

The echoes of the machinery which produced the morning papers have hardly died away when the whir of the presses throwing off the evening papers is heard. The earliest editions of the evening papers are out before midday; and edition after edition, including Special and Football, is poured forth until late in the evening. This goes on day after day without intermission from January to December. There is no business in which there are more worries and petty annoyances. The newsagent will have much to try his temper, and while avoiding servility on the one hand will find the business of the newsagent an excellent school for cultivating the virtues of patience and courtesy, without which he will inevitably fail.

The Colonial Newsagent. In the Colonies, and notably Canada, the newsagent's business is a much more lucrative one than it is in the old country. This is true especially of the western provinces, where the coin unit is 5 cents. Although the face value of a newspaper is one cent, it cannot be bought for that price. Of course, if delivered by the publishers the face value only is charged; but if a one cent newspaper be bought on the street, or in a shop, the charge is 5 cents—the Irishman's modest 5 per cent. profit. Even in the west, however, the spirit of competition is developing, and the newsboys are beginning to cut the price. The visitor will be not a little amused when accosted by the pushful youngster to buy the evening paper, and as a special inducement is offered "two for five." Until recently the rate at which newspapers were supplied to the newsagents was two copies for one cent. Lately, however, in April, 1906, the proprietors, who did not see the fun of all the profit going one way, raised the price to one cent per copy, which still leaves, at five cents a copy, or even "two for five," a handsome profit to the newsagent.



OIL-PUMP AND MEASURING APPARATUS

OIL AND COLOURMEN

In the days of home-made tallow candles, "farthing dips," and 'a'penny rushlights, the tallow-chandler frequently carried on a distinct trade, his wares being mainly candles and soap. In his minute investigation of London trades, Mr. Charles Booth found this calling no longer in separate existence; the soap and candles are now sold by the grocer or the oilman. The oilman himself, who once dealt mainly in paints and paint oils, now sells illuminating oils, paints and paint oils, brushes, varnish, baskets, lamps, candles, soap, and also, very commonly, tinned and potted goods, which cannot be injured, like groceries or provisions, from shop contact with the more odoriferous goods. Ironmongery, garden tools, china and glass, mats, buckets, brooms, grocers' sundries—it would be a long list that exhausted the goods conjoined in modern oil-shops in London and elsewhere. The "Practical Grocer" (Gresham Publishing Company) devotes several chapters to the oilman and the goods he deals in.

Starting in Business. A capital of about £200 should be sufficient, if the beginner is a practical man. The choice of stock will depend a good deal upon the ascertained needs of the neighbourhood, but an oilman's stock is always of a highly miscellaneous character. It is usually found the best plan to specialise in one or two particular departments of the business, and in those to carry as far as possible a completely representative stock; although in buying such stock the beginner with limited capital must not forget that some small items may have to lie in stock for a long time before being asked for by customers. All such goods should therefore bear a high profit.

Oil Licence. A preliminary question is whether or not a licence will be required under the Petroleum Acts. This depends upon whether or not the oil sold has a "flash-point" below 73°F. "Petroleum," in the meaning of the Petroleum Acts, is rock oil, Rangoon oil, Burmah oil, oil made from petroleum, coal, schist, shale, peat, or other bituminous substance, and any other product of petroleum, or any of the abovementioned oils, which, when tested in a prescribed manner, gives off a vapour inflammable at a temperature less than that stated. Oil for burning in lamps ought never to flash at a temperature less than 73°F., otherwise it is too dangerous for ordinary use. Therefore the oil usually sold is not subject to the Petroleum Acts, and its sale necessitates no licence. Petroleum spirit, benzine, petroleum ether, and similar articles, come under the Acts, and can be stored, transported, or sold only under licence from the local authority. Carbide of calcium, used for making acetylene, etc., needs a licence, if more than five pounds be kept, and this quantity must be in separate sealed metal vessels, each containing not more than one pound. Methylated spirit needs a special licence, must be sold in bottles marked with its name, and must not be sold between 10 p.m. on Saturday and 8 a.m on the Monday following. Fireworks come under the Explosives Act, and shops where they are sold have to be registered [see Gun and Ammunition Dealers]; they must not be sold to children under thirteen.

Storage. The storage of the oil is the chief matter in an oil-shop. The safest plan is to have an underground tank, capable of holding 150 gallons or 200 gallons, in the yard outside the shop, the oil being carried from it into the shop by a pipe under the floor, which supplies a kind of "engine" or pump, with a measuring siphon. The metal tank should be hermetically closed, with the exception of an air-hole, which should be covered with very fine copper wire gauze. If it is not possible to have the tank outside the shop, it may be placed in the cellar, providing there is ventilation. The accompanying illustration shows an arrangement by which oil may be drawn from a tank in the cellar into a measuring cylinder, which shows the quantity, and allows sales to be made without handling measure or filler. Turpentine is usually kept in metal drums. Vegetable oils should be kept in a cool place, and covered.

Such goods as matches may be stored on shelves, but keep them well away from the gas-jets or other lights. Candles should not be placed on the upper shelves—these are likely to be the hottest part of the shop. A stand or an enclosed glass show-case may be used for displaying long-handled brooms and brushes. Small wares can be kept in drawers or boxes, arranged so as to classify them conveniently: Very often they can be kept in parcels, to save deterioration. On the top of each drawer or box put a card indicating the contents. It should be noted that when edible goods are stocked they should be kept away from others the smell of which may affect them. Pickles and curry powder in bottles are best not exposed in windows, the contents being affected by the light. Note also that such goods as whiting draw moisture when in paper parcels, and not in bags; while others, like washing soda, evaporate.

Cautions in Trading. In view of the requirements of the law, it is well to bear in mind that oils and other goods are sometimes adulterated, so that the retailer handling them may incur risk quite innocently. Particular care is necessary in seeing that oils intended for consumption as food, or with food, are vegetable, and not to any extent mixed with mineral oils. A guarantee of genuineness should therefore always be insisted upon when buying such oils. If "sweet" oil be asked for, mineral oil must on no account be supplied. If "olive" oil be demanded, cotton-seed oil will not serve as a substitute. If the retailer is at all doubtful of the genuineness of his "olive" oil, he should sell it only as "salad" oil, or he may be caught when he least expects it. In regard to vinegar, again, if "malt" vinegar be asked for, malt vinegar must be supplied, and not acetic acid or wood vinegar. Note that tinned goods are apt to deteriorate sometimes, although when properly prepared they may keep for years unaltered. Stock of this kind should be carefully inspected at regular intervals for the discovery of "blown" or puffed-out tins, this puffing being the result of the formation of gas from the decomposition of the contents. It goes without saying that such tins should be immediately withdrawn from the stock; indeed, it is not safe to keep them on the premises, since discovery by an inspector would involve the retailer in appearance before the magistrate to answer a charge of having unsound food in his possession. Washing soda, again, is an article that has involved oilmen in trouble, owing to its adulteration with Glauber salts—which "won't wash." The leading firms are usually willing to analyse doubtful samples.

Oil-shop Sundries. These include a bewildering variety of such goods as metal polishes, boot polishes, blacklead, bathbrick, furniture polishes, inks, blues, cements, glue, size, etc. Oilmen often have such articles made and put up for themselves. Many useful recipes will be found in the "Practical Grocer," already named, and in "Law's Grocer's Manual" (Gilbert and Rivington, Ltd.); while a number of collections of the kind are issued by the proprietors of the "Oil and Colourman" and "Oils, Colours, and Drysalteries."

Staff. Managers of branches in London expect about 30s. per week salary and rooms for branch doing £20 a week; 35s. for shop doing £20 to £30; 40s. for shop doing £30 to £50; above this 1½ per cent. extra. The wages of assistants are usually: First hands, 25s. to 30s.; second hands, 21s. to 25s.; porters, 20s.; boys, 10s. a week. A little extra is sometimes given as good-conduct pay if all orders are delivered in reasonable time and without complaints from customers. In some instances the rules specify: Shops opened at 8 a.m., closed 9 p.m.: Thursdays, 2 p.m.; Saturdays, 10 p.m.; branches have check tills, and the manager is responsible for the takings, with a percentage on net profits; managers, assistants and boys wear white coats and aprons, and boys sometimes have caps with the proprietor's name upon them. Managers render an account once a week of takings, expenses, and goods received and returned. Yard and cellars are cleaned and trucks washed weekly.

Proprietary Goods. It may be useful to the beginner to note that, if he has not sufficient practical knowledge of such departments as paints to handle material in bulk, he may still make a fair show, so many articles dealt in by the oilman and grocer being now put up by the manufacturer as proprietary articles, ready packeted or canned, with full directions for use. The number of such proprietary goods included in the list of some retail stores literally runs into thousands. Soaps, candles, ready-mixed paints, oils, matches, blacking, and similar sundries, firelighters, screws, tacks, pickles—it is difficult rather to say what is not packed than what is. Moreover, the retailer may himself possess proprietary brands if he chooses, a number of firms laying themselves out for this class of business. Needless to say, the profits on proprietary articles not the retailer's own brands are commonly exiguous, and with many of them there is no small trouble, owing to the various schemes of present-giving, coupon distribution, and so on, which are adopted by the proprietors to push their goods with the public and create a demand which almost compels the retailers to stock them. A large number of the most important, however, are now protected by the Proprietary Articles Trade Association, which, secures to the retailer his fair profit.

Continued from page 3903

By Dr. A. J. HERBERTSON, M.A., and F. D. HERBERTSON, B.A.

AMERICA, or the New World, consists of two great peninsulas—North America (8,000,000 sq. miles) and South America (7,000,000 sq. miles), united by the long, narrow isthmus of Central America.

NORTH AMERICA

At the Isthmus of Tehuantepec, which may be taken as the southern limit of North America, the distance across is 130 miles. Rather less than 4,000 miles due north is Cape Murchison, the most northerly point of the mainland. The maximum breadth of the continent is about the same. The whole of the north, except Alaska, is British, forming the self-governing colonies of Canada and Newfoundland. South of Canada is the Republic of the United States, to which belongs Alaska. South of the United States is the Republic of Mexico.

Oceans, Seas, and Gulfs. The northern shores are washed by the Arctic Ocean, the western by the Pacific, and the eastern by the Atlantic. An archipelago of islands stretches across the Arctic Ocean north towards the Pole, and east towards Greenland, which is separated by Baffin Bay from the North American mainland. In the extreme north-west, America is less than 40 miles distant from Asia across Behring Strait. The Aleutian Islands, off Alaska, continue the island fringe of Eastern Asia.

The coast of North America is much indented. On the Atlantic coast, which has marginal lowlands, are (1) Hudson Bay; (2) the Gulf of the St. Lawrence, entered north or south of the island of Newfoundland, and leading to the great lakes of Ontario, Erie, Huron, Michigan, and Superior; (3) the Gulf of Mexico. The latter, with the Caribbean Sea, which is almost cut off by the island of Cuba, is sometimes called the American Mediterranean. The islands which define its eastern limits are the West Indies. Let us look out all these on a map, and notice the names of the straits leading to them. On the Pacific coast, which is bordered by high mountains, there are fiords in the north like those of Western Scotland or Norway in the north-west. In the south is the Gulf of California, the largest gulf on the Pacific coast. It may be contrasted with the Atlantic gulfs.

Mountains. The highlands and lowlands of America are arranged in parallel belts. Along the whole length of the Pacific coast runs a continuous belt of broad high mountains, sometimes called the Cordilleras. These sink in the east to a broad, rolling plain, which extends from the Arctic Ocean to the Gulf of Mexico. Two breaks occur in its surface, which elsewhere slopes imperceptibly but uniformly from west to east. The first of these is the region west of Lake Superior. Though nowhere over 2,000 ft. high, it gives rise to the St. Lawrence, flowing due east to its gulf; the Mississippi, which flows almost due south across the central lowland to the gulf; and the Red River, which flows north to Lake Winnipeg. The second is the Ozark Mountains, which separate two of the parallel tributaries of the Mississippi which rise in the east. In the east the Central Lowland gradually rises to the Atlantic or Eastern Highlands, which, under various local names and with some breaks, can be traced from Hudson Bay almost to the Gulf. North of the St. Lawrence they are known as the Labrador Highlands, south of the St. Lawrence as the Appalachian Highlands. These highlands fall steeply on the east to the Atlantic lowland, which widens towards the south, and is connected round the south of the Appalachians with the central lowlands, there forming what is often called the Gulf Coastal Plain.

Rivers. From this arrangement of highlands and lowlands it follows that we shall have a series of (1) short rivers flowing west to the Pacific; (2) long rivers from the eastern slopes of the western mountains, flowing east or south; (3) long rivers from the gentler west slopes of the Appalachians, flowing west; and (4) short Atlantic rivers from the steep eastern slopes of the Appalachians. The rivers from the central heights have already been named.

The longest of the Pacific rivers flow for considerable distances parallel to the mountain chains. Of these, the chief are the Yukon, flowing to Behring Strait in a long, narrow valley parallel to the coast; the Fraser and Snake-Columbia, flowing to the Pacific from the central region of the western mountains; and the Colorado, flowing to the Gulf of California.

The northernmost of the long rivers flowing east is the Mackenzie, flowing with a course nearly parallel to that of the Yukon through Athabasca, Great Slave and Great Bear lakes to the Arctic Ocean. Parallel to its upper valley are those of the Saskatchewan, which flows east to Lake Winnipeg, and thence, as the Nelson, to Hudson Bay, and those of the great rivers which flow east to the Mississippi, the Missouri, Platte, Arkansas, and Red River. The Mississippi also receives the waters of long west-flowing rivers from the eastern Appalachians, which are gathered up and carried to it by the Ohio. Of the short, rapid rivers of the Atlantic seaboard the most important are the Connecticut, Hudson, Delaware, James, Potomac, Susquehanna, and Alabama.

Ease of Water Communication. No other continent has such admirable facilities for water communication. North America is covered by a network of lakes and rivers, separated by inconsiderable distances, permitting easy water communication in all directions. The Great Lakes, with the St. Lawrence, open up the very heart of the continent. Lake Erie is quite near the Ohio tributary of the Mississippi. Lake Superior is even nearer to (1) the Winnipeg-Nelson system of lakes and rivers; and (2) the Mississippi. A very short canal thus gives through communication between the Gulf of St. Lawrence and the Gulf of Mexico. The source of the Mississippi is only a few miles distant from that of the Winnipeg or Northern Red River, and the three systems, St. Lawrence, Northern Red River, Nelson, and Mississippi may almost be regarded as one great system, linking together the three great Atlantic gulfs. The Mackenzie is easily reached from the Saskatchewan, thus giving access to the Arctic Ocean; but as it is frozen for many months of the year, this is of little practical importance.

The Western Mountain System. It is impossible in our limited space to study this great system in detail. In the east, the lofty Rocky Mountains rise steeply from the plains. West of these are a series of plateaux, or basins, and west of these again another series of ranges, locally known under different names. An outer coastal range is less well marked, but can be traced on the mainland and bordering islands.

The basin of the Yukon is separated from the Mackenzie by spurs of the Rockies. West and south of the valley are two parallel volcanic ranges, the northern forming the mountains of Alaska, which are connected through the Aleutian Islands with the volcanic highlands of East Asia. Mount McKinley is the highest point in North America north of the Yukon. The southern range is a labyrinth of glacier-filled valleys and snow peaks rising precipitously from the sea, the highest being St. Elias (18,000 ft.) and Logan (19,700 ft.). Over the wild southern mountain chain difficult passes, closed by snow for many months, lead to the gold-mining districts of Klondike and other centres in the Yukon basin.

British Columbia. British Columbia is a high, rugged plateau enclosed between the Rockies on the east and the Northern Cascades on the west. Beyond the Cascades a coastal range appears in the islands of Queen Charlotte and Vancouver. Where they are crossed by the Canadian Pacific Railway the Rockies are a broad system, consisting of the Summit, Selkirk, and Gold ranges. These parallel ranges are separated by long valleys in which flow the tributaries of the rivers running west. The easternmost or Summit range of the Rockies rises in sheer cliffs or escarpments above the plains, towering up in rock walls 3,000 or 5,000 ft. high. The highest summit, Mount Columbia (14,000 ft.), overlooks the sources of the Athabasca, flowing to the Mackenzie, the Saskatchewan, flowing to Hudson Bay, and the Fraser and Columbia, flowing to the Pacific. Many peaks rise to 12,000 ft., and vast glaciers and snowfields feed the rivers. The forests are much thinner than in the Selkirks, whose fine combination of forest, glacier, and snow peak has earned the title of the Switzerland of America. The Gold and Cascade ranges are lower, and forested almost to their summits. Across these ranges, which presented great difficulties to the railway engineers, the rivers have cut deep, gloomy cañons in which a raging river boils along at the base of perpendicularly steep walls of rock.

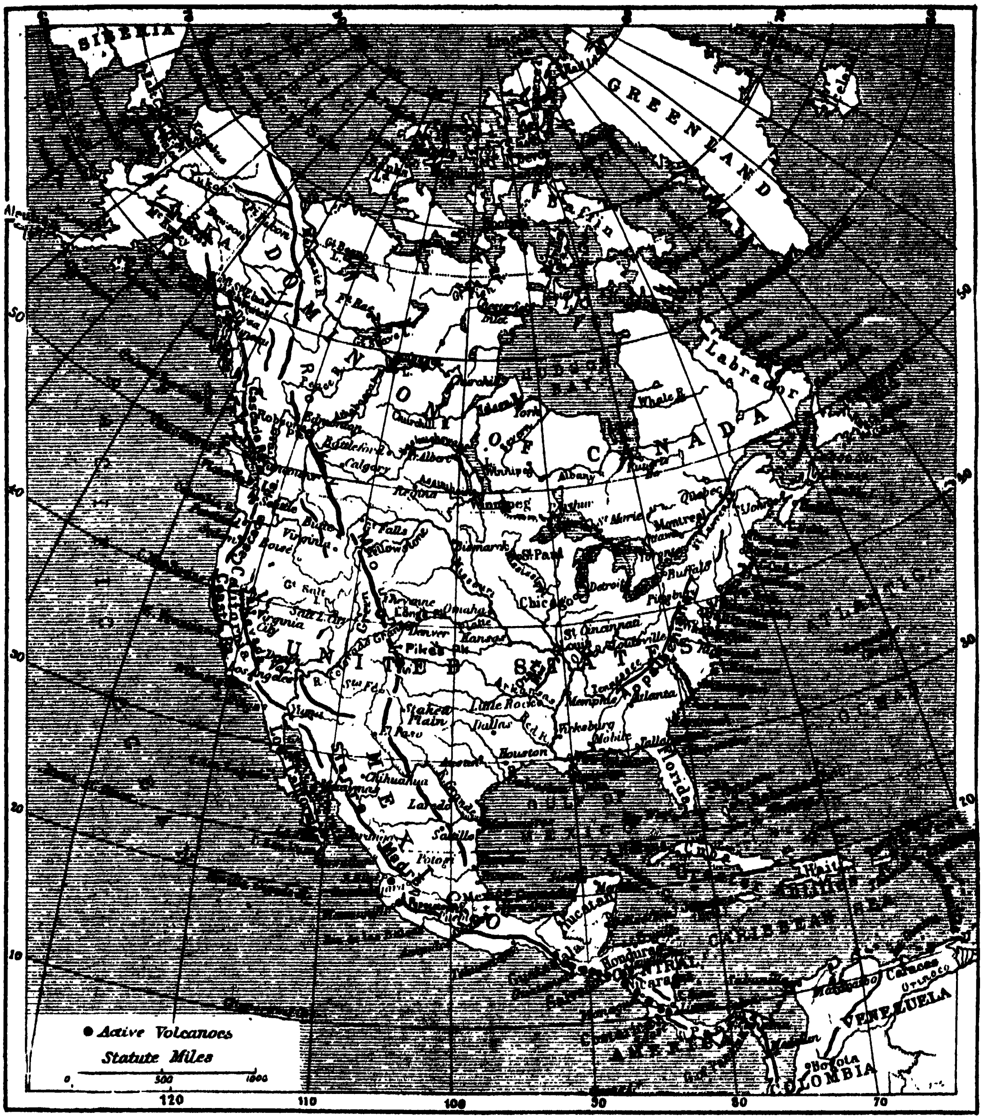
Western Mountains of the United States. The Rockies and Cascades continue south into the United States, diverging as they go. The Rockies become an intricate system of parallel ranges, which enclose high intermont valleys, locally called parks. They form the continental divide between the Atlantic and Pacific rivers. Within a relatively small area are the sources of the Missouri and Yellowstone tributaries of the Mississippi, the Snake tributary of the Columbia, the Green and Grand head streams of the Colorado, and the Rio Grande del Norte. There are spots on the Divide where the sources of two streams, one flowing to the Atlantic, the other to the Pacific, are hardly 200 yards apart.

The Yellowstone Park. The finest of these parks, set apart for national enjoyment, is the Yellowstone Park, some 75 miles square, situated on the Great Divide, about 7,000 ft. above the sea. Surrounded by an amphitheatre of mountains, and containing magnificent cascades, beautiful lakes, many geysers, hot springs, and wonderful coloured sinter terraces, it forms a natural museum unique in the world.

Far surpassing everything else in beauty is the Yellowstone Cañon, into which the river falls over the famous Yellowstone Falls. In places the walls of the cañon are 1,500 ft. high, while the width of the chasm is only half a mile. It has been cut down by the river through pale yellow or pinkish rocks, and the rocks do not weather uniformly. All along the cañon walls the harder parts project in a series of massive fretted buttresses and jagged pinnacles of the most fantastic shapes. "The whole gorge is painted in the most brilliant hues, from pale lemon yellow to deep orange, streaked with warm vermilion, crimson and purple, which, mingling with the deep green of the pines that clothe the brink of the chasm make up a picture of transcendent beauty."

Somewhat similar cañons are cut by the rivers south of the Yellowstone, where Long's Peak and Pike's Peak are both over 14,000 ft.

Idaho, Utah and Colorado. West of the Rockies lies the lava desert of Southern Idaho, cloven by the deep gorges of the Snake and Columbia Rivers. In their descent they pass over many falls, of which the Soshone Falls of the Snake are the finest. South of the Snake is the Great Basin, a district as large as France, whose waters flow to the Great Salt Lake, and other basins without an outlet. The surface is covered with short ranges of tilted block mountains, varied in colour and bare of vegetation. Between these are wide valleys covered with dry scrub, or with nitrates and other alkaline deposits. Under irrigation the



139. NORTH AMERICA

soil is very fertile, and the region round Salt Lake City is a veritable garden. The Wahsatch Mountains separate the Great Basin from the Colorado plateau to the east. This region consists of high arid plateaux, above which rise table-shaped mesas, or steep-sided pinnacle-shaped buttes. The Colorado and its tributaries flow in cañons similar to that of the Yellowstone but on an infinitely vaster scale. The Marble Cañon in the Painted Desert of Arizona, and the Grand Cañon of the lower Colorado, 300 miles long and in places a mile deep, are the most wonderful. This extraordinary region long baffled exploration, and is still imperfectly known. All these regions are arid, and bare of vegetation. West of the Colorado, in the lee of the Sierra Nevada, the country becomes a desert, where such names as Death Valley, a region of enormous mineral wealth, tell their own sinister tale. It is a land of burning sands, weird, distorted cactus vegetation, mirage and thirst.

The Western Rampart. The western rampart of these vast plateaux and basins is formed by the Southern Cascades, the Pacific slopes of which are densely forested. By intercepting the rainy winds they produce the arid conditions just described. Of many volcanic cones the finest are Tacoma, Hood, and Shasta (14,500 ft.), beyond which the system is continued south by the Sierra Nevada. Across the Southern Cascades there is only one natural route, the gorge of the Columbia, which cuts its way to the sea between great basaltic cliffs in places 2,000 ft. high. The Sierra Nevada contains many peaks over 13,000 ft., whose snowy summits have suggested its name. Hidden between its parallel ranges is the Yosemite Valley, one of the beauty spots of the world. It is enclosed between rock walls of stupendous height, over which the rivers leap in magnificent cascades, the wonderful panorama of crag, forest, and cascade being mirrored in the lovely lakes of the valley floor. Between the Cascades and the Coast range is the fertile Willamette valley of Oregon, whose northern extremity forms Puget Sound. Between the Sierra Nevada and the Coast range is the rich valley of California, drained by the Sacramento.

In Mexico, the Rocky Mountains are continued by the eastern, and the Sierra Nevada by the western Sierra Madre. These form the margins of the Mexican plateau, which rises to the south, where the Sierras converge to a great volcanic chain, containing many lofty snow-clad active and extinct volcanoes. The highest are Popocatepetl and Orizaba (18,000 ft.). Beyond this the mountains sink gradually to the Isthmus of Tehuantepec, which is less than 500 ft. high.

The Great Plains. The central plains of North America extend from the Arctic to the Gulf of Mexico. In the extreme north they are a tundra region, covered by a network of lakes. This passes at the south into forests, and these in turn into grasslands. In the United States the eastern forests have been largely cleared, and rolling treeless prairies form a monotonous landscape. Some unfertile tracts occur, such as the Bad Lands of South Dakota, and the Staked Plain of Texas. Along the Gulf of Mexico the plain is of alluvial formation, and fringed with swamps and lagoons. The peninsula of Florida consists of porous limestone, through which the rivers sink. The southern part forms the Everglades, a region of forested waterways and islands. The Atlantic plain is wide and swampy in the south, but becomes narrow in the north.

The Appalachians. These stretch from Newfoundland to within 200 miles of the Gulf, averaging 450 miles in width. Newfoundland, an island of low mountains and many lakes, is cut off by the Gulf of St. Lawrence from the very similar New Brunswick and Nova Scotia.

In the United States the rugged New England Highlands are separated by the Hudson valley from the Appalachian ranges, in the narrower sense of the term. The Appalachian system, which is in reality a very ancient plateau dissected out in the course of ages into parallel ranges separated by long narrow parallel valleys, becomes higher, broader, and more rugged. To the east is the Blue Ridge, and to the west the Alleghany Plateau. The structure of the region in its present form is very complicated. The ranges have local names, which can be looked out on the map.

These broad, rugged, and densely forested highlands long prevented the westward extension of colonisation. The rivers descending from the eastern slopes, which front the Atlantic plain as steep escarpments, did indeed lead to excellent passes, but these gave access only to trough-like valleys, beyond which rose a barrier similar to that just crossed. Population for 150 years moved up and down these valleys, but could not push westward into the central plains, except in the north, where the only natural break across the entire breadth of the highlands occurred.

The Gateway of the Appalachians. This gateway of the Appalachians was the Hudson valley, a great natural opening shut in by the escarpments of the plateau on either side. Nowhere 200 ft. high, and occupied by the Hudson and Lake Champlain, it opened a natural route to the St. Lawrence, and thence by the great lakes to the west. The importance of this route is shown by the enormous prosperity of the cities founded at its terminal points—New York and Montreal.

A still more direct route to the great lakes and the west opens from the Hudson, by the valley of its tributary, the Mohawk, which leads west to the lowlands around Lake Ontario. "Seen from the railway, which follows it, the valley appears to be a trench about 500 ft. deep, with moderately steep sides, and an average width of half a mile. Seen more truly from above the bordering uplands, it is a vast gap, 1,500 to 2,000 ft. deep, and several miles wide in its higher part," cut across the entire breadth of the plateau. The Mohawk valley, which commands the great route to the west, is followed by the New York Central Railway to Buffalo. "There is not a difficult grade or an embankment or a trestle of any importance between New York and Buffalo (490 miles), and with slight exception, this holds good from Buffalo to the Rockies. Two thousand miles of splendid country are made tributary to the harbour of New York through this river gateway."

Climate. In a continent nearly 4,000 miles long we have every kind of climate, from polar to tropical, modified by elevation and distance from the sea. If we look at a map of the January isotherms, these show the same southward sweep from west to east as in Europe. Thus a great part of the continent has frost for longer or shorter periods in winter, and the centre of the continent, in the latitude of Central Italy, is as cold as Iceland. South of 35° N., there are no winter frosts. Florida and California have a January like that of Egypt, and the tropical lowlands of Mexico have a January temperature of 70° F.

In summer the isotherms are bent north. Over most of the mainland the summer temperature is not below 50° F. The isotherm of 60° F., which crosses central England, traverses North America at the southern end of Hudson Bay, and runs north as we go west. The same regions which have very severe winters have thus warm summers. The isotherm of 70° F. strikes the west coast in about latitude 30° N., and runs almost due north for 20 degrees and then crosses the continent. South of latitude 30° the summers are hot, especially in the interior, where the lands in the lee of the Rockies are cut off from cooling ocean winds.

Rain falls abundantly on the Atlantic coast from Labrador southwards, and south of Newfoundland at all seasons. The rainfall diminishes slowly but steadily as we go west, and becomes extremely scanty west of the Mississippi, where the lands in the lee of the Rockies have a very dry climate. The west coast has abundant rain, especially in the north, where it falls at all seasons. Further south is California with winter rains, or a Mediterranean climate. In the trade wind area, the rainfall diminishes, and this explains why in the lee of the southern Rockies rainless deserts are found. If the continent were here broad like North Africa, instead of narrow, we should have a Sahara. As it is, we have desert resembling the Kalahari.

Vegetation. The vegetation of Arctic North America is of the familiar tundra type. Much of this region, especially round the northern part of Hudson Bay, has the expressive name of the Barren Grounds. Vegetation consists of moss and lichens, or of low berry-bearing bushes, with stunted trees in protected spots. To the south it passes gradually into poor woodland, the birch being found as far north as any of the conifers. In winter the tundra is frozen, and in spring, when the rivers are melting, it is flooded. Only in summer does it tempt north the caribou—the American reindeer. The caribou has never, like the reindeer, been domesticated, and there is consequently no summer migration of population north, as in the Old World. The Indian hunter, indeed, follows the trail of the caribou, but only for purposes of destruction. In the worst parts of the Arctic region, however, where vegetation practically ceases, we get the interesting Eskimo people, who live by slaying the creatures of the Polar Seas—bear, walrus, whale, etc., and show great ingenuity in supplying all their wants from these animals.

Forests and Steppes. Forests succeed the tundra, both in east and west. Thousands of square miles are covered with virgin forests, containing magnificent timber This gives rise to the important industry of lumbering. When the forest streams are frozen in winter, the lumbermen start for the woods, where they remain for several weeks, felling trees and dragging them over the firm frozen ground to the banks of the streams. When these thaw in spring, the swollen current whirls along its burden of logs to one of the great timber or lumber centres, where innumerable saw mills, turned by the river, soon transform the lumber into timber, wood pulp, etc. Beyond the forests, in the dry centre of the continent, we find the dry steppes or grass lands, generally called the prairies. Where the rainfall is sufficient for cereals, wheat is grown in the north and maize further south. The dry western prairies are used for cattle breeding. Many thousands of acres go to form a cattle ranche, on which thousands of head of stock run in a semi-wild condition.

The belt of desert in North America is relatively small. Neither savanas nor tropical forests are found, except in parts of Mexico and Florida.

Occupations. Hunting is the only means of livelihood for the Eskimo of the Arctic Ocean, Hudson Bay, and Greenland. The trapping of fur animals is important on the tundra and forest margins. Large herds of buffalo once roamed the prairies, and were hunted by numerous Indian tribes, but the white man exterminated them with more than savage recklessness.

In the forests, lumbering is important, and supports such industries as saw-milling, pulping, paper-making, etc., in the towns on the forest margin. In the eastern prairies wheat is grown on a vast scale. Flour-milling is important in towns adjacent to the prairie wheat belt. Further west stock raising or ranching suits the drier climate better. It leads to an immense trade in meat and other animal products. All the western mountains are rich in minerals, and mining is important in many parts. The sea fisheries of both the east and west coast are very valuable, especially in Canada and Newfoundland. The northern rivers of the Pacific slope teem with salmon, which are canned in immense quantities.

The industries of the towns are very varied. Manufactures are carried on with cheap water power in many of those of the east, especially in the United States at the base of the Appalachian highlands and on the coalfields.

Races. The original Indian inhabitants are now comparatively few in number, and confined to the tundra, the forests, or their own reservations. The modern American is of European descent. Except in the lower St. Lawrence basin British blood predominates in Canada, as well as in the United States, though all European nations are well represented. Spanish blood is pre-eminent in Mexico, where Spanish is spoken, and the religion is Roman Catholic. The rest of the continent is English speaking and mainly Protestant Negroes of African descent are numerous in the southern United States, and Chinese have settled on the Pacific coast.

CANADA

Let us look out in a map the frontiers of Canada, noticing that its boundary with the United States is quite artificial. Of its total area (3,460,000 sq miles), large portions are of little value. Its natural advantages include (1) vast forests, supplying timber, an asset of ever increasing value ; (2) immense and fertile wheat lands ; (3) great mineral wealth, including the rich Klondike goldfields of the Rockies ; (4) valuable fisheries ; (5) an unrivalled series of natural waterways ; (6) a healthy, bracing climate, stimulating to exertion.

British Columbia. This, the Switzerland of Canada, is the largest province of the Dominion (383,000 sq. miles). It has an equable climate, with much rain in the west. Its mountain scenery is among the finest in the world. The mountains provide two valuable sources of wealth—minerals and timber. There are gold mines round Rossland, in the rich Kootenay district. Thick seams of fine steam coal occur near the Crow's Nest Pass, much of which is sent west to the Pacific ports, and east to the plains. Mining towns are continually springing up in all directions. The rivers, which are navigable only for a short distance above their mouths, teem with salmon, the canning of which is a flourishing industry. The sea fisheries off the Pacific coast, whose fiords recall those of Norway, are also valuable. The most important city on the mainland is Vancouver, whence lines of steamers sail to China, Japan and Australia. The capital is Victoria, on Vancouver Island, near the naval station of Esquimalt. The Nanaimo coal mines in the vicinity are extremely important.

Arctic Canada. Round the Arctic Ocean and Hudson Bay lie the thinly-peopled districts of Yukon, Franklin, which includes the Arctic islands, Mackenzie, with its great lakes, Keewatin, the cold "land at the back of the north wind," and Ungava. The surface is tundra, or thin forest country, the home of many fur-bearing animals. Along the coast live a few Eskimos, but the bulk of the inhabitants are Indian hunters. A few white men are found at the trading posts scattered along the margin of the hunting grounds. Winter lasts several months, and then all travel is performed by dog teams or on snow-shoes. In summer, light bark canoes are used on the numerous rivers and lakes. There are no towns.

Saskatchewan and Alberta. These provinces are in process of settlement. Most of their surface is prairie land, though certain parts are wooded. In Eastern Saskatchewan are fertile wheat lands, the area of which is growing rapidly. In the drier districts of South-western Alberta ranching is important. Warm chinook winds descend from the Rockies and melt away the snow, so that stock can forage for themselves for a great part of the winter. These territories are rich in minerals. Coal is widely distributed in Alberta, and is mined for local consumption, helping to make up for the lack of timber. Petroleum is said to be abundant in the north. Towns are few as yet. Regina is the capital of Saskatchewan, and Calgary of Alberta. Medicine Hat, an important station on the Canadian Pacific line, is in a ranching district. Edmonton, in North Alberta, in an extensive agricultural district, is the largest fur market in North America. Lethbridge has large coal mines.

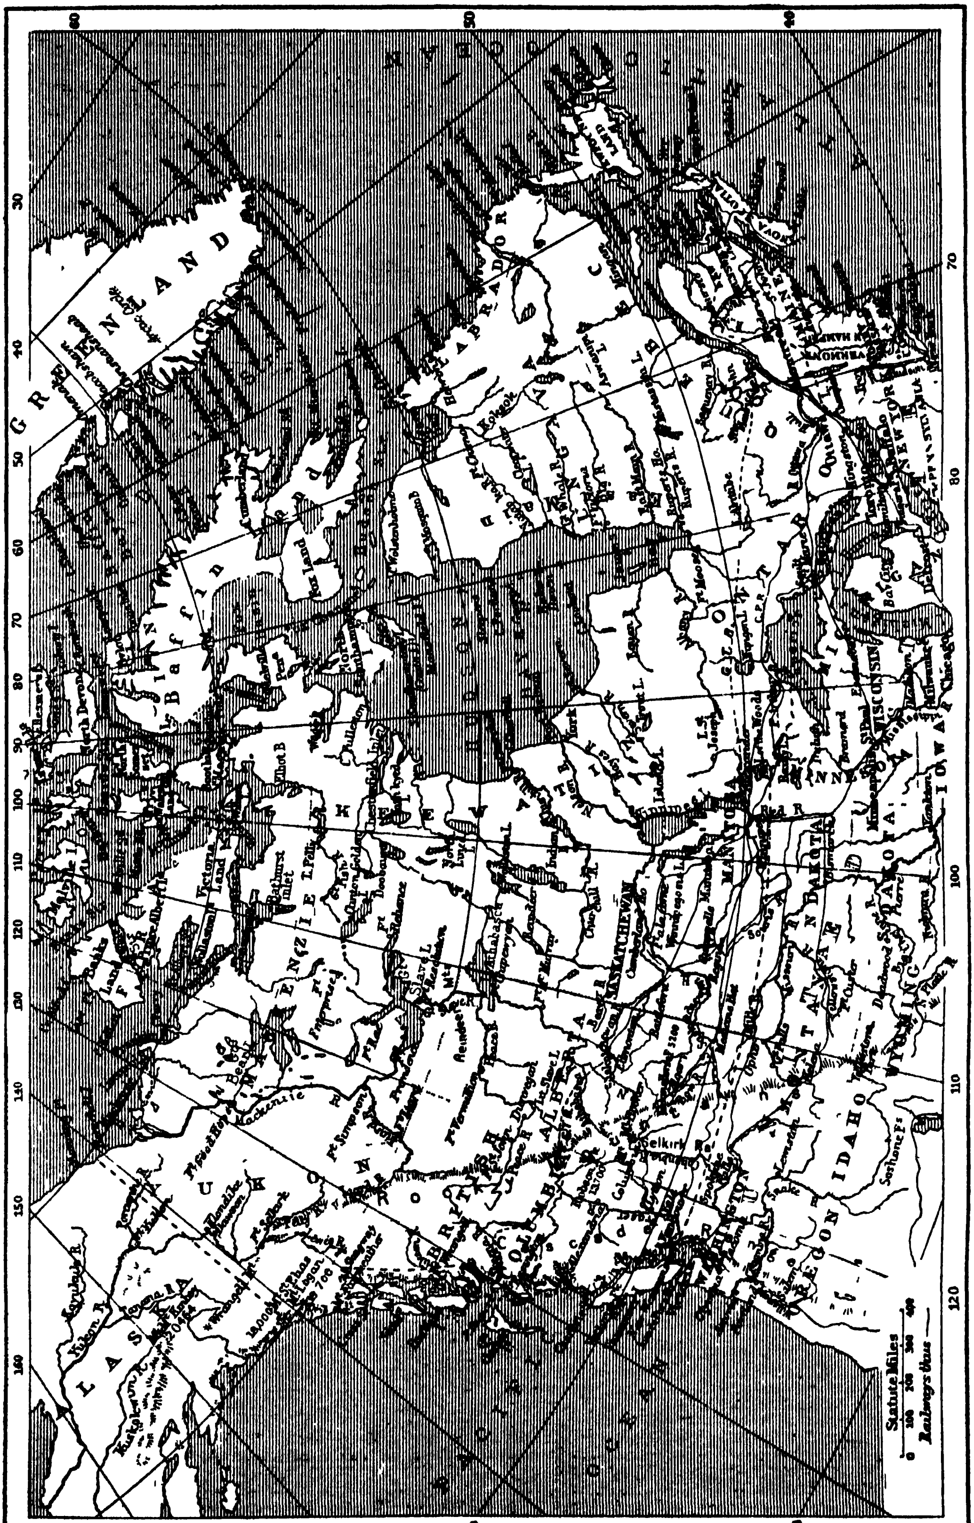
Manitoba. The lake province of Manitoba, in the centre of the continent, lies partly in the prairie wheat belt and partly in the forest country, where lumbering is important. In the agricultural districts wheat is the mainstay, but dairy farming and the fattening of hogs and stock are rapidly becoming important. "Formerly, if an early frost damaged a farmer's wheat, he sold it at about half price, and lost heavily. Now he feeds his hogs with it, and in the end the return is almost as great as it would have been from the uninjured wheat." Manitoba is thus at a higher stage than the provinces just described, where the prosperity of a whole district depends on a single staple. The capital is Winnipeg, a great railway centre, with excellent facilities for water communication in all directions. In autumn the railway traffic is enormous, as the whole wheat harvest of the prairies has to be forwarded to the eastern markets. Winnipeg has an important university, and is rapidly becoming the political, social, educational, and commercial capital of the west. The other considerable towns are Brandon, a wheat market, and Portage la Prairie, with flour mills.

Farming in the Great West. In the wheat-growing prairies ploughing begins in autumn, and goes on steadily till stopped by the frosts of November or December. In April, wheat is sown first, when the soil is still moist after the thaws. The early summer months may be spent in breaking up new fields in the virgin prairie, or in the care of dairy and other needful farm work. The hay harvest is carried in July, and if cattle are extensively kept, there will be a maize harvest to get in for winter fodder for the dairy cows. "As the wheat begins to head, the western farmer casts many an anxious glance at the weather, for occasionally a late frost comes and damages his crop. In August the wheat is ripe and the harvest begins. The grain is rapidly cut and bound by machines called binders. In the east it is stored in barns, to be threshed later, but in the west the crop is too heavy for this, so it is hauled to a stack, and piled ready for the threshers. Just before cutting, the western wheat fields present a lovely picture. As far as the eye can reach the grain waves and ripples in the warm summer breeze like a sea of gold."

As soon as the grain is cut and stacked comes the threshing. In the west, farms are far apart so a threshing gang travels with the threshing mill. The gang sleep in a large van. This is taken from place to place by the traction engine, which draws the threshing machine and supplies the driving power when the mill is at work. As the hum of the threshing mill begins, the scene is a lively one. Every man has his appointed place, and the stack of grain grows rapidly smaller as the pile of straw heaps up, and the sacks are filled with the bright clean grain. As soon as threshing is over the farmer hauls his grain to the nearest railway station, where it is sold and stored in the elevator ready for transport to the east over the Canadian Pacific Railway.

Ontario. Ontario (222,000 sq. miles), the richest province of Canada, larger than Germany, lies between the great lakes and James Bay, a gulf of Hudson Bay. The northern climate is dry, bracing and extreme; but the neighbourhood of the great lakes makes Southern Ontario moist and rather enervating. Ontario is a region of lower hills, lakes and rivers, many of which have falls. The north is densely forested, supplying valuable lumber. The Ottawa river brings down enormous quantities to be sawn in the innumerable saw mills turned by the Chaudière Falls. The southern part is cleared and dotted with towns and villages at short intervals.

The occupations of Ontario are numerous and varied. Lumbering in the backwoods makes saw milling, pulping, and other methods of working up timber important. Southern Ontario is a farmer's country. Unable to compete with



140. THE DOMINION OF CANADA

the wheat lands of the virgin west, farmers find dairy and mixed farming more profitable, and cheese and butter are produced in enormous quantities. The Lake peninsula, between Huron and Erie, is a land of orchards, where every kind of fruit is grown, especially peaches and grapes. Wine is made in considerable quantities. Special fruit trains run from this district in the season, supplying cheap fruit to the large cities of Canada and the United States. Round Lake Huron are deposits of salt and mineral oil. Nickel is abundant round Sudbury, and copper north of Lake Superior. Other minerals, including gold and iron, are probably widely distributed though unworked.

Industries. The fisheries of the great lakes employ large numbers of persons, and fish trains with refrigerating cars distribute the fish to inland centres.

Manufactures, carried on by water or electric power, are developing, and include textiles, railway plant, brewing, distilling, etc. Hamilton, on Lake Ontario, is a manufacturing centre.

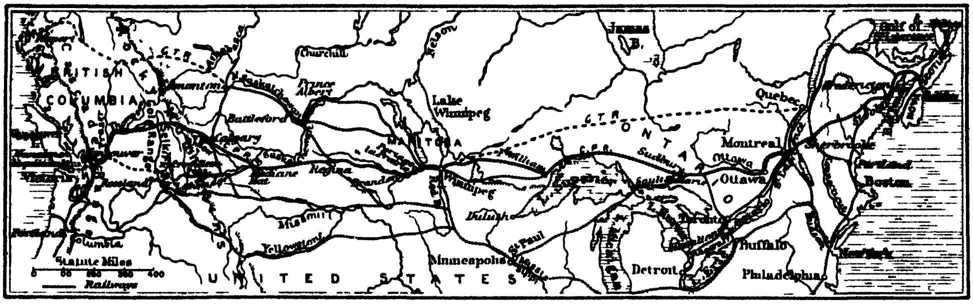
Toronto, the provincial capital, with a university, is a handsome town with a good harbour on Lake Ontario. The Dominion capital, Ottawa, a great lumber centre, is finely situated at the foot of the Chaudière Falls. It is connected by the Rideau Canal with Lake Ontario.

Ontario is well situated for commerce. Railways run in all directions, and there are many excellent harbours on the lakes. Canals have been cut to avoid the rapids between the lakes, the most important being the Soo, or Sault Ste. Marie Canal, between Huron and Superior, where an industrial town is growing up. The tonnage which passes through the canals on the Canadian and United States sides of the rapids, in spite of being frozen five months every year, exceeds that of the Suez Canal, so enormous is the volume of trade carried by this magnificent system of inland waterways.

Niagara Falls. Lakes Erie and Ontario are connected by the short Niagara river, on which are the famous Niagara Falls. The river is a mile wide where it makes its great leap sheer down 160 ft. into the narrow boiling ravine below, down which its waters surge to Ontario. There are practically two distinct falls, separated by an island. The fall on the Canadian side is the Horseshoe Fall, a little lower than the American fall. The power supplied by the falls generates electricity for lighting Buffalo, in New York State, and for industrial purposes.

Towns. Quebec (347,000 sq. miles) was founded by French settlers, and many of the inhabitants are French speaking and of French descent. The province, which is half as large again as Ontario, is densely forested, and lumbering is a leading industry. Agriculture and fishing are also very important. Minerals are abundant, except coal. There is, however, ample water power, and manufactures will be carried on by electric power.

The largest city is Montreal, with excellent communication by river, rail and canal. It is built at the foot of Mont Royal, and has many fine buildings. The shores of the St. Lawrence are lined for miles with wharves, from which are shipped the wheat, timber and dairy produce of the Dominion, and to which imports of all kinds are brought. The manufactures of Montreal are growing rapidly. Quebec, the capital, is one of the oldest cities in America. Its commanding situation on cliffs above the broad river makes it the Gibraltar of the St. Lawrence. Hull, on the Ottawa opposite Ottawa, and Sherbrooke near Montreal are manufacturing towns.



141. THE CANADIAN PACIFIC RAILWAY

New Brunswick. The maritime province of New Brunswick (28,000 sq. miles) has immense forests, which are often ravaged by disastrous fires. Much lumber is cut in winter, floated down in spring, and sawn and worked up in summer. Minerals are abundant, but hardly worked; the fisheries, however, are extremely valuable. The south and east are settled, but the towns are small. The capital is Fredericton, at the head of the tidal waters of the St. John river, at the mouth of which is St. John. This port is never closed by ice, and in winter it is the shipping port of the Canadian Pacific Railway.

Nova Scotia. Nova Scotia (20,600 sq. miles) consists of the Nova Scotia peninsula and Cape Breton Island. It has high hills and broad valleys, with many lakes and rivers. The climate resembles that of England, but is more extreme. Atlantic fogs are common. The coast islands are rocky and poor, but the western valleys of the interior are famous for their apple orchards. Much of the country is forested and lumbering is important. Shipbuilding, a flourishing occupation before the days of iron and steel, has declined, but will develop as the coal-mines and ironworks around Sydney, on Cape Breton Island, increase their output. The fisheries are important. The capital is Halifax, with a magnificent ice-free harbour capable of holding the whole British Navy.

Cape Breton Island somewhat resembles Scotland. Its occupations are lumbering, fishing, mining and shipbuilding. Sydney is the chief town.

Prince Edward Island. This small island (2,000 sq. miles) owes much of its fertility to "mussel-mud," the decomposed remains of shell-fish, of which there are deposits many feet thick along the coast. The mud is raised by machinery and spread over the land, most of which is under cultivation. Dairy farming is important. Hay and potatoes are grown for the United States markets. The fisheries, especially of shell-fish, are very valuable. The capital is Charlottetown.

Newfoundland. Newfoundland (42,000 sq. miles) has been called the Norway of the New World. There is no little resemblance in the character of the island with its long fiords running inland between high walls of rock, but the mountains are very much lower. The chief occupation in both is fishing, supplemented by some farming. The Newfoundland fisheries are among the most valuable in the world. Three parts of the catch consist of cod, taken on the shores of Newfoundland itself, on the Great Banks a day's sail away, and off the desolate Labrador coast, which is included in Newfoundland. Many vessels go north annually to the seal fisheries.

Newfoundland is mountainous in the west, but flatter in the east. The interior is forested. Both lumbering and shipbuilding are important. Minerals, especially copper, are abundant; iron is exported to Canada from Bell Island. Dairy farming and agriculture are developing. The capital is St. John's.

Trans - Canadian Railways. The C.P.R., or Canadian Pacific Railway, crosses Canada from ocean to ocean. The Atlantic ports are Halifax and St. John, open all the year, and the summer ports of Quebec and Montreal. The Grand Trunk line is constructing a railway from Quebec to Port Rupert on the Pacific, north of the C.P.R., viâ Winnipeg and Edmonton. A network of lines covers the regions round the great lakes, and connects with the lines of the United States, that by the Hudson to New York being the most important.

The C.P.R. The trans-continental part of the C.P.R. begins at Fort William, on Lake Superior, whence the line runs west through a thinly forested region. About 50 miles from Winnipeg the country opens out into level prairie, covered over vast areas by wheatfields. At Winnipeg the sight of many miles of sidings and innumerable elevators brings home to the traveller the magnitude of the harvest of these vast plains. Beyond Medicine Hat the line follows the Saskatchewan valley, and reaches Alberta in the ranching country. The distant Rockies appear on the horizon, and the line soon enters the foot hills. The ascent is made by the Bow valley, amid glimpses of fine forest, mountain and glacier scenery, to the summit of the pass (5,000 ft.). The descent on the opposite side is by the precipitous Wapta valley. "The railway follows the river, crossing from side to side, and clinging to the ledges of dizzy precipices." In the first part of the descent there is a drop of 1,150 feet in five miles, and in the steepest parts the speed is reduced to five miles an hour. At last the cañon opens to the broad valley of the Columbia, with a fine prospect of the Rockies on the one hand, and the Selkirks on the other, with their steep forested slopes rising to the glaciers and snow-peaks beyond [141].

A Wonderful Climb. This range is next crossed by a triumph of engineering. The line turns up the narrow gorge of the Beaver, clinging to the sides of the mountains, and turning up side valleys till at last, between gigantic peaks, and in sight of imposing glaciers, the summit of the pass is reached (4,500 ft.). The descent to the valley of the Columbia, which has gone round the Selkirks while the line has crossed them, is made by the valley of the Illicilliwaet, a descent almost as steep as that of the Wapta gorge. Those who have travelled in the Alps will form an idea of the skilful engineering devices employed—the winding tracks, the loops, and curves, used to reduce the sheerness of the descent. Often as many as four tracks, one below the other, are in sight at once. At last, however, the Columbia valley is reached, and the line is carried across the Gold range by a low pass, which runs for many miles between vertical cliffs. Four beautiful lakes occupy the whole width of the summit level, and the line proceeds west by the Shoushwap and Kamloop lakes, to plunge at last into the gloomy Thompson cañon, from which it emerges to follow the wild cañon of the Fraser.

"Through this gorge, so deep and narrow in places that the sun's rays hardly enter it, the black waters of the river force their way. We are in the heart of the Cascade range, and above the walls of the cañon we see mountain peaks gleaming against the sky. Hundreds of feet above the river is the railway, notched into the face of the cliff, and continually crossing some deep chasm by a great viaduct, or disappearing into a tunnel through some projecting spur." At last the cañon widens to a valley, meadows appear, farms and orchards vary the scene, and the sight of steamboats on the Fraser show that the great descent is over. The blue waters of the Pacific come in sight, and the train reaches Vancouver, the Pacific terminus.

PERSONAL PRONOUNS—continued

Use of the Conjunctive Forms. The conjunctive forms of the personal pronouns may be combined together, and then the forms *mi, ti, si, ci, vi, gli*, are changed into *me, te, se, ce, ve, glie*, when they occur with *lo, la, le, li, ne*, which they always precede. *Glie* is always written in one word with *lo, la, le, li, ne*, and, in this case, it stands for *to him* as well as for *to her*. Thus we have the following forms, which are placed before the verb.

Mi, to me
me lo, me la, it, him, her to me
me li, me le, them to me
me ne, of it, of him, of them, etc., to me

Ti, to thee
te lo, te la, it, him, her to thee
te li, te le, them to thee
te ne, of it, of him, of them, etc., to thee

Si, to himself, etc.
se lo, se la, it, him, her, to himself, etc.
se li, se le, them to himself, etc.
se ne, of it, of him, etc., to himself, etc.

Ci, to us
ce lo, ce la, it, him, her to us
ce li, ce le, them to us
ce ne, of it, of him, etc., to us

Vi, to you
ve lo, ve la, it, him, her to you
ve li, ve le, them to you
ve ne, of it, of him, of them, etc., to you

Gli, to him ; *le*, to her
glielo, gliela, it, him, her, to him or to her
glieli, gliele, them, to him or to her
gliene, of it, of him, of them, etc., to him, to her

NOTE. The forms *glielo, gliela, glieli, gliele, gliene* are also used for it, him, her, them, of it, etc., to them, and, as we shall see later, to you. Note here the forms *ci, vi*, there (*e.g.*, *ci sono*, there are; *vi sarà*, there will be), which in combination become *ce, ve*, with meanings that will be easily gathered from the following:

ce lo troverete = you will find him there
ce la troverete = you will find her there
ce li troverete = you will find them there
ce ne troverete = you will find some there

EXAMPLES: 1 *Me lo promìsero*, They promised it to me. 2. *Me ne hanno parlato*, They have spoken to me of it. 3. *Te li darò*, I shall give them to thee. 4. *Te la mostrerò*, I shall show her [or it] to thee. 5. *Se li sono spesi*, They have spent them themselves. 6. *Ce ne presteranno*, They will lend us some. 7. *Ve lo proibisco*, I forbid it you. 8. *Glielo spiegheremo*, We shall explain it to him, etc. 9. *Non gliene parlate*, Do not speak of it to him, etc. 10. *Non ce n'è più*, There is no more of it.

Position of the Conjunctive Forms. It has been seen that the conjunctive pronouns (*mi, ti, si*, etc.) and their combined forms (*me lo, te lo*, etc.) are, as a rule, placed before the verb. But when they occur with the *imperative* (the third persons excepted), the *infinitive*, the *gerund*, and the *past participle*, they are placed after the verb, and are written in one word with it. They are also joined in the same way to the word *ecco*, as: *èccoli*, here they are ; *èccoci*, here we are. The infinitive drops the final *e* before the conjunctive forms, as: *vèndere*, to sell ; *vènderlo*, to sell it ; *vènderglielo*, to sell it to him. If the infinitive ends in *-rre* the final *-re* is dropped, as: *indurre*, to induce ; *indurci*, to induce us. When the infinitive is governed by another verb, the above forms may be placed before this verb, as: *Non posso darvelo*, or *non ve lo posso dare*, I cannot give it to you. But if the pronoun depends upon the first verb it must never be placed after the infinitive, as: *Vi làscio andare*, I let you go, and not *lascio andarvi*. In the imperative negative it is better to let the pronoun precede, as: *Non me ne parlate*, Do not speak of it to me.

In poetry and in literary style the conjunctive pronouns may be added to other forms of the verb, besides those mentioned above, as: *rispòsegli*, he answered him. When the verb ends in an accented vowel, the written accent is omitted and the conjunctive forms (*gli* excepted) double the initial consonant, as: *dammi*, give me: *dicci*, tell us ; *mostrerovvi*, I will show you ; *dirogli*, I will tell him.

NOTE. *Loro* is generally placed after the verb, but is never joined to it: *L'ho mandato loro*, I have sent it to them.

EXAMPLES: 1. *Devo scrìverglielo*, I must write it to him. 2. *Che essi glielo restituiscano*, That they give it back to him. 3. *Dàtemelo*, Give it to me. 4. *Non glielo date*, Do not give it to him. 5. *Avèndomene parlato*, Having spoken to me of it. 6. *Vedùtolo*, Having seen him. 7. *Èccoci*, Here we are. 8. *Èccolo lì*, There he is. 9. *Non potete negarlo*, You cannot deny it. 10. *Lo fècero arrestare*, They had him arrested.

EXERCISE XXIX.

1. Avevamo pensato di vèndergli dei biglietti, ma non ne ha voluto comprare. 2. Me ne hanno mostrato di diverse qualità. 3. Se ne avessi ancòra, ve ne darei. 4. Dov'è vostra zia ? 5. Eccola qui, parlàtegliene. 6. Sono molto

belli questi quadretti; se andate in Italia non dimenticate di compràrmene. 7. Ho comprato dei giocàttoli per questo ragazzino, ma ho dimenticato di portàrglieli. 8. Non glieli portate, perchè è stato cattivo tutto il giorno. 9. Se la sarta ha finito la mia veste, ditele di mandàrmela sùbito. 10. Non mancherò di dirglielo.

EXERCISE XXX.

1. Don't you see that this little girl's face is all dirty with smoke? Wash it for her. 2. If you have some fresh roses and carnations, make a nice bouquet of them, and send it to this address. 3. I had begged of you not to tell her anything, and you have told her everything. 4. Here is the letter that we have received, read it to her, and see what impression it makes on her. 5. If she had said such words to us, we should have known how to answer her fittingly (*per le rime*). 6. This telegram was handed to you at twenty past seven. How is it that you give it to me after more than two hours? 7. If you like to go to the theatre, go [there]; I prefer not to go out (*uscire*). 8. I will treat him as my brother, I promise [it] you. 9. Here is the telegram that we have received: "Received cycles; will send them you." 10. It is in Italian; I do not understand it; translate it for me, please.

CONVERSAZIONE

Se il signor N. domanda di me, dìtegli che lo aspetto al cìrcolo.

Glielo dirò.

Mandate a comprare delle sigarette e offrìtegliene.

Gliene abbiamo già offerto.

Perchè non me ne avete mai parlato prima? Avreste dovuto parlàrmene.

Me n'ero dimenticato.

Se non vi sarà possibile di venire, non dimenticate di avvertirci.

Certamente; vi manderò un telegramma.

Gli hai domandato di prestarti del danaro?

Gliel'ho domandato e me ne ha prestato.

Quando restituirete il danaro alla vostra amica?

Per il momento non ho danaro; ma appena ne avrò glielo restituirò.

Avete risposto alla lèttera di mio cugino?

Non ancòra; aspetto che il fotògrafo mi consegni le mie fotografie, perchè voglio spedirgliene una.

VERBS—continued

The Passive Verb

As in English, the passive voice is formed in Italian by simply adding the past participle of an active verb to the various parts of the verb *èssere*: *egli è*, he is; *egli è amato*, he is loved; *egli sarà*, he will be; *egli sarà lodato*, he will be praised. The past participle after *èssere*, as we have already seen, must always agree in gender and number with the subject to which it refers: *egli è lodato, essa è lodata, i miei fratelli sono lodati, le mie sorelle sono lodate.*

The preposition *by*, which follows a passive verb, is translated *da*. She is loved *by* her brother, ***Essa è amata da suo fratello.***

Essere amato, *-a, -i, -e,* to be loved

INDICATIVE MOOD

Present

I am loved, etc.	We are loved, etc.
Sono amato, -a, etc.	*Siamo amati, -e, etc.*

Past Indefinite

I have been loved, etc.	We have been loved, etc.
Sono stato, -a, amato, -a	*Siamo stati, -e, amati, -e*

Imperfect

I was loved	We were loved
Ero amato, -a	*Eravamo amati, -e*

First Pluperfect

I had been loved	We had been loved
Ero stato, -a, amato, -a	*Eravamo stati, -e, amati, -e*

Past Definite

I was loved	We were loved
Fui amato, -a	*Fummo amati, -e*

Second Pluperfect

I had been loved	We had been loved
Fui stato, -a, amato, -a	*Fummo stati, -e, amati, -e*

Future

I shall be loved	We shall be loved
Sarò amato, -a	*Saremo amati, -e*

Future Perfect

I shall have been loved	We shall have been loved
Sarò stato, -a, amato, -a	*Saremo stati, -e, amati, -e*

IMPERATIVE

Be loved	Be loved
Sia amato, -a	*Siate amati, -e*

SUBJUNCTIVE MOOD

Present

That I be loved	That we be loved
Sia amato, -a	*Siamo amati, -e*

Perfect

That I have been loved	That we have been loved
Sia stato, -a, amato, -a	*Siamo stati, -e, amati, -e*

Imperfect

If I were loved	If we were loved
Fossi amato, -a	*Fòssimo amati, -e*

Pluperfect

If I had been loved	If we had been loved
Fossi stato, -a, amato, -a	*Fòssimo stati, -e, amati, -e*

CONDITIONAL MOOD

Present

I should be loved	We should be loved
Sarei amato, -a	*Saremmo amati, -e*

Perfect

I should have been loved	We should have been loved
Sarei stato, -a, amato, -a	*Saremmo stati, -e, amati, -e*

INFINITIVE MOOD

Present—Essere amato, -a, -i, -e, to be loved

Perfect—Essere stato, -a, -i, -e, amato, -a, -i, -e, to have been loved

Gerund

Present—Essèndo amato, -a, -i, -e, being loved

Perfect—Essendo stato, -a, -i, -e amato, -a, -i -e, having been loved

OBSERVATIONS

1. In the Present, Imperfect, Past Indefinite, Future, and Conditional, instead of the verb *èssere,* may be used the corresponding tenses of the verb *venire* (to come), as: *vengo lodato,* I am praised; *vènnero trovati,* they were found. Occasionally the verbs *andare* (to go), and *stare* (to stay), are used in the same way, as: *andò perduto,* it was lost; *sta scritto,* it is written. *Andare* has sometimes the meaning of to be obliged to be, as: *Questo libro va custodito gelosamente,* This book must be carefully kept; *Questa parola va scritta così,* This word is to be written so.

2. The passive voice may also be formed by using the third persons (singular and plural) of the active verb preceded by *si,* as: *si dice,* it is said, they say, people say, etc; *si lèggono,* they are read, etc.

EXERCISE XXXI.

oràrio (*oràhreeo*), time-table
ferrovia (*fehrroveèah*), railway
operaio (*opeh-ràh-eeo*), workman
schivare (*skee-vàhreh*), to avoid
ferito (*fehreèto*), wounded
avaro (*ahvàhro*), miser
calamite (*cahlahmeètah*) magnet
fuoco (*foo-òco*), fire
carbone (*cahr-bòneh*), coal
ladro (*làhdro*), thief
guerra (*guèh-rrah*), war
noioso (*no-ee-òso*), tiresome

1. Quel ragazzo fu salvato per miràcolo. 2. Oggi è stato pubblicato il nuovo oràrio delle ferrovie. 3. Gli operai vèngono pagati ogni cinque giorni. 4. Fummo invitati, ma non ci andammo. 5. Egli è amato e stimato da tutti quelli che lo conòscono. 6. Mi dispiace di non potere accettare il vostro invito, perchè devo (I must) partire sùbito per Roma, dove sono stato chiamato telegraficamente. 7. E vietata l'affissione. 8. Si dice che la guerra fra i due paesi sia ormai inevitàbile. 9. Dìcono che il Generale N. sia stato ferito nell' ùltima battàglia. 10. Non èssere noioso, se no sarai schivato da tutti. 11. Questa storiella ci è stata raccontata da un nostro amico. 12. L'avaro viene attratto dall'oro, come il ferro dalla calamita. 13. Il fuoco è stato finalmente isolato; ma venti case e due depòsiti di carbone sono stati interamente distrutti. 14. Il ladro è stato arrestato.

KEY TO EXERCISE XXIX.

1. Speak more slowly, please, because I do not understand you. 2. Do not call him yet, let him finish writing. 3. Be silent; I forbid you to speak ill of a friend in my presence. 4. Which of these two do you prefer? 5. I prefer the first one, because it is cheaper. 6. If he asserts it, that means that it is true. 7. That poor child does nothing but cough all day. 8. Did you sleep well last night? 9. This tea is not good; you have poured the water on before it boiled. 10. Tell the servant to dress the children, because it is time to go. 11. If the artists sing well, we will applaud them. 12. This is already the third time that you ask me whether it is true; I must inform you that I never speak a falsehood. 13. Do not say so, please, because you have so many times told me falsehoods that I no longer believe anything that you say. 14. Eggs and meat are very nourishing. 15. I do not understand why you wish to be always right.

PRONOMINAL VERBS

General Remarks

1. Pronominal verbs are so called because they are conjugated with two personal pronouns which refer to the same person and of which one is the subject, the other the object of the verb, as *je me flatte,* I flatter myself.

2. The majority of pronominal verbs are reflexive—that is to say, they express an action of which the same person is both the "doer" and the "sufferer," as *il se blessera,* he will wound himself.

3. Pronominal verbs are either (*a*) essentially pronominal, or (*b*) accidentally pronominal. Essentially pronominal verbs are those that are never used otherwise than with two pronouns, such as *se repentir,* to repent; *s'emparer,* to seize, to get possession of; *s'abstenir,* to abstain.

Accidentally pronominal verbs are those which are sometimes conjugated with a single pronoun, that which represents the subject, and sometimes with two, thus: *il trompe,* he deceives; *il se trompe,* he is mistaken (lit., he deceives himself).

4. In the third person singular, and the third person plural, a noun may take the place of the subject; thus: *L'enfant se blessera,* The child will wound (hurt) himself; *L'armée s'empara de la ville,* The army took possession of the town.

4. The pronoun, which is the object of a pronominal verb is not necessarily a direct object, or accusative; it may also be an indirect object, or dative; thus: *Je me rappelle ce que vous m'avez dit,* I remember (lit., recall to myself) what you have told me. The use of the pronoun as an indirect object is particularly frequent when the direct object is a part of the body; thus: in *il se lave,* he washes himself, *se* is a direct object, whereas in *il se lave les mains,* he washes his hands (lit., he washes to himself the hands), *se* is an indirect object.

5. Pronominal verbs are reciprocal when they indicate an action which several subjects mutually do to each other, thus: *Nous nous voyons tous les jours,* We see each other every day. These verbs can only be used in the plural forms.

6. When the reciprocity of the action expressed by the verb is quite clear, the pronominal form is sufficient, thus: *ils s'embrassèrent,* they embraced (each other). If, however, it is not obvious whether the subjects do the action to each other or to themselves, reciprocity must be expressed by the addition of *l'un l'autre* (m.), *l'une l'autre* (f.), *les uns les autres* (m. pl.), *les unes les autres* (f. pl.), each other, or by the use of *mutuellement,* mutually, or *réciproquement,* reciprocally. Thus, *ils se flattent,* may mean either "they flatter themselves," or "they flatter each other." By saying *ils se flattent les uns les autres,* the latter meaning is made quite plain.

7. Pronominal verbs are very numerous in French. They are frequently used to express an action for which a simple verb is sufficient in English, as *se repentir,* to repent; *se lever,* to rise; *se coucher,* to lie down (go to bed); *se vanter,* to boast. A common use of the pronominal verb with reflexive meaning is to render the English passive voice, when that passive does not refer in a special manner either to the doer of the action or to the state resulting from that action. Thus: *Chaque volume se vend séparément,* Each volume is sold separately

8. All pronominal verbs form their compound tenses by means of the auxiliary *être,* to be. Thus: *Je me suis levé,* I got up; *Il s'était vanté,* He had boasted; *Tu te seras enrhumé,* You will have caught cold.

9. Although pronominal verbs take *être* in their compound tenses, the rule for the agreement of the past participle in those compound tenses is the same as if the auxiliary were *avoir*—that is to say, the past participle does not agree with the subject, but agrees with the direct object if that direct object precedes the past participle. Thus: *Nous nous sommes lavés,* We have washed, *lavés* agreeing with the *second* "nous," which is the direct object, and which precedes *lavés.* In *Elles se sont lavé les mains,* They (f.) have washed their hands, the direct object is not *se* (to themselves), but *les mains,* which comes after the verb. There is, consequently, no agreement of the past participle

10. When given in the infinitive form (as in vocabularies, dictionaries, etc.), pronominal verbs are always accompanied by *se,* oneself, to oneself, as *se flatter,* to flatter oneself. In actual use, the infinitive may be preceded by *me, te, nous, vous*: *Je vais me promener,* I am going for a walk; *Il est temps de te lever,* It is time for you to get up; *Nous avions peur de nous tromper,* We were afraid of making a mistake; *Je vous prie de ne pas vous déranger,* I beg you will not put yourself out.

Se lever, to rise

PRINCIPAL PARTS: *se lever, se levant, s'étant levé, je me lève, je me levai.*

INDICATIVE

Present	*Past Definite*
I rise, etc.	I rose, etc.
je me lève	*je me levai*
tu te lèves	*tu te levas*
il se lève	*il se leva*
elle se lève	*elle se leva*
nous nous levons	*nous nous levâmes*
vous vous levez	*vous vous levâtes*
ils se lèvent	*ils se levèrent*
elles se lèvent	*elles se levèrent*

Imperfect	*Future*
I was rising, etc.	I shall rise, etc.
je me levais	*je me lèverai*
tu te levais	*tu te lèveras*
il se levait	*il se lèvera*
elle se levait	*elle se lèvera*
nous nous levions	*nous nous lèverons*
vous vous leviez	*vous vous lèverez*
ils se levaient	*ils se lèveront*
elles se levaient	*elles se lèveront*

COMPOUND TENSES

Past Indefinite

I have risen, etc.
je me suis levé, or *levée*
tu t'es levé, or *levée*
il s'est levé
elle s'est levée
nous nous sommes levés or *levées*
vous vous êtes levés, or *levées*
ils se sont levés
elles se sont levées

Pluperfect

I had risen, etc.
je m'étais levé, or *levée*
tu t'étais levé, or *levée*
il s'était levé
elle s'était levée
nous nous étions levés, or *levées*
vous vous étiez levés, or *levées*
ils s'étaient levés
elles s'étaient levées

Past Anterior

I had risen, etc.
je me fus levé, or *levée*
tu te fus levé, or *levée*
il se fut levé
elle se fut levée
nous nous fûmes levés, or *levées*
vous vous fûtes levés, or *levées*
ils se furent levés
elles se furent levées

Future Anterior

I shall have risen, etc.
je me serai levé, or *levée*
tu te seras levé, or *levée*
il se sera levé
elle se sera levée
nous nous serons levés, or *levées*
vous vous serez levés, or *levées*
ils se seront levés
elles se seront levées

CONDITIONAL

Present

I should rise, etc.
je me lèverais
tu te lèverais
il se lèverait
elle se lèverait
nous nous lèverions
vous vous lèveriez
ils se lèveraient
elles se lèveraient

Past

I should have risen, etc.
je me serais levé, or *levée*
tu te serais levé, or *levée*
il se serait levé
elle se serait levée
nous nous serions levés, or *levées*
vous vous seriez levés, or *levées*
ils se seraient levés
elles se seraient levées

IMPERATIVE

Present

lève-toi, rise (thou)
qu'il se lève, let him rise
qu'elle se lève, let her rise
levons-nous, let us rise
levez-vous, rise ye
qu'ils se lèvent, let them (m.) rise
qu'elles se lèvent, let them (f.) rise

SUBJUNCTIVE

Present	*Imperfect*
That I may rise, etc.	That I might rise, etc.
que je me lève	*que je me levasse*
que tu te lèves	*que tu te levasses*
qu'il se lève	*qu'il se levât*
qu'elle se lève	*qu'elle se levât*
que nous nous levions	*que nous nous levassions*
que vous vous leviez	*que vous vous levassiez*
qu'ils se lèvent	*qu'ils se levassent*
qu'elles se lèvent	*qu'elles se levassent*

Past

That I may have risen, etc,
que je me sois levé, or *levée*
que tu te sois levé, or *levée*
qu'il se soit levé
qu'elle se soit levée
que nous nous soyons levés, or *levées*
que vous vous soyez levés, or *levées*
qu'ils se soient levés
qu'elles se soient levées

Pluperfect

That I might have risen, etc.
que je me fusse levé, or *levée*
que tu te fusses levé, or *levée*
qu'il se fût levé
qu'elle se fût levée
que nous nous fussions levés, or *levées*
que vous vous fussiez levés, or *levées*
qu'ils se fussent levés
qu'elles se fussent levées

INFINITIVE

Present	*Past*
se lever, to rise	*s'être levé, levée*, to have risen

PARTICIPLES

Present	*Past*
se levant, rising	*s'étant levé, levée, levés, levées*, having risen

Pronominal Verb Conjugated Negatively

Pronominal verbs are conjugated negatively:

1. In simple tenses, by putting *ne* between the two pronouns and *pas* after the verb.
2. In compound tenses, by putting *ne* between the two pronouns, and *pas* between the auxiliary and the past participle.

Ne pas se tromper, not to be mistaken

INDICATIVE

SIMPLE TENSES

Present

I am not mistaken, etc.
je ne me trompe pas, etc.

Imperfect

I was not mistaken, etc.
je ne me trompais pas, etc.

Past Definite

I was not mistaken, etc.
je ne me trompai pas, etc.

Future

I shall not be mistaken, etc.
je ne me tromperai pas, etc.

COMPOUND TENSES

Past Indefinite

I have not been mistaken, etc.
je ne me suis pas trompé, or *trompée*, etc.
nous ne nous sommes pas trompés, or *trompées*, etc.

Pluperfect

I had not been mistaken, etc.
je ne m'étais pas trompé, or *trompée*, etc.
nous ne nous étions pas trompés, or *trompées*, etc.

Future Anterior

I shall not have been mistaken, etc.
je ne me serai pas trompé, or *trompée*, etc.
nous ne nous serons pas trompés, or *trompées*, etc.

IMPERATIVE

Present

ne te trompe pas	*ne vous trompez pas*
be (thou) not mistaken	be (ye) not mistaken
qu'il ne se trompe pas	*qu'ils ne se trompent pas*
let him not be mistaken	let them (m.) not be mistaken
qu'elle ne se trompe pas	*qu'elles ne se trompent pas*
let her not be mistaken	let them (f.) not be mistaken
ne nous trompons pas	
let us not be mistaken	

SUBJUNCTIVE

Present

That I may not be mistaken, etc.
que je ne me trompe pas, etc.

Imperfect

That I might not be mistaken, etc.
que je ne me trompasse pas, etc.

Perfect

That I may not have been mistaken, etc.
que je ne me sois pas trompé, or *trompée*, etc.
que nous ne nous soyons pas trompés, or *trompées*, etc.

Pluperfect

That I might not have been mistaken, etc.
que je ne me fusse pas trompé, or *trompée*, etc.
que nous ne nous fussions pas trompés, or *trompées*, etc.

INFINITIVE

Present

ne pas se tromper, not to be mistaken

Past

ne pas s'être trompé, e, és, ées
not to have been mistaken

PARTICIPLES

Present

ne se trompant pas, not being mistaken

Past

ne s'étant pas trompé, e, és, ées
not having been mistaken.

KEY TO EXERCISE XXVII.

1. Nous recevons deux journaux tous les jours.
2. Elle reçoit ses amis le jeudi.
3. Nous aperçûmes une petite maison blanche au pied de la colline.
4. N'avez-vous pas encore reçu de réponse à votre lettre ?
5. Il est facile d'énoncer clairement ce que l'on conçoit bien.
6. Quand vous recevrez cette lettre je ne serai plus en Angleterre.
7. Vers dix heures du matin nous aperçûmes l'armée ennemie dans le lointain.

8. Il doit cinquante francs à son tailleur.

9. Si vous lui devez tant, ne me devez-vous rien ?

10. Vous devriez planter des arbres le long de cette allée.

11. Quand doit-il y avoir une assemblée des actionnaires ?

12. Si la bonne foi était exilée du reste de la terre, elle devrait se retrouver dans le cœur des rois.

13. Vous devriez d'abord me payer ce que vous me devez.

14. Elle a dû être bien étonnée de vous voir.

15. Vous auriez dû lui rendre l'argent qu'il vous a prêté.

16. Si vous n'avez rien mangé depuis ce matin, vous devez avoir bien faim.

17. Quelle heure est-il ? Il doit être au moins quatre heures et demie.

18. J'ai reçu une invitation, mais j'ai dû la refuser.

Key to Exercise XXVIII.

1. Entendez-vous ce que je vous dis ?

2. N'ayez pas peur du chien ; il ne vous mordra pas.

3. Vous perdez toujours quelque chose.

4. Pourquoi n'avez-vous pas répondu à sa lettre ?

5. Nous entendîmes du bruit en haut.

6. Qu'ils nous attendent maintenant, nous les avons attendus assez longtemps.

7. Attendez-les ; ils ne sont pas encore prêts.

8. Ne perdez pas tant de temps à bavarder.

9 Les ennemis, descendant de leurs montagnes, pillaient toute la contrée.

10. On vendra ces maisons aux enchères à onze heures précises.

11. Je fermai les yeux et j'entendis un fracas épouvantable.

12. Vous ne perdrez rien pour attendre.

13. La découverte de l'Amérique a beaucoup étendu le commerce européen.

14. Le Seigneur a étendu sa main sur la mer ; il a ébranlé les royaumes.

15. Le thermomètre a descendu de quatre degrés depuis hier.

16. Le jeune homme nous remercia sans embarras du service que nous lui rendions.

17. Rendez à César ce qui est à César, et rendez à Dieu ce qui est à Dieu.

18. Les coups que nous sentons le plus sont ceux que nous ne pouvons (pas) rendre.

19. Quelques grains rendent cent pour un, d'autres soixante, et d'autres trente.

20. Samson rompit ses cordes comme on romprait un fil.

21. A brebis tondue Dieu mesure le vent, dit le proverbe.

22. Ce chien est dangereux ; il mord.

23. Il y a des personnes dont les louanges mordent et dont les caresses égratignent.

24. L'or fond à un moindre degré de chaleur que le fer.

GERMAN

Continued from page 3933

By P. G. Konody and Dr. Osten

LXXXVIII. The Subject Clause. Wer gar zu viel bedenkt, wird wenig vollbringen, He who considers too much will achieve little. Here the subordinate clause replaces the subject and answers the question „wer (oder was) wird wenig vollbringen?“ (Answer: Wer gar zu viel bedenkt, which is the subject of the compound sentence.)

The subordinate subject-clause is introduced by interrogative pronouns (ob, whether; wie, how; wann or wenn, when; wo, where; warum, why, etc.), or by relative pronouns (wer, who; was, what), or by the conjunction daß, that. Examples: Was nicht taugt, iſt geſchenkt zu teuer, What is useless, is too dear even as a present. Es iſt erfreulich, daß die Sonne ſcheint, It is pleasing that the sun shines.

LXXXIX. The Object Clause. This, like the object it serves to replace, answers the question Weſſen? whose? or Wem? to whom? or Wen oder Was? whom or what? It is introduced by an interrogative or by a relative pronoun. For the sake of greater clearness, a correlative demonstrative pronoun is often introduced into the principal sentence. Examples: Ich freue mich (weſſen?) ſeiner Ankunft (object in the genitive), or, with a subordinate object clause: Ich freue mich, daß er angekommen iſt, I am glad that he has arrived. Wen das Herz liebt, des (demonstrative pronoun) gedenkt es gern, Whom the heart loves it remembers gladly (proverbial sentence). Was geſchehen muß, das (demonstrative pronoun) ſoll man nicht verſchieben, What has to be done ought not to be postponed. If prepositions are needed, they are contracted with the demonstrative pronoun —an das into daran, von dem into davon, etc.: Was ein Geheimnis bleiben ſoll, davon (von dem) ſoll man nicht ſprechen, What is to remain a secret should not be talked about.

XC. Contraction of Object Clauses. Object clauses introduced by the conjunction daß (*a*) can be contracted if the subject of the principal sentence is identical with that of the subordinate clause: Ich verſprach ihm, daß ich gehen wurde, I promised him that I should go; and Ich verſprach ihm zu gehen Contraction can also take place if the subject of the subordinate clause figures as object in the principal sentence, or if this relation is implied, though not actually expressed: Gott befahl den Menſchen, daß ſie (die Menſchen) einander lieben, God commanded men that they should love each other, can thus be contracted into Gott befahl den Menſchen einander zu lieben. As may be seen from the above examples, the contraction consists in the omission of the conjunction daß and of the subject in the subordinate clause, whilst the verb takes the prepositional infinitive with zu.

(*b*) In other cases tho conjunction daß can be dropped, whilst the subordinate clause assumes the same sequence of words as an independent sentence, the subject preceding the predicate, etc.: Er erzählte uns, daß er das Feuer geſehen habe (dependent clause with finite verb at end), He told us that he had seen the fire; or, with the conjunction daß omitted: Er erzählte uns, er (subject) habe (predicate) das Feuer (object) geſehen, He told us he had seen the fire. Ich erinnere mich, daß ich das Feuer geſehen habe, I remember that I have seen the fire, is, on the other hand, contracted into: Ich erinnere mich, das Feuer geſehen zu haben, the subject being the same in the principal sentence and in the dependent clause.

(*c*) In some interpolated subordinate object clauses introduced by wie, as, this conjunction can be dropped, and the clause assumes the same sequence of words as the independent sentence of question (the verb preceding the subject): Er hat, wie er uns erzählte, das Feuer geſehen, He has, as he told us, seen the fire, or contracted: Er hat, erzählte er uns, das Feuer geſehen.

(*d*) In conditional clauses the conjunctions wenn, falls, if, can be dropped, in which case the clause is arranged as in (*c*): Wenn du nicht gehen willſt, ſo bleibe daheim, If you don't want to go, stay at home; or, with omission of the conjunction wenn: Willſt du nicht gehen, ſo bleibe daheim.

(*e*) With verbs with separable prefixes the preposition zu is inserted between the prefix and the stem: fort-gehen, to go away; Ich befahl ihm, daß er fortgehe, or contracted: Ich befahl ihm fort zu gehen, I bade him go away; but entfernen (inseparable prefix ent-): Ich befahl ihm, daß er ſich entferne, or: Ich befahl ihm, ſich zu entfernen.

XCI. The Subjunctive in Subordinate Clauses. In subject and object clauses the subjunctive is employed if the person speaking wishes to suggest that the context of the subordinate clause is merely an opinion of the "subject" in the principal sentence, or if something is expressed (wish, demand, hope, command, etc.) that has not yet been performed and has yet to become a reality: Ich glaubte, daß er angekommen ſei, I thought that he had arrived; or, with the omission of the conjunction: Ich glaubte, er ſei angekommen. For further rules as to the use of the subjunctive see LXVIII., page 3502.

NARRATIVE CLAUSES. The object clauses include those in which the speech of other persons is related, either directly (direct speech) or by circumlocution (indirect speech). The quotation, with the subjunctive of the verb, is frequently introduced by the conjunction daß; and the indirect clause of question by ob, whether, unless there is already a conjunction of question: Er fragte mich, ob ich kommen würde, He asked me whether I should come; and: Er fragte mich, wann ich kommen würde, He asked me when I should come.

EXAMINATION PAPER XXII.

1. Which cases are ruled by adjectives in German?
2. How many adjectives govern two alternative cases, and which are these cases? Enumerate the adjectives.
3. What prefix expresses the negative meaning of adjectives?
4. What is the difference between co-ordinate and subordinate clauses in a compound sentence?
5. What is the characteristic feature of the subordinate clause with regard to the verb?
6 What are the positions of the subordinate clause in a compound sentence?
7. How does the use of different classes of conjunctions affect the mutual relation of co-ordinate clauses?
8. Why is it often necessary to employ subordinate clauses, and when are they to be avoided?
9. How can the subordinate clauses be classified?
10. What is a subject clause, and by what words is it introduced?
11. What question (with regard to the case) is answered by the object clause?
12. By what words is the object clause introduced?
13. Which correlative pronouns are sometimes introduced into the principal sentence, and for what reasons?
14 When can a subordinate clause be contracted?
15. How does contraction by omission of certain words affect the verb in the subordinate clause?
16. What is the sequence of words in a contracted interpolated subordinate clause?
17. What considerations necessitate the use of the subjunctive in subordinate clauses?
18. By which conjunction are "narrative clauses" frequently introduced?

EXERCISE. Contract the following sentences:

Dem Kinde wurde befohlen, daß es im Zimmer bleibe.
The child was bid to stay in the room.
Dem Kinde wurde befohlen, daß es dableibe.
The child was bid to stay here.
Ich bat ihn, daß er mir helfe.
I begged him to help me.
Ich bat ihn, daß er mir mit einigem Gelde aushelfe.
I begged him to assist me with some money.
Ich bat ihn, daß er ſich einſtweilen ohne mich behelfe.
I begged him to get on meanwhile without me.
Er erklärte, daß er nichts davon wiſſe (Two variations possible). Der
He declared that he knew nothing about it. The

Vater fürchtete, daß ihm ſein Sohn nichts mitteilen würde.
father feared that his son would tell him nothing.
Ich hoffe, daß ich morgen früh abreiſen werde. (Two forms, as above.)
I hope that I shall start to-morrow morning.
Es war, wie er mir ſagte, ſchrecklich. Der Konig wurde,
It was, as he told me, terrible. As the paper
wie die Zeitung berichtete, glänzend empfangen.
reported, the king was given a splendid reception.
Den Truppen wurde der Befehl erteilt, daß ſie das Feuer
The troops were given the order to open
eröffnen. Geſtatten Sie mir, daß ich Ihnen alles erzähle.
fire. Allow me to tell you all.
Erlauben Sie mir, daß ich Sie nachſtens beſuche. Ge-
Allow me to call on you shortly. Cer-
wiß, aber trachten Sie, daß Sie nicht den Zug verſäumen.
tainly, but try not to miss your train.
Wenn es ſich ſo verhalt, dann bleibe ich noch. Falls
If this is the case, I shall stay yet [a while]. If
Sie es nicht wunſchen, ſo wird es einfach nicht geſchehen.
you do not wish it, it will simply not be done.

Key to Exercise in Examination Paper XXI.

(Page 3932)

Ich war meiner Pflicht eingedenk. Der Sohn iſt ſeinem Vater ahnlich. Die Lüge war den Athenern angeboren. Die Sache ſchien dem Beamten bedenklich. Er hielt ihn eines ſolchen ſchrecklichen Verbrechens fahig. Der Gefangene war des Urteils gewartig. Die Eltern ſind der Sprache nicht machtig. Die Soldaten waren des Dienſtes überdrüſſig. Den Soldaten war der Dienſt überdrüſſig. Das Kind iſt ſeinen Eltern Gehorſam ſchuldig. Dieſe Handlung iſt deiner unwürdig. Man uberhob mich der Mühe. Die Verfolger wurden des Diebes habhaft. Dieſer Zwiſchenfall erwies ſich mir gunſtig. Das iſt ihr ganz gleichgultig. Das Volk iſt dem Konig untertan. Trotzdem der Fall dem Richter unklar war, fand er ihn des Verbrechens ſchuldig. Der Feldherr war dieſer großen Überzahl nicht gewachſen, und ergab ſich, als er der heranruckenden friſchen Truppen anſichtig wurde.

VII. At the Theatre

What piece is played to-night at your theatre? Wagner's "Tannhäuser."	Was für ein Stück wird heute in Ihrem Theater geſpielt? Wagner's „Tannhäuſer".
Can I have a ticket?	Kann ich ein Billet haben?
Yes, but the only vacant seats are in the last rows of the stalls.	Ja, aber es ſind nur Sitze in den letzten Reihen des Parketts frei.
There are no more seats in the front rows?	In den vorderen Reihen gibt es keine Sitze mehr?
Can you see well from the back rows?	Sieht man gut in den ruckwartigen Reihen?
Oh, yes; the theatre is built like an amphitheatre.	O ja, das Theater iſt amphitheatraliſch gebaut.
Can I have a corner seat?	Kann ich einen Eckſitz haben?
No, I am sorry, only the centre seats are vacant.	Leider nicht, nur in der Mitte ſind welche frei.
How much is the seat? Four marks.	Was koſtet der Sitz? Vier Mark.
When does the performance begin?	Wann beginnt die Vorſtellung?
At 7.30 p.m.	Um halb acht Uhr Abends.
And when is it over? At 10.30.	Und wann endet ſie? Um halb elf Uhr.
Is the cast good?	Iſt die Beſetzung gut?
The cast is excellent.	Die Beſetzung iſt vorzuglich.
Can I have a programme?	Kann ich einen Theaterzettel haben?
You will get that at the theatre.	Den bekommen Sie im Theater.
Is it also possible to get a book of the words?	Iſt da auch ein Textbuch erhältlich?
Yes, you only have to ask at the box-office.	Ja, das bitte nur vom Billetteur zu verlangen.
Are there no automatic machines for opera-glasses?	Gibt es keine Opernglas-Automaten?
No, they have not been introduced here.	Nein, das iſt bei uns nicht eingeführt.
How many minutes is the long interval?	Wie viele Minuten dauert die große Zwiſchenpauſe?
Where is the buffet? On the second floor.	Wo iſt das Buffet? Im zweiten Stockwerke.
Is smoking permitted in the passages?	Darf man in den Couloirs rauchen?
Oh, no; it is not allowed anywhere within the theatre.	O nein, das iſt in keinem Raume innerhalb des Theaters geſtattet.
Must one's stick be left in the cloak-room?	Muß man den Stock in der Garderobe abgeben?
Will you give me my overcoat?	Wollen Sie mir meinen Überrock geben?
Will you, please, get me a cab after the theatre.	Bitte, beſorgen Sie mir eine Droſchke nach dem Theater.

VIII. At the Barber's

I want a shave. Will you sit down, please.	Wollen Sie mich raſiren? Bitte Platz zu nehmen.
Will you soap me well, as my beard is stiff.	Bitte mich gut einzuſeifen, da mein Bart hart iſt.
Is the brush well cleaned?	Iſt der Pinſel gut gereinigt?
We always clean everything most carefully after use.	Bei uns wird alles nach jedesmaliger Benützung auf das Sorgfältigſte rein gemacht.
The razor is scraping a bit. Could you not sharpen it a little?	Das Raſirmeſſer kratzt ein wenig. Konnten Sie es nicht ſcharfer machen?
It is better now.	Jetzt iſt es beſſer.
After washing, you can give me some eau de Cologne. And now a little rice powder.	Nach dem Waſchen könnten Sie mir etwas Kolniſch Waſſer geben. Und nun etwas Poudre de Riz.
Will you cut my hair, but not too short.	Bitte mir die Haare zu ſchneiden, aber nicht zu kurz.
I also want a shampoo.	Sie können mir auch den Kopf waſchen.
How much do I owe you?	Was bin ich ſchuldig? or Was habe ich zu bezahlen?
Altogether it amounts to 60 pfennigs.	Alles zuſammen macht 60 Pfennige.

By Amalia de Alberti & H. S. Duncan

REGULAR VERBS—continued

Third Conjugation

Model Verb—**Vivir,** to live

INFINITIVE	GERUND
vivir, to live	*viviendo* living

PAST PARTICIPLE

vivido, lived

INDICATIVE MOOD

Present	*Imperfect*
vivo, I live	*vivía*, I was living
vives, thou livest	*vivias*, thou wast living
vive, he lives	*vivía*, he was living
vivimos, we live	*vivíamos*, we were living
vivís, you live	*vivíais*, you were living
viven, they live	*vivían*, they were living

Past Definite	*Future*
viví, I lived	*viviré*, I shall live
viviste, thou livedst	*vivirás*, thou wilt live
vivió, he lived	*vivirá*, he will live
vivímos, we lived	*vivirémos*, we shall live
vivísteis, you lived	*viviréis*, you will live
vivieron, they lived	*vivirán*, they will live

CONDITIONAL MOOD

viviría, I should live
vivirías, thou wouldst live
viviría, he would live
viviríamos, we should live
viviriais, you would live
vivirían, they would live

IMPERATIVE MOOD

—	*vivamos*, let us live
vive, live (thou)	*vivid*, live (ye)
viva, let him live	*vivan*, let them live

SUBJUNCTIVE MOOD

Present

viva, I may live	*vivamos*, we may live
vivas, thou mayst live	*viváis*, you may live
viva, he may live	*vivan*, they may live

IMPERFECT

viviera, or *viviese*, I might live
vivieras, or *vivieses*, thou mightst live
viviera, or *viviese*, he might live
viviéramos, or *viviésemos*, we might live
vivierais, or *vivieseis*, you might live
vivieran, or *viviesen*, they might live

Future

viviere, when I shall live
vivieres, when thou wilt live
viviere, when he will live
viviéremos, when we shall live
viviereis, you will live
vivieren, they will live

NOTE. The compound tenses are formed with the verb *haber* and the participle *vivido*. Example: *he vivido*, I have lived, etc. Only the second person singular and plural are original forms, the rest are all borrowed from the subjunctive present. The original imperatives cannot be used in the negative; the negative imperative must be rendered by the subjunctive present.

ORIGINAL IMPERATIVES	NEGATIVE IMPERATIVES
ama, love (thou)	*no ames*, do not love
amad, love (you)	*no améis*, do not love
come, eat (thou)	*no comas*, do not eat
comed, eat (you)	*no comáis*, do not eat
vive, live (thou)	*no vivas*, do not live
vivid, live (you)	*no viváis*, do not live

The other persons being already in the subjunctive, need only the addition of *no* to become negative.

amemos, let us love	*no amemos*, let us not love

Euphonic Changes. The following changes are made in the spelling of certain regular verbs in order to retain the same pronunciation of the stem throughout the conjugation.

1. All verbs ending in *car* change the *c* into *qu* before *e*—that is, in the first person singular of the past definite, throughout the subjunctive, and in those persons of the imperative which are borrowed from the subjunctive. Example:

Tocar, to touch

Past Def —*toqué, tocaste, tocó*, etc.

Sub. Pres.—*toque, toques, toque, toquémos, toquéis, toquen.*

Imp.—*toca, toque, toquémos, tocad, toquen.*

2. All verbs ending in *gar* take *u* after the *g* in the same persons. Example:

Pagar, to pay

Past Def.—*pagué, pagaste, pagó*, etc.

Sub. Pres.—*pague, pagues, pague, paguémos, pagueis, payuen.*

Imp.—*paga, pague, paguémos, pagad, paguen.*

3. All verbs ending in *zar* change the *z* into *c* in the same places. Example:

Alcanzar, to reach

Past Def.—*alcancé, alcanzaste, alcanzó*, etc.

Sub. Pres.—*alcance, alcances, alcance, alcancémos, alcancéis, alcancen.*

Imp.—*Alcanza, alcance, alcancémos, alcanzad, alcancen.*

4. Verbs ending in *guar* take the diæresis in the same tenses—that is, before *e*. Example:

Averiguar, to ascertain

Past Def.—*averigüé, averigüaste, averigüó*, etc.

Sub. Pres.—*averigüe, averigüeis, averigüe*, etc.

Imp.—*averigüa, averigüe, averigüemos, averigüad, averigüen.*

5. Verbs ending in *cer* and *cir* preceded by a consonant change *c* into *z* before *a* or *o*; that is, in the first person singular of the indicative present, throughout the subjunctive present, and in imperatives borrowed from the subjunctive. When the ending *cer* and *cir* is preceded by a vowel *z* is inserted before *c* whenever the latter is followed by *a* or *o*—that is, in the aforesaid places. Example:

Vencer, to vanquish

Ind. Pres.—*venzo, vences, vence*, etc.

Sub. Pres.—*venza, venzas, venza*, etc.

Imp —*vence, venza, venzámos, venced, venzan.*

Esparcir, to scatter

Ind. Pres.—*esparzo, esparces, esparce*, etc.

Sub. Pres.—*esparza, esparzas, esparza*, etc.

Imp.—*esparce, esparza, esparzámos, esparcid, esparzan.*

Nacer, to be born

Ind. Pres.—*nazco, naces, nace*, etc.

Sub. Pres.—*nazca, nazcas, nazca*, etc.

Imp.—*nace, nazca, nazcamos, naced, nazcan.*

6. Verbs ending in *ger* and *gir* change *g* into *j* before *a* and *o*. Example:

Coger, to gather

Ind. Pres.—*cojo, coges, coge*. etc.

Sub. Pres.—*coja, cojas, coja, cojamos, cojais, cojan.*

Imp.—*coge, coja, cojamos, coged, cojan.*

Dirigir, to direct

Ind. Pres.—*dirijo, diriges, dirige*, etc.

Sub. Pres.—*dirija, dirijas, dirijamos, dirijais, dirijan.*

Imp.—*dirige, dirija, dirijamos, dirigid, dirijan.*

7. Verbs ending in *guir* drop the *u* before *a* and *o*. Example:

Distinguir, to distinguish

Ind. Pres.—*distingo, distingues, distingue*, etc.

Sub. Pres.—*distinga, distingas, distinga*, etc.

Imp.—*distingue, distinga, distingamos, distinguid, distingan.*

8. Verbs with stems ending in *ch, ll*, or *ñ*, drop the *i* in the diphthongs *ie, io* whenever these occur in the terminations—that is, in the gerund, third person singular and plural of the past definite, and in the imperfect and future of the subjunctive. Example:

Bullir, to boil. Gerund, *bullendo*, etc.

Plañir, to lament. Gerund, *plañendo*, etc.

Henchir, to fill. Gerund, *hinchendo* (irreg.), etc.

Vocabulary	Vocabulario
Adhere	Adherir
To confer	Conferir
To consent	Consentir
To convert	Convertir
To give the lie	Desmentir
To amuse oneself	Divertirse
To wound	Herir
To infer, to deduce	Inferir
To invert	Invertir
To lie	Mentir
To pervert	Pervertir
To speak, to express	Proferir
A quack	Un empirico
A table	Una fabula
A fatalist	Un fatalista
Womanly	Femenil
The fair	La féria
The railroad	El ferrocarril
Thin	Flaco
Frivolous	Frivolo
The smoking-room	El salon para fumar
The fugitive	El fugitivo
The foundry	La fundición
Gallantly	Galantemente
The gallery	La galeria
The gallop	El galope
The picklock	La ganzúa

Exercise XIII (1)

Translate the following into Spanish:

1. Since when has the banker M . . . . had the cross of . . . . . . ? 2. It was conferred on him after the war. 3. I shall be pleased to deny the false rumours which have been current in the town. 4. He was wounded in the right arm by a pistol shot. 5. Was it the right or the left ? 6. I have already said it was the right. 7. I inferred that he was ill. I have not seen him for many days. 8. That man is capable of perverting the wisest person, his doctrines are scandalous. 9. Let us go (vamos) to the fair, we shall certainly be able (podrémos) to buy good colts and horses. 10. The smoking-room is at the end of the garden. 11. To-morrow we will go (irémos) to the cannon foundry. 12. The thief opened the door with a picklock. 13. The sentinel is in the sentry-box. 14. Have you sufficient grapes for the vintage ? No, I have not sufficient ; but I have beautiful bunches. 15. Have you a vine ? I have two—one in Moguer, the other in Jeres 16. The axle broke when the horses were galloping (iban al galópe) and the carriage upset. 17. Death is represented with a scythe and hour-glass. 18. The reapers hold the superstition that if they cut any animal in reaping, whether bird, rabbit, or any living thing whatever, they have cut their own lives. 19. After the harvest is finished, the harvesters dance on the threshing floor ; it is a custom which dates from the Middle Ages. 20. The fountain in the garden is of marble, and the water very limpid.

Exercise XIII (2)

Translate the following into English:

1. Vengo para averiguar los pormenores del robo que tuvo (took) lugar ayer. 2. Nada mas podemos decir, á lo ya expuesto. 3. Sería posible coger á los ladrones si nos dieramos prisa. 4. No vale la pena, lo que cojieron es de poco valor, y despues de todo aquello de "vivir y dejar vivir" viene bien aqui. 5. Es hombre de gran voluntad, nació de la nada, y vea la posicion que ocupa ; piense en todas las dificultades que ha tenido que vencer. 6. Es muy distinguido. 7. Vamos á coger el tren. Es tarde y si no llegarán Vds á tiempo ; no lo cogerán. 8. ¡ Ten cuidado ! esparces esa semilla en el camino, y si no quedará ninguna para el jardin. 9. Esa mujer es muy frivola y superficial. 10. Fuimos anoche á la galería del Teatro Real, no me gustó la tragédia, la primera dama es demasiado vieja, y el primer galan no sabe declamar.

PROSE EXTRACT XI.

From a satirical essay by Antonio de Valbuena, entitled:

"Academicalities."	"Academiquerías."
You are all aware that the worst writer in Spain is the Academy, the Royal Spanish Academy, whose office, according to itself, is	Ya saben ustedes que quien peor escribe en España es la Academia, la Real Academia Española, encargada, según ella dice, de

to purify, define, and add lustre to our native tongue. But though you have known this for a long time, it will be as well to remind you of it, in case you should forget it.

It will also be as well to warn you, in order to spare you a shock, that the document we are about to examine emanates from the aforesaid Academy. Because it is the report of a solemn academical function, and it is a well-known fact that the Academy does not trust anyone with the task of singing its glories, but always does it itself. And it does well, because if it did not sing them, nobody else would.

The Academy understands this, and therefore it is well known that after a session one of the Academicians present writes the eulogistic broadsheet to be sent to "La Correspondencia" and other newspapers having a large circulation. He reads it aloud, and after a few corrections, which make it, if possible, worse than before, it is approved, and sent to the editors with the trade-mark of the firm.

The broadsheet, or rather the short article in question—for it is almost an article—appeared with two headlines. The first says: "In the Spanish Academy," and the one below, "Rewards of Virtue." Then it begins:

"Yesterday the Spanish Academy held a solemn public session in order to distribute the prizes awarded by the St. Gaspar Fund, which is governed by that learned body."

Here we have the trade mark of the firm, which I mentioned a little while ago. For now no one alludes to the Academy as a "learned body," except the Academy itself, or some aspirant.

Therefore, the authenticity of the document is beyond dispute.

Antonio de Valbuena (1844), a leading journalist, well known for literary and political satires. The above extract is a good example of light journalistic Spanish.

limpiar, fijar y dar lustre al idioma patrio. Pero aunque lo saben ustedes hace ya mucho tiempo, no será malo recordárselo para que no se les olvide.

Y tampoco será malo advertir á ustedes para evitarles algún susto, que el escrito que vamos á examinar ahora pertenece á la Academia referida. Como que es la reseña de un acto Académico solemne, y es cosa bien averiguada que la Academia no fia á nadie el encargo de cantar sus glorias, sino que lo hace por sí misma. Y hace bien, porque si no las cantara ella, no las cantaría nadie.

Asi lo entiénde la Academia, y por eso ya se sabe, al concluirse cualquiera sesión, uno de los Académicos asistentes á ella escribe el suelto laudatorio para enviarlo á "La Correspondencia," y demás periódicos dè gran circulacíon, le lee en voz alta, se aprueba después de alguna enmienda que lo empeore algo si es posible, y se remite á las redacciones con el sello de la casa.

El suelto, ó más bien el articulejo de referencia, porque es casi un artículo, salió con dos rótulos. El primer dice: "En la Academia Española," y el que está debajo: "Premios á la virtud." Y empieza:

"Ayer celebró la Academia Española sesion solomne y pública para repartir los premios de la Fundación denominada de San Gaspar, que está regida, por aquella docta corporación."

Aqui está el sello de la casa, de que hablé hace poco. Por que nadie llama ya *docta corporacion* á la Academia, mas que la Academia misma ó algún aspirante.

De modo que no cabe duda de la autenticidad del escrito.

Antonio de Valbuena (1844), uno de los primeros periodistas bien conocido por sus sátiras literarias y politicas. El extracto que mas arriba citamos es un buen ejemplo del estilo ligero de los periódicos Españoles

KEY TO EXERCISE XII (1)

1. Compro la carne, los huevos y la leche en la hacienda; el hortelano es muy honrado.
2. Los compraré tambien así, tambien compraremos pollos, mi hija y yó.
3. ¿ Comen Vds muchas aves ?
4. Si, nos gustan mucho.
5. Yó cómo mucha ave, hemos comprado perdices y faisanes.
6. Deseo demostrar á Vd este problema.
7. El juez ha fallado el pleito.
8. La fama de Shakespeare ha llegado hasta el fin del mundo.
9. Esa mujer amiga de Vd es capaz de embrollar á la familia más unida.
10. El carruaje, yendo por el camino real, volcó y el cochero y los caballos fueron lastimados.
11. Con prisa lleváron al prisionero á la cárcel.

LIVING FLOWERS OF THE SEA

[See Natural History, page 4081]

continued from page 3960

THE SIMPLEST FORMS OF LIFE

Sea-lilies, Starfishes, and Sea-urchins. Sea-anemones. The Life History of a Coral. Jelly-fishes. Sponges. Animalcules. The Origin of Limestone

By Professor J. R. AINSWORTH DAVIS

ECHINODERMS, or hedgehog-skinned animals [see Plate facing], differ from all the forms so far considered in the nature of their symmetry. Instead of being two-sided, with a well-marked distinction between right and left and front and back (bilateral symmetry), they resemble a star or regular flower in shape, as in 550. The skin is hardened by the deposition of salts of lime, and the body is often covered with spines, as more particularly in sea-urchins [544].

Five existing subdivisions are recognised: (1) Sea-lilies and feather-stars (*Crinoidea*); (2) starfishes (*Asteroidea*); (3) brittle stars (*Ophiuroidea*); (4) sea-urchins (*Echinoidea*); and (5) sea-cucumbers (*Holothuroidea*). All are marine

Sea-lilies. Sea-lilies are deep-sea animals, once numerous and flourishing, but now comparatively rare, and only to be obtained by dredging in the deeper parts of the ocean. They are fixed by a long jointed stalk bearing circlets of sensitive threads and terminating in a cup, in the centre of which the mouth is situated [547]. Radiating from the edges of the cup are five branching, feather-like arms, all of which are grooved above, the grooves uniting, and finally converging to the mouth. They are beset with cilia, and minute organisms are conducted inwards along them to serve as food. Owing to their sedentary mode of life, the once abundant sea-lilies are now on the way to extinction

Z. Thalassema Neptuni—a siphon-worm

Feather-stars. The closely related feather-stars [548], however, flourish exceedingly, for they have given up the stalk, and are able to swim about actively by bending and straightening their long arms. They can also hold fast to seaweed, or even climb by means of a whorl of jointed threads attached to the under side of the cup, and representing one of the numerous circlets to be found on the stalk of a sea-lily.

The life-history of the individual often affords a clue to the geological history of its group. The feather-star is a particularly good example of this, for in early life it is a stalked larva [538], closely resembling a minute sea-lily. After a time the stalk is cast off, and a fixed life exchanged for an active one. The best-known species (*Comatula rosacea*) is bright red in colour, and very conspicuous—another example of that "warning coloration" which denotes inedibility.

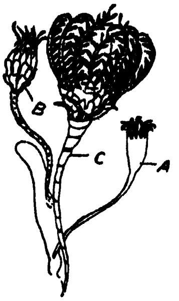
Starfishes. Starfishes are among the most familiar objects of the seashore, and the commonest kinds, such as the five-finger (*Asterias rubens*) and the comb-star (*Astropecten aurantiacus* [550], possess five radiating arms. The mouth is in the centre of the under side, and leads into a capacious stomach [540], of which the first part can be protruded from the body to surround such prey as mussels and oysters.

A starfish crawls slowly by means of numerous *tube-feet*, which are lodged in five grooves radiating from the mouth [550], and make up a part of the *water vascular system*, so called because it is full of sea-water. Some of the details will be understood by reference to 540. On the upper side of the central disc, in the interval between two of the arms, is a furrowed *madreporic plate*, perforated like the top of a pepper castor. Sea-water continually flows through it into a calcified stone canal which opens below into a ring canal running round the gullet. From this a radial canal runs along each arm-groove, and bears a double series of tube-feet (only one set is shown in 540).

There is a little swelling (*ampulla*) at the base of each tube-foot, and by its contraction water is forced into the foot, which is thus extended. In the common five-finger and many others the tube-feet end in adhesive suckers, which materially aid crawling over rock and weed. But in the comb-star [540] the feet are pointed, and adapted for progression on sand. At the end of each arm is an unpaired tube-foot acting as a feeler, while on its under side there is an orange-red eye-spot.

Remarkable Powers of the Starfish. The water vascular system also assists in breathing. It was probably first evolved in the interests of respiration, and this is its chief use in the sea-lily. Some of the spines are formed of little two-bladed pincers, which clean the surface of the body.

A starfish hatches from the egg as a two-sided *bipinnaria* larva, the body of which is drawn into soft arms [539] covered with cilia. After a time two rounded thickenings appear in its skin, one on each side. These are the beginnings of the adult body, which appropriates the stomach and some other of the larval organs, while the rest of these, including the soft arms, are absorbed.



538. STALKED LARVA OF FEATHER-STAR
a, *b*, and *c* show three successive stages

Starfishes are remarkable for their powers of restoring lost parts. A detached arm can grow a fresh disc and another four arms.

Brittle Stars. The arms of an ordinary starfish are merely continuations of the central disc, and glandular prolongations of the stomach extend into them. But this is not the case in a brittle star [549], where the arms are slender, extremely mobile appendages, which are readily detached. They are the agents of locomotion, one being kept to the front, while the others "row" the body rapidly along over sand or seaweed in a somewhat spasmodic fashion. There is no crawling by means of tube-feet as in an ordinary starfish, and on examining the under side of the body the five-rayed mouth will be seen [549], but no grooves below the arms. These, in fact, have been floored-in by plates, at the sides of which project the tube-feet, used in this case only for breathing and as feelers.

A brittle star hatches out as a *pluteus larva* [541], with stiff arms supported by calcareous rods. The adult body arises in much the same way as in an ordinary starfish.

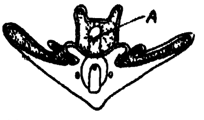
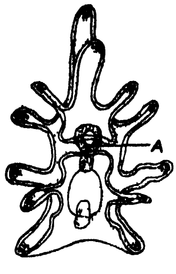
The Sea-urchin. An ordinary or *regulat* sea urchin [544] is spheroidal in shape, the mouth being in the centre of the under side. The calcareous plates in the skin are very regularly arranged in twenty series running from the upper to the lower pole, and disposed in ten double sets, comparable to the "gores" of a balloon. Five of these sets are perforated by minute holes through which the tube-feet project. These are used for crawling and climbing. The body is covered with numerous spines attached by ball-and-socket joints. They constitute formidable defences, and in some tropical species can effect poisoned wounds. Many of the spines are modified into little pincers, as in starfishes, but in this case there are three instead of two jaws.



541. PLUTEUS LARVA OF BRITTLE STAR
a. Mouth

A regular sea-urchin feeds upon seaweed and the small animals attached thereto, and to deal with these there is a complicated biting arrangement consisting of five pointed teeth (which grow continuously like the front teeth of a rabbit), and numerous plates for the attachment of chewing muscles. The whole arrangement when dissected out looks like an antique lantern, and is, in fact, known as "Aristotle's lantern."

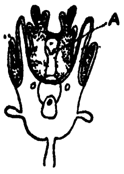


539. BIPINNARIA LARVA
a Mouth

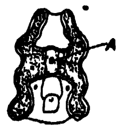
The *irregular* sea-urchins [546] are of more specialised nature, and markedly two-sided, as well as more or less flattened. The mouth has been shifted forwards towards the front, and is devoid of any chewing apparatus, here unnecessary, for the food consists of the nutritious matter contained in sand, which is swallowed in large quantities.

A sea-urchin hatches out as a *pluteus larva* [542], which differs in detail from that of a brittle star. The egg-producing organs or ovaries of sea-urchins are valued as food by some of the primitive coast-dwelling peoples, such as Fuegians, and are the object of a not unimportant industry in the West Indies.

Life on the Floor of the Sea. Sea-cucumbers are elongated tough-skinned creatures [545] which crawl on the sea-floor or burrow in its deposits, and are much more muscular than other hedgehog-skinned animals. The mouth, at one end of the body, is surrounded by blunt tentacles which help to shovel food into it. The skin is hardened by lime to a less extent than in the groups so far considered, but contains scattered plates of characteristic form, resembling wheels, anchors, etc., and making attractive microscopic objects. The tube-feet are generally arranged in five longitudinal bands, though they are sometimes scattered over the surface of the body[545], or, more rarely, they may be entirely absent. In some forms which creep on the floor of the deep sea there is a well-marked distinction between upper and under sides, the latter being flat, and reminding one of the muscular foot of a snail.



542. PLUTEUS LARVA OF SEA-URCHIN
a. Mouth



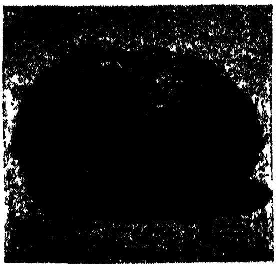
543. AURICULARIA LARVA OF SEA-CUCUMBER
a. Mouth

A sea-cucumber begins life as an *auricularia* larva [543], which is of somewhat simpler character than the larvæ of starfishes and sea-urchins.

The dried bodies of sea-cucumbers, commercially known as trepang or *bêche-de-mer*, are

544. REGULAR SEA-URCHIN

545. SEA-CUCUMBER *a* Mouth



546. IRREGULAR SEA-URCHIN

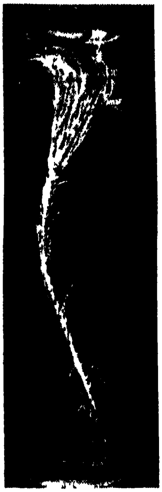
largely used as food by the Chinese and some other Eastern peoples. One of the most important trepang fisheries is that of the Great Barrier Reef, off the east coast of Australia.

ZOOPHYTES

"Simply a Stomach." Zoophytes (*Cœlentera'ta*) [see Plate facing page 4081], of which sea-anemones, corals, and jellyfishes are familiar examples, are distinguished by the ray-like symmetry we have already noticed among starfishes and their kind, though here, as a rule, it is more perfect. In structure they are much simpler than any of the animals so far considered. For such a creature is to all intents and purposes simply a stomach, the wall of which is made up of two layers of cells, one (*ectoderm*) external, and the other (*endoderm*) internal. In higher animals a third layer (*mesoderm*) is interposed.

The ectoderm is studded with innumerable microscopic capsules (*thread-cells*), from which poisoned threads with barbed bases can be shot out, serving as formidable weapons of offence and defence. These assist in procuring food, which consists of crustaceans, small fishes, and various other animals, for these creatures are highly carnivorous.

The name "zoophyte" (Greek: *zoon*, animal; *phyton*, plant) was originally applied to some of the fixed members of this group at a time when their animal character was a matter of doubt. Two chief sub-divisions are recognised: (1) Sea-flowers (*Anthozoa*); and (2) Hydroids (*Hydrozoa*).



547. SEA-LILY

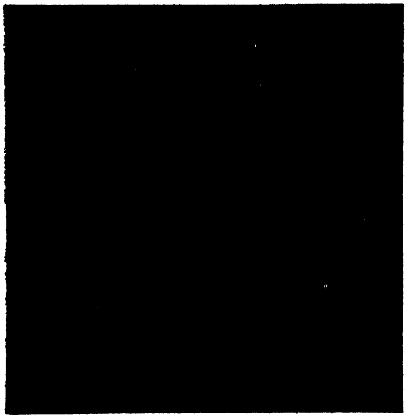
Sea - flowers. Visitors to the seashore certainly will have noticed coloured jelly-like blobs, adhering to rocks, and opening out when placed in water, exhibiting a central mouth surrounded by circlets of tentacles. These are the sea-anemones [see Plate facing page 4081], which well deserve their name, for they are very flower-like in appearance. Mention has been made on page 3808 of the way in which some of them are associated with crabs and hermit crabs. The mouth of a sea-anemone leads into a short gullet, that hangs down into the cavity of the body, with the wall of which it is connected by radiating fleshy partitions (*mesen'teries*) Between these are numerous smaller structures of the same kind as project from the body-wall only part of the way to the gullet.

One of the largest of our native anemones (*Tealia*) has sticky knobs on its body to which small stones adhere to form a protective covering. When the animal is shut up or retracted it is very inconspicuous, looking like a small heap of fine gravel. It may be noted in passing that the bright colours which distinguish anemones and their kind are probably of "warning" nature, such as advertise unpleasant properties, in this case the ability to sting. Anemones, and the same is true for other zoophytes, propagate not merely by eggs, but also by budding (*gemmation*) and splitting (*fission*), especially the latter, which may often be seen in process in a marine aquarium. In anemones, however, the products do not remain united to form a colony.

548. FEATHER-STAR **549.** BRITTLE STAR (UNDER SIDE) **550.** STARFISH (UNDER SIDE)

(Photographs by Prof. B. H. Bentley)

Corals. *Corals* are closely related to sea anemones, but differ from them by secreting a hard limy skeleton in the base of the body. They are either *simple* or *compound* (colonial). The well-known mushroom coral may be taken as an example of the former. Its skeleton is a shallow cup [552], exhibiting numerous radiating plates (*septa*), corresponding to the intervals between the fleshy mesenteries of the polype. If we look at the upper surface of such a coral in the living state [551], we shall see a mouth surrounded by circlets of tentacles, much as in a sea anemone.

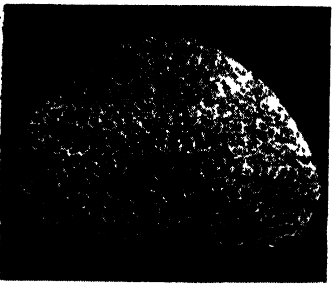


551. MUSHROOM CORAL (SOFT PARTS)

A *colonial* coral consists of a number of individuals, relatively small in size, connected together by a common flesh (*cœnosarc*), and formed by the budding or splitting of a single original polype, the results of the process remaining united. Part of such a coral (*Siderastrœa*) is here figured [555], showing four polypes and the calcareous cups from which several others have been scraped away.

552. MUSHROOM CORAL (SKELETON)

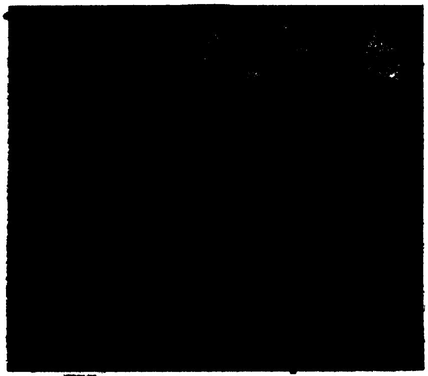
553. BRANCHING CORAL



554. BRAIN CORAL

(Photographs by Prof. B. H Bentley)

Development of Coral. Another figure is given [556] in illustration of the life-history of the last-named coral. An elongated ciliated larva hatches from the egg, and after swimming about for some time fixes itself to some firm object, and develops the tentacles and mesenteries characteristic of the adult. It will be noticed that the tentacles are at first clearly arranged in sixes, and the same thing is true of the mesenteries, the position of which is indicated by lines.



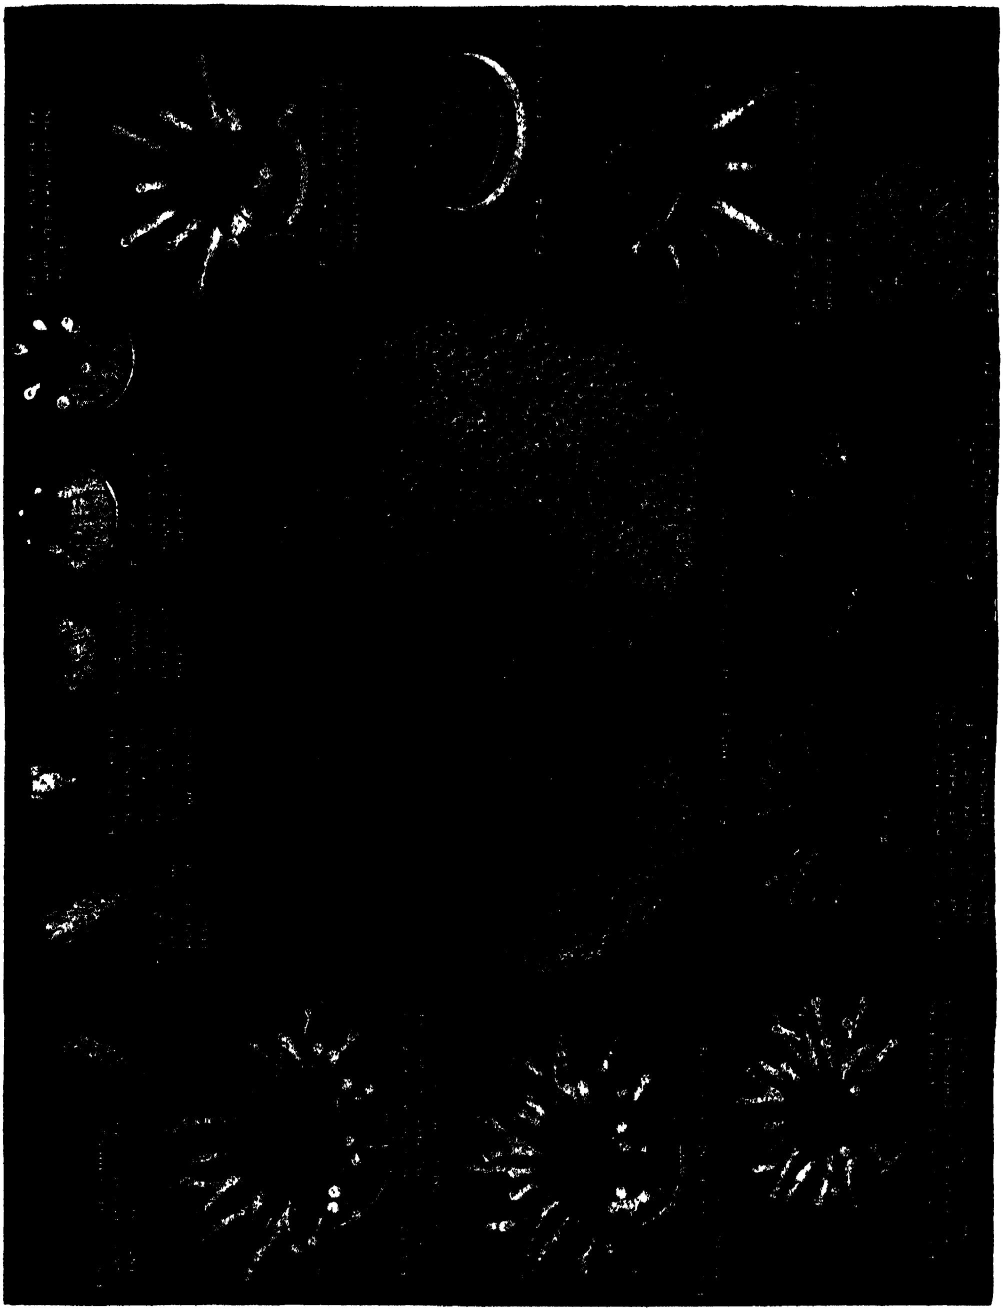
555. PART OF COLONIAL CORAL

Many corals branch [553], while others form compact masses, as in the kind above described, and also in the brain coral [554], where the boundaries between the individuals are not clearly marked.

Coral Reefs. Corals are marine creatures widely distributed, some living even in cold latitudes, and others on the floor of the deep sea. Coral reefs, however, made up of the skeletons of such animals, are only found in the warmer parts of the ocean, where the water is clear, particularly favourable conditions being afforded by the Pacific and Indian Oceans. Three varieties of coral reef may be distinguished: (1) Fringing Reefs, situated close to the land and separated from it by shallow water; (2) barrier reefs, further from the land and separated from it by deeper water (when round an island they are termed *encircling reefs*); (3) atolls, rings of coral with a central lagoon much shallower than the surrounding water.

Much discussion has taken place regarding the origin of coral reefs. It is known that the polypes can only live and flourish in comparatively shallow water, yet barrier reefs and atolls make up walls of coral which descend for hundreds, or even thousands, of feet into the depths. How is this to be accounted for? Darwin supplied the most plausible explanation, which certainly applies to a great number of cases. It may best be illustrated by taking the case of an island.

A Skeleton Island. There is no difficulty in understanding how a fringing reef can be formed round the shores of an island if we bear in mind that it is slowly sinking. Such slow downward movements are known to have taken and to be taking place in various parts



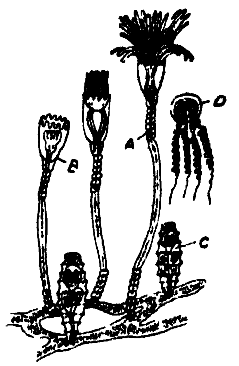
556. LIFE HISTORY OF A CORAL

of the world. As depression goes on, the corals will continue building on the dead skeletons of their predecessors, and after a time will form an encircling reef, with the remains of the island in the centre. When this is finally submerged, the atoll stage is reached.

Dead Men's Fingers. We now come to sea-flowers of another kind, in which there are *eight* feathery tentacles, and a corresponding number of mesenteries. All of them are colonial. One of the commonest examples is afforded by lobed fleshy masses often cast up on our shores, and known by the rather depressing name of dead men's fingers (*Alcyonium*). When expanded, these are very attractive in appearance [567], the individual polypes projecting like little flowers from the fleshy common body. In this case the skeleton consists of scattered spicules of lime. In some of the related forms, however, it is of more compact character.

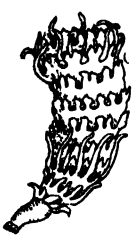
In the red or precious coral (*Corallium rubrum*), for instance, the branching colony is supported by a firm limy skeleton of pink colour. This is covered by the common flesh, from which the polypes can be protruded much as in alcyonium. Somewhat similar in general character is the fan-coral (*Gorgonia*), of which the curious horny skeleton [563] is often brought home by sailors. Much more beautiful is the organ-pipe coral (*Tubipora musica*), where each member of the colony lives in an elegant red tube [564]. The tubes are connected by thin platforms at regular intervals, and from these new polypes grow up, so that the colony gradually increases in size from the base upwards.

557. FRESHWATER POLYPE
a. Buds



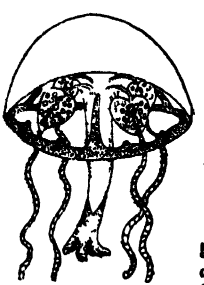
558. HYDROID ZOOPHYTE
a. Extended polype
b. Retracted polype
c. Urn d Jelly-fish

Growth on Seaweeds. Growing upon seaweeds, and often cast up by storms on the shore, will be seen branching structures, frequently mistaken for plants, and technically known as *hydroid zoophytes*, of which an example (magnified) is figured in 558. The branches of the apparent plant are horny tubes, enclosing the common flesh of the colony, and in this case they end in little cups which shelter the individual polypes. Each of these resembles a simplified sea-anemone in structure. It has fewer tentacles, and is devoid of a gullet and mesenteries. The life-history of the form known as *Campanularia* [558]) is of special interest.



559. HYDROID POLYPE SPLITTING TRANSVERSELY

Umbrella-like Jelly-fishes. Attached to the base of the colony are elegant urn-shaped receptacles, in which buds of special character are produced, destined to be liberated as free-swimming jelly-fishes (*Medusæ*), representing the egg-bearing stage. Free-swimming larvæ develop from the eggs, which after a time settle down and give rise to fixed branching colonies. Such a life-history is an example of "alternation of generations," as previously described for many plants and some of the parasitic worms. That is to say, it includes an egg-producing stage, and a stage which propagates by budding or splitting. In the last form described, the medusæ are produced by budding, but in some other cases they arise by a process of splitting. This is illustrated by 559, which shows a fixed polype dividing transversely into a number of little jelly-fishes. A jelly-fish, or medusa, may be compared to a fleshy umbrella with a thickened handle, at the end of which the mouth is situated [560]. Swimming is effected by the opening and shutting of the umbrella.



560. JELLY-FISH

Pond-dwelling Polypes. There are some hydroid zoophytes in which the medusæ are never set free, and still others in which the egg-producing buds are more or less unlike medusæ in form. An extreme case is afforded by the fresh-water polype (*Hydra*), one of the common inhabitants of ponds [557], and a simple, not a colonial, organism. During the summer this animal propagates by buds, which are detached when mature; but on the approach of autumn one or two small rounded prominences appear on the basal part of its body, and in each of these an egg is formed. This surrounds itself with a horny coat, falls down into the mud of the pond, and remains in a dormant state during the winter, when most of the adults perish.

Most of the larger jelly-fishes [560], such as may be seen swimming in shoals during the summer, or stranded on our shores, have no fixed stage in the life-history, their eggs developing at once into new jelly-fishes. There are also many colonial jelly-fishes in existence, differing ends being served by different members of the colony. In the example figured [561] the top individual is a float, beneath which is a series of swimming-bells, and below these again are feeding and egg-producing individuals, some of which are provided with long fishing lines. The Portuguese Man-of-war (*Physalia*), often mentioned in accounts of voyages, is a compound jelly-fish, provided with a particularly large float.

A few of the relatives of the hydroid zoophytes secrete a calcareous skeleton, and rank as corals. A common form is Millepora [565].

SPONGES

Sponges (*Porifera*) are animals of peculiar structure, which resemble zoophytes in many respects, but possess neither tentacles nor thread-cells. Some are simple, but most of them are colonial. A simple sponge may be compared to a cup or vase with a wall perforated by numerous small holes, through which currents of sea-water stream into the central cavity, to make their exit by the main opening. They are set up by ciliary action. The horny skeleton of a simple cup sponge is represented in 562. The ordinary bath-sponge is the similar skeleton of a colonial form.

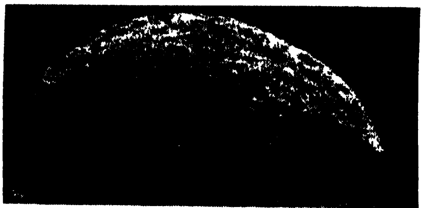
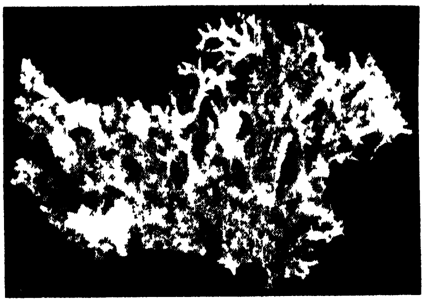
(Gorgonia)



564. ORGAN-PIPE CORAL
(Tubipora)



565. MILLEPORE CORAL
(Millepora)

Venus's Flower-Basket. In the majority of cases the skeleton of a sponge is mostly or entirely made up of sharp needles of lime or flint, which may be welded together into a definite form. A very beautiful deep-sea siliceous sponge of the kind is Venus's Flower-basket (*Euplectella*), the figure of which [566] shows very clearly the small holes into which the currents of water stream. In this case the opening of the vase is provided with a convex perforated covering. Another elegant form is the Glass-rope Sponge (*Hyalonema*), native to the Japanese seas [568]. It is rooted in the mud by a bundle of long glassy spicules, which are slightly twisted.

Most sponges are marine, and, despite their fixed habit and apparent helplessness, are pretty free from the attacks of most other creatures partly because of the innumerable sharp spicules they contain, and partly because their taste and smell are unpleasant. These deterrent qualities are often associated with bright warning colours, generally red, yellow, or orange. The relations of some crabs to sponges has been mentioned on page 3808

A few sponges of greenish colour live in canals or slowly-moving streams, attached to various firm objects. Like so many fresh-water organisms, they have a special device for tiding over the winter, which is very destructive to the adults. Towards autumn they develop little internal buds (*gemmules*), enclosed in cases made of peculiar spicules, shaped something like two little stars united by a rod. These buds remain snugly in the mud till the winter is over, and then sprout into adult sponges.

ANIMALCULES

In the botanical part of this course we found that the lowest plants are mostly of a microscopic size, and *unicellular*—*i.e.*, consisting of a single cell or structural unit, essentially a fragment of living matter (protoplasm), part of which is specialised into a nucleus. The latter appears to regulate the vital activities.

Amœba. The lowest animals are also unicellular, and the popular term "animalcule"—*i.e.*, a little animal—has reference to their diminutive size. One of the simplest known cases is afforded by the Proteus Animalcule (*Amœba*), a mere droplet of semifluid substance without any definite form [569], or more correctly with a form that is constantly altering. THE WONDERFUL RÖNTGEN RAYS

The Discovery of the Röntgen Rays, and their Use in Surgery. Their Benefit to Humanity, and Theories Concerning their Effects

By Dr. C. W. SALEEBY

WE are already quite familiar with the fact that the radiations called light have variously been conceived as consisting of undulations or vibrations in the ether, or of minute material particles moving through space at high speeds. We know, also, that the latter or Newtonian view is now disproved; but it is extremely important for us to recognise that the word *radiation* is now used in physical science to cover two very different things—first, various wave motions in the ether; and, secondly, various corpuscular motions which are not light but which have a very striking resemblance to Newton's theory of light. We may quote from Mr. Soddy, one of the most distinguished of the workers in this field, a definition of the use of the word radiation in its wide modern sense. He says "the term *radiation* is properly applied to indicate an influence transmitted *radially* from its source to its surroundings, and capable of traversing vacuous space without occupying in its transmission a period of time great enough to be sensible under ordinary circumstances." The reader will not be misled by Mr. Soddy's use of the word *vacuous*. It means vacuous as regards ponderable matter, but certainly not vacuous as regards the ether.

The Work of Sir William Crookes. It was Sir William Crookes who first recognised the existence of radiations more or less corresponding to the type imagined by Newton. In order to understand his discovery, we must briefly note the elementary facts of a vacuum tube. An electric current can be made, under favourable conditions, to spark across a gap of air, but a very great measure of electric force is necessary to maintain any appreciable discharge across even a very small interval of air at the atmospheric pressure, while a still greater force is needed to start the process. The passage of the spark is made very much easier by lowering the atmospheric pressure. This can be easily shown by sealing platinum wires, which act as electrodes, or conveyers of electricity, into small glass tubes, most of the air of which has been removed. But at this point we cannot do better than quote from another distinguished worker in this field, Mr. Whetham.

"For many years these vacuum tubes, as they are called, were the electrical playthings of the laboratory and popular lecture-room. Recent discoveries have raised them from the position of scientific toys to the rank of pieces of apparatus whereby have been made some of the greatest discoveries in physical knowledge that the present generation has seen. Through such a tube, in which the pressure of the air is only a small part of an atmosphere, a discharge may readily be passed by the aid of a voltaic battery and an induction coil, or by the use of an influence electric machine. As in liquid conductors, the electrode by which the current enters is called the *anode*, and that by which it leaves, the *cathode*. Starting from the cathode, we first see a bright glow covering its surface, then a space, succeeded by a second dark space, beyond which is a luminous column reaching to the anode. Within certain limits of pressure and strength of current this positive column, as it has been called, shows fluctuating striations. If the length of the tube be increased, it is this positive column alone which increases with it; the two dark spaces and the negative glow vary very little with the length of the tube."

The Cathode Rays. Sir William Crookes proceeded to study the consequences of making the vacuum in such a tube extremely high, and he discovered, as certain of his predecessors had suspected, that certain rays are produced, which we now know as *cathode* rays. The greater the exhaustion of the tube the greater becomes the size of the dark space or "Crookes' dark space," around the cathode. At last this fills the whole tube, and the glass opposite the cathode begins to display a green phosphorescent appearance. Furthermore, if a mica screen be interposed between the phosphorescent glass and the cathode, a shadow which is notable for its sharp definition appears, demonstrating that some kind of rays, able to produce phosphorescence in glass, are being thrown out from the cathode in straight lines. The properties of these cathode rays are extremely remarkable. They produce heat in any body which obstructs them, and they possess energy, since they will drive round a little windmill placed in their way. They will actually produce so much heat as under favourable conditions will suffice for melting a piece of platinum wire or charring a diamond.

The Cathode Rays and Magnetism. Most interesting of all are the relations of these cathode rays to a magnet, *which deflects them*. The deflection is that which would be expected in the case of negatively-electrified particles travelling along the path of these rays. Says Professor J. J. Thomson, summing up the researches which have since been made on this point: "Thus the cathode rays carry a charge of negative electricity, they are deflected by an electric field as if they were negatively electrified, and are acted on by a magnetic force in just the way this force would act on a negatively-electrified body moving along the path of the rays. There is, therefore, every reason for believing that they are charges of negative electricity in rapid motion, and by measuring the deflection produced by magnetic and electric fields we can determine the velocity with which these particles move and the ratio of the mass of the particle to the charge carried by it."

The Lenard Rays. We cannot here enter at great length into the various properties of the cathode rays. Nevertheless, certain facts concerning them must be noted. It was shown by Hertz that all solids are not entirely opaque to them, and by Professor Lenard that, under certain conditions, the cathode rays can actually be made to pass from the inside of a discharge tube to the air outside. Cathode rays after transmission through solids are now known as Lenard rays. They are really one and the same with the cathode rays. Says Professor Thomson: "The properties of the rays outside the tube resemble in all respects those of cathode rays; they are deflected by a magnet and by an electric field, they ionise the gas through which they pass, and make it a conductor of electricity, and they affect a photographic plate and change the colour of the halide salts of the alkaline metals. As, however, it is convenient to distinguish between cathode rays outside and inside the tube, we shall call the former Lenard rays."

It is interesting to note that Sir William Crookes gave a correct explanation of the cathode rays from the first. He said that they were "streams of negatively-electrified particles projected normally from the cathode with great velocity." Outside this country his explanation was not accepted, but we now know that he was right. In truth, the work done by observers in this country in this new field of physics is incomparably more important than all the work which has been done elsewhere. When we have concluded this subject, we shall have quoted from Crookes, Thomson, Whetham, Soddy, and Strutt. It is in Germany and America that science is appreciated, but the land of Newton and Harvey and Darwin is still pre-eminent in its creation.

Röntgen's Remarkable Discovery. Professor Röntgen was enabled to observe the invisible rays that go by his name, in virtue of the fact that he happened to be keeping some photographic plates, well covered, in the neighbourhood of a very highly exhausted vacuum tube. He then found that these plates looked as if they had been exposed to light. This was well worth looking into. He found that if he used a screen covered with some phosphorescent substance, it began to glow brilliantly under the influence of *something* that emerged from the tube. Further, he found that certain substances obstructed this something while others did not. "He found that if a thick piece of metal were placed between the bulb and the phosphorescent screen a sharp shadow of the metal was cast upon the screen, but that other substances, such as wood and thin pieces of aluminium, cast but slight shadows, showing that the agent which produced the phosphorescence could traverse with considerable freedom bodies which are opaque to ordinary light. He found that as a general rule the greater the density of the substance the greater its opacity to this agent. Thus, while the effect produced by the phosphorescence could pass through the flesh, it was stopped by the bones of the hand, so that if a hand were held between the discharge tube and the phosphorescent screen the outline of the bones was distinctly visible as a shadow cast on the screen; or if a purse containing coins were placed between the tube and the screen the purse itself threw but little shadow, while the coins cast a dark one."

Characters of the X-Rays. Professor Röntgen was worthy of his good fortune, and made the most of it. He showed that the rays move in straight lines, and that on passing from one medium to another they undergo no refraction. Unlike the cathode rays, they are unaffected by a magnet. Professor Thomson says that he has "sent the rays through a magnetic field of about 8,000 lines of force per square centimetre for a distance of about a centimetre without producing any appreciable defect." Many attempts made to polarise the rays failed; and these facts seemed to suggest that the rays must differ fundamentally from those of light. Nevertheless, on certain points they resemble light. Like light they are propagated in straight lines, they feebly stimulate the retina, they affect the photographic plate, they are not deflected by electric or magnetic influence, and so on. On the other hand, the absence of any refraction does not exclude the possibility of their being really identical with light. Professor Thomson points out that, according to any theory of refraction—which we must conceive as dependent upon the ratio between the period of vibration of the refracting body and the period of the vibrations of light—"there would be no refraction for light of very small period, and this would also be true if, instead of regular periodic undulations, we have a pulse of electromagnetic disturbance, provided the time taken by light to travel over the thickness of the pulse be small compared with the periods of vibration of the molecules of the refracting substance."

The Distinctive Property of Röntgen Rays. In the year following the discovery, the late Sir George Stokes suggested that perhaps the Röntgen rays differ from ordinary light in that they consist not of trains or series of waves, but of irregular disconnected waves or pulses: "single disturbances, propagated with the same velocity as light, but not followed by a train of waves." Professor Thomson has shown that whenever the cathode rays—or, rather, his corpuscles—strike a solid, intense electromagnetic pulses must be set up. Since this must be so, what can be more probable than that the Röntgen rays, produced under these very conditions, are none other than the pulses which must occur? Very probably, then, Sir George Stokes was right, and the X-rays consist of intermittent ethereal pulses produced by the impact of the negative corpuscles upon the glass —which is proportionately intermittent—and, furthermore, differing from ordinary light in the extreme shortness of their wave length.

At a comparatively early stage in the inquiry it was found that the Röntgen rays vary somewhat according to the conditions under which they are produced. This is an important matter theoretically, since it suggests, for instance, that there may be a whole series of "notes" of Röntgen rays corresponding to the notes or colours of visible light. Physicians and surgeons also have come to recognise the extreme importance of distinguishing the various kinds of Röntgen rays, since one kind may have a curative effect which is entirely absent from the others. If the vacuum tube has not been exhausted to any very great degree—the gaseous pressure within it, therefore, remaining pretty high—with the consequence that the potential difference between its electrodes is small and the velocity of the corpuscles between them correspondingly low—the Röntgen rays produced outside the tube are called *soft* rays, and have the character that they are very readily absorbed.

Penetrating Power of the Rays. Very different, indeed, is the penetrating power of the rays produced in a tube which is very highly exhausted. In such a tube, where the potential difference between the two electrodes is high, the cathode rays travel with much greater speed, and the variety of the Röntgen rays they then produce are called *hard* rays. Says Professor Thomson: "With a highly exhausted tube and a large induction coil it is possible to get appreciable effects from rays which have passed through sheets of iron or brass several millimetres thick. The penetrating power of the rays thus varies with the pressure in the tube; as the pressure in the tube gradually diminishes, when the discharge is kept running through the tube, the type of discharge proceeding from the tube is continually changing. Not only do different bulbs emit different kinds of rays, but the same bulb may emit, at the same time, rays of different kinds. The property by which it is most convenient to identify a ray is the absorption it suffers when it passes through a certain thickness of aluminium and tinfoil." But, nevertheless, experiments made on this point show that the rays vary among themselves even more than was thought, and, as has before been stated, this question of the difference between various kinds of Röntgen rays is not only one of great physical interest but may also frequently be a matter of life and death.

The Effects of the Rays. Until quite lately it could not be said that the real nature of the Röntgen rays was *proved*, though in all probability they were neither material particles nor longitudinal waves in the ether, as the discoverer himself had suggested, but consisted of transverse ethereal disturbances. But if they were transverse they ought to be polarisable, and until quite lately all attempts to polarise them had failed. The use of tourmaline plates gave no evidence of polarisation. Quite lately, however, another method has been employed, in describing which we may quote from Mr. Strutt, who is the son and heir of Lord Rayleigh, the President of the Royal Society, and affords a conspicuous instance of inherited scientific genius. He has made very important contributions to various aspects of the subject which we are now discussing.

"The rays," says Mr. Strutt, "are allowed to fall on some light substance, such as paper or carbon. Under these circumstances the paper or carbon becomes itself a source of rays—secondary rays as they are called. The amount of secondary radiation in any fixed sideways direction is found to vary, as the vacuum bulb giving out the original rays is made to turn round in such a way as to rotate the beam of rays on itself, without changing its direction. This proves that the beam has a one-sided character, and establishes most satisfactorily that the vibrations must be in a transverse direction; for if the vibrations were longitudinal it is impossible to conceive how turning the beam round could make any difference. Later and more elaborate experiments have shown that this one-sidedness is much more marked in the secondary rays themselves than in the original ones from the bulb."

The Use of the Rays. This must obviously be regarded as conclusively proving that the Röntgen rays are essentially identical with light. If we could show finally that the rays have the same speed as light we might regard our proof of their nature as complete. It has recently been attempted "to compare the speed of the rays with the speed of electric waves travelling along a wire, which is known to be the same as that of light." So far as these experiments have hitherto gone they seem to show that, as might be expected, the velocity of the Röntgen rays is identical with that of light. We may note that M. Blondlot, whose alleged discovery of the N-rays is still under discussion, claimed some two or three years ago to have shown that the Röntgen rays are polarisable and that they move with the velocity of light.

Let us now turn from the purely physical aspect of this study to the question of utility, which, as a matter of fact, has advanced very much more rapidly than the purely scientific question. No sooner had Professor Röntgen demonstrated the fact that he could see his own bones, or rather their shadows, projected by the rays, than the surgeons turned the fact to account. Plainly, this property would be very much to the point if it were applied to broken bones, the position of which it is often very difficult but always very important to ascertain. Nowadays a thoroughly up-to-date surgeon with a perfect equipment and plenty of time not only uses the Röntgen rays in every case of fracture, but, after the fracture has been set, and the bandages and splints and all have been put on; takes another photograph so as to make quite sure that the fragments of the bone are lying in perfect position.

The Enormous Gain to Humanity. The surgeon acts similarly, in the case of dislocations, in the case of bullets, and needles. On this mere point of finding needles the reader can have little idea how many women the discovery of the Röntgen rays has benefited. Furthermore, it is quite easily possible to see the movements of the heart by means of the Röntgen rays, and this has enabled doctors to confirm the theories formerly held as to the causation of the various sounds produced by the normal and the abnormal heart. Many cases of the disease known as aneurism can also be readily detected by the size of the shadow which the diseased artery throws upon the screen. Furthermore, the early signs of consumption or tuberculosis of the lungs can be detected by the increased opacity which this disease causes to these rays, and some observers are of opinion that the disease can be thus diagnosed sooner than by any other means. Again, there is a large number of different kinds of stone occurring in the body, the presence of which can be detected by the shadow which they cast under these rays—a means of diagnosis which is now of the utmost value in surgery.

The Röntgen Rays and Living Matter. It is a curious circumstance that, so far as can be judged, the X-rays have no deleterious action upon microbes. This is curious, because, as we shall see, they are of very great value indeed in the treatment of various diseases of microbic origin. When the Röntgen rays are allowed to act upon the skin, they cause a number of remarkable changes in time. They very often destroy entirely the roots of the hair, though hitherto it has not been possible to control the production and character of the rays in sufficient degree to justify their use as a substitute for the razor in the case of priests or other persons who are compelled to spend a considerable part of their lives in keeping down a beard which might be arrested for ever by the Röntgen rays. The skin itself is also apt to undergo various changes which may amount either to severe inflammation or even to actual destruction. It is the lamentable fact, also, that the ulcers produced by these rays sometimes become cancerous. Doctors and their assistants, working the Röntgen ray departments of hospitals, are now learning that it is necessary to protect themselves by means of leaden gloves or shields. The most opaque substances of all to the Röntgen rays are platinum, mercury, bismuth, lead, and silver.

The Displacement of the Knife. The public are already familiar with the use of the Röntgen rays in diagnosis, but in quite recent times they have been employed as a means of treatment, and in many cases their use has been followed by the most astonishing, not to say unexpected success. Like ultra-violet light, the Röntgen rays are perfectly effective in curing lupus, but their penetrative power is far greater. In the therapeutic use of ultra-violet light, great importance is attached to the exclusion of as much blood as possible from the area of the skin to be acted upon, for even the thinnest film of blood absorbs these rays. Very different, however, are the Röntgen rays, which will pass right through the body, and thus their range of employment as therapeutic agents is very much greater than that of ultra-violet light. The Röntgen rays will cure deeply-situated cases of lupus against which the Finsen treatment is powerless. Besides this disease, a dozen other diseases of the skin might be named, including notably ringworm and its allies, which are curable, and are now constantly treated, by the Röntgen rays. Much more important is the conquest by this means of one variety of cancer—that known as *rodent ulcer*. It is true that this is by far the least malignant variety of cancer, and the reason why it alone is susceptible to the action of the Röntgen rays is doubtless that it is also the most superficial variety. But rodent ulcer is a common disease, and no words can say how magnificent is the gain involved in the displacement of the knife by these rays in the treatment of this once terrible disease.

Cures by Röntgen Rays. These facts raise questions of the very greatest scientific interest, and more especially when we realise that the rays apparently have no antiseptic action in the ordinary sense. The cures they effect seem to be due to their stimulation of the tissues of the body, and the question we must ask ourselves, without any possibility as yet of answering, is—How do these electromagnetic pulses so affect living matter as to give rise to these consequences? Science will have advanced much further before it is possible to explain these facts in physico-chemical terms.

The rapid advance of the physics of the Röntgen rays has been of great value, of course, as regards their application in what used to be called physic. Notably, it is now being found that when rays of the right kind are employed in sufficient abundance their therapeutic action is very far from being confined to the surface of the body. On the contrary, there are various diseases of the internal organs, most of them responsive to no other kind of treatment, in which great gain results to the patient from the employment of the Röntgen rays. It is nothing short of amazing to contemplate the revolution in many branches both of surgery and of medicine which has been effected in a few short years as a direct consequence of Professor Röntgen's first observation.

The Theory of Radiation. We have now completed our discussion of many various kinds of radiation. We have said all that there is time to say of the rays of ordinary light, the ultra-violet rays, the infra-red rays of radiant heat, the still somewhat dubious N-rays, and the Röntgen rays. The proposition has been submitted that, widely though these differ from one another in respect of their physical properties, and still more widely in respect of their influence upon our senses, yet they are one and all to be regarded, together with many other radiations known and unknown, as fundamentally identical.

For our present purposes, then, we must dismiss the differences between these various kinds of rays, and must consider the extremely difficult subject of radiation in general, recognising that by this term we include radiations visible and invisible.

Radiation and Temperature. This is one of the most complex subjects in the whole of physics, and we can present it merely in outline. More important than any of its details is the recognition by the student that there is, or may be, a general theory of radiation. Perhaps the first fact worthy of being insisted upon is the extreme intimacy of the relation between radiation and temperature. This is of the utmost importance in respect of theory and of equal importance because of the remarkable information which the application of this principle affords us when we turn to the study of the stars. Let us recall for a moment what we have learnt regarding heat. We have seen that heat may be transferred by conduction, by convection, or by radiation; but now we may consider more critically this last process, which we shall find to be fundamentally different from the other two. We know that a radiant body in consequence of its radiation cools. We know also that the bodies which absorb the radiation are heated, but are we entitled to apply the term heat to that which passes between the radiating and the absorbing bodies? The nature of the problem is usually obscured by the language we employ. We describe what passes as *radiant heat.* But the critical reader will have already noticed that there is a fundamental distinction between this radiant heat which, according to our latest studies, is none other than an electromagnetic phenomenon of the ether, and the ordinary heat, which consists, as we have said, of a vibration of certain material molecules

We may utilise the words of Professor Tait in proof that radiant heat is not really heat at all, though it may be in some way caused by heat and in some way cause heat. "When a piece of clear ice is cut into the form of a large burning-glass, it can be employed to inflame timber by concentrating the sun's rays, and the lens does the work nearly as rapidly as if it had been made of glass. It is certainly not what we ordinarily call heat which can be transmitted under conditions like these. Radiation is undoubtedly a transference of energy, which was in the form commonly called heat in the radiating body, and becomes heat in a body which absorbs it; but it is transformed, as it leaves the first body, and retransformed when it is absorbed by the second."

Visible and Invisible Light. The reader will understand that the term "radiating" in the above quotation includes all luminous bodies. We are speaking now not merely of radiant heat, but of light as well. This we shall see by another quotation showing the absolute continuity between the visible and the invisible "The more intensely a cannon-ball is heated the more luminous does it become, and also the more nearly white is the light which it gives out. So well is this known that in almost all forms of civilised speech there are terms corresponding to our 'red-hot,' 'white-hot,' etc. As another instance, suppose a powerful electric current is made to pass through a stout iron wire. The wire becomes gradually hotter, up to a certain point, at which the loss by radiation and convection just balances the gain of heat by electric resistance. And as it becomes hotter the amount of its radiation increases, till at a definite temperature it becomes just visible in the dark by red rays of low refrangibility. As it becomes still hotter, the whole radiation increases; the red rays formerly given off become more luminous, and are joined by others of higher refrangibility. This process goes on, the whole amount of radiation still increasing, each kind of visible light becoming more intense, and new rays of light of higher refrangibility coming in, until the whole becomes white—that is, gives off all the more efficient kinds of visible light in much the same relative proportion as that in which they exist in sunlight. When the circuit is broken, exactly the same phenomena occur in the reverse order, the various kinds of light disappearing later as their refrangibility is less. But the radiation continues, growing weaker every instant, even after the whole is dark."

This illustration affords one more proof of the continuity between the visible and the invisible, but it also constitutes an illustration of the proposition that there is a definite relation between temperature and radiation. If we translate what happens into the best symbols that we know, we must imagine that as the molecules of the wire become hotter and the character of their vibrations alters, so they give rise to ethereal waves of shorter and shorter wave lengths and greater and greater frequency.

The Laws of Radiation. The whole of radiation, then, is one phenomenon, and to have discovered this constitutes a great triumph of the mind over the imperfections of our senses. Let us now consider what general propositions can be advanced beside that of the relation between temperature and radiation Nearly half a century ago Balfour Stewart showed "the absolute uniformity, qualitative as well as quantitative, of the radiation at all points and in all directions within an enclosure impervious to heat when thermal equilibrium has once been arrived at." He showed, by many experiments and observations, that radiation and absorption rigorously compensate each other, not merely in quantity but in quality also, so that a body which is specially absorptive of one particular ray is in the same proportion specially radiative of the same ray, its temperature being the same in both cases. Stewart's final statement was that "at any temperature a body's radiation is exactly the same, both as to quality and quantity, as that of its absorption from the radiation of a black body at the same temperature."

The last proposition shows that Stewart worked first at radiant heat, but his propositions were true alike of light. In short, they are true of radiation in general. Balfour Stewart's work was, indeed, a confirmation and extension of the very important idea first enunciated by Prévost in 1791, and called by him the *Law of Exchanges.*

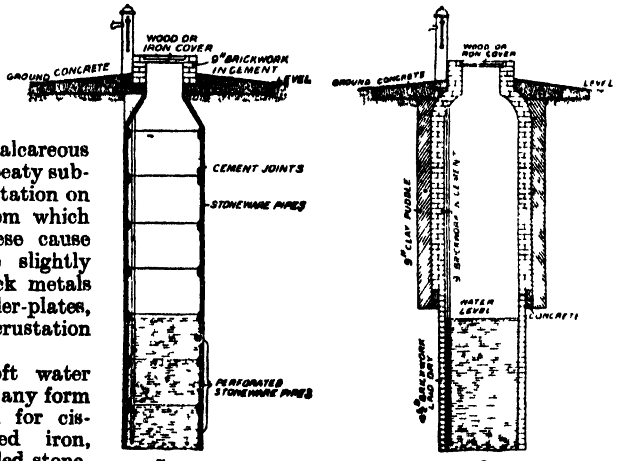
WATER SUPPLY
continued from page 4029

By Professor HENRY ROBINSON

Wells for Cottages. At the Conference on "Water Supplies and River Pollution," held by the Royal Sanitary Institute in London in 1901, the question of the water supply to isolated cottages and small groups of cottages was brought forward by Dr. Thresh, the Medical Officer of Health, Essex County Council, and he showed two of the simplest methods of well construction that had been adopted to ensure the exclusion of pollution from the well by making the first 12 ft. or so watertight. Figs. 5 and 6 are illustrations of these wells.

Impurities in Water. Water contains mineral impurities in the form of soluble salts which have been absorbed during its flow over or through the various geological formations from which the supply is obtained Where the water has come into contact with metalliferous deposits containing salts of lead or copper it must be regarded as dangerous to health.



5. 6.

TYPES OF SIMPLE COTTAGE WELLS

Soft water, being free from calcareous matter, dissolves peaty substances from vegetation on the watershed from which it flows, and these cause the water to be slightly acid and to attack metals such as lead, boiler-plates, and to form incrustation thereon.

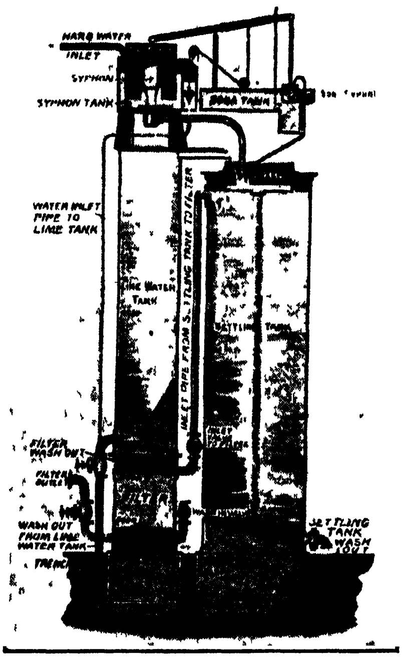
For storing soft water in houses, lead in any form must be avoided for cisterns. Enamelled iron, porcelain, enamelled stoneware, and slate, are used for cisterns to hold soft water. Iron is sometimes used, having a protective coating of quick-drying asphalte varnish.

The effect of storing polluted water in copper vessels has attracted attention of late years owing to its having been observed that in India, during a cholera epidemic, one district escaped. It was found that the people there stored water in copper vessels and were immune, although the condition of the water was the same as in the neighbouring districts which were affected. Recent research has shown that copper is destructive of pathogenic organisms.

Impure water can be sterilised by applying to it electrolysed salt water. By passing a current of electricity at a low voltage through a saline solution a fluid is produced which has an intensely sterilising effect, and destroys all bacteria. The writer has carried out works where this was successfully accomplished, a very foul sewage-polluted water being freed from all micro-organisms by passing into the flowing water automatically an amount of the sterilising fluid called *electrozone*.

Taking Samples of Water. Samples of water for chemical and bacteriological examination require to be taken in a definite way. The bottle, generally a Winchester quart, is carefully washed with distilled water and exposed in an oven to a high temperature to sterilise it In taking the sample the bottle should be quite immersed before the stopper is removed, and it should be replaced under the water when the bottle is full, so as to prevent any surface scum from entering If the sample is from a shallow stream or well, care must be taken not to disturb the sediment. The top of the bottle should have a descriptive label attached to it, the stopper having been replaced and securely closed, so that nothing can gain access to the bottle until it is consigned to the care of the analyst.

Hardness of Water. Hardness in water is caused by the presence of carbonates, sulphates and nitrates of lime and magnesia. Hardness is either temporary or permanent. It is called temporary if the carbonates are present, as they are not to any practical degree soluble in water, but they are in the carbonic acid, which is in solution, and which can be driven off by boiling the water, when the carbonates are precipitated and the water is made soft. To soften water on a large scale, caustic lime as lime-water is added to the water, and, combining with the carbonic acid, forms carbonate of lime, which precipitates. The term hardness implies that a certain quantity of soap has to be decomposed before a lather can be formed. When water is said to have a certain number of degrees of hardness, it is meant that a gallon of water will curdle and precipitate as much soap as would be precipitated by a gallon of pure soft water in which that number of grains of carbonate of lime had been dissolved. Water of 12 degrees of hardness will precipitate as much soap as pure water would to which 12 grains of carbonate of lime had been added per gallon. Lime alone will reduce the degree of hardness from 18 degrees to 4 degrees, and will effect a saving in the use of soda and soap. A hundredweight of quicklime, costing 8d. or 9d., is productive of softening represented by 4¾ cwt. of carbonate of soda and 20¼ cwt of soap. The writer carried out works to soften very hard water at a large public institution, and it was found that the saving effected in various ways more than covered the repayment of the loan for the works, besides the attendant comfort and convenience of the people.



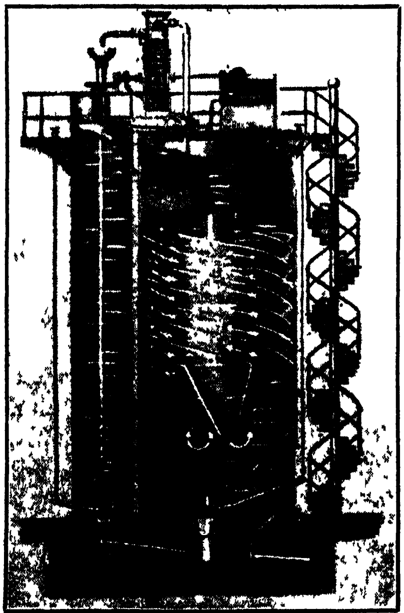
7. CRITON WATER SOFTENER

Deposits in Boilers. Hard water causes deposits in boilers, which are most undesirable as the scale formed leads to unequal heating of the metal and the risk of explosions. The writer applied a simple softening arrangement to water of 14 5 degrees of hardness at an installation of boilers, and reduced the hardness to about 4 degrees, using a pound of lime to a thousand gallons of water, incrustation being prevented.

Water Softening. Permanent hardness is caused by the water containing certain salts in solution, the chief of which are calcium chloride, magnesium sulphate and chloride, and sulphate of lime. These can be removed by adding carbonate of soda to the water in proper proportions, and storing the same in suitable chambers, where deposition takes place. Several mechanical arrangements have been devised to accomplish this. One is called the Criton Water Softener [7], made by the Pulsometer Engineering Co.

The quantities of the reagents are measured by filling vessels of given capacities adjusted to give the required proportion of reagents to the hard water.

The hard water is admitted to a tank divided by a partition into two unequal portions; the larger of these, which contains a syphon, is called the *syphon-tank*, and the smaller the *measurer*. The top of the partition is two inches below the level at which the syphon begins to discharge. When the level of the water in both compartments has reached the discharge point, the syphon automatically discharges the contents of the syphon-tank into the mixer, leaving the other compartment brim full. In the syphon-tank is a float, which, as it descends, lifts, by means of a lever, a valve at the bottom of the measurer, and permits the accurately measured quantity of water to run into the limer, displacing an equal quantity of clear lime-water, which overflows into the mixer. During its passage upwards in the limer the water passes through a bed of slaked lime, and on reaching the top has become saturated lime-water. The bed of lime is kept stirred up by an agitator worked from the float of the syphon-tank.

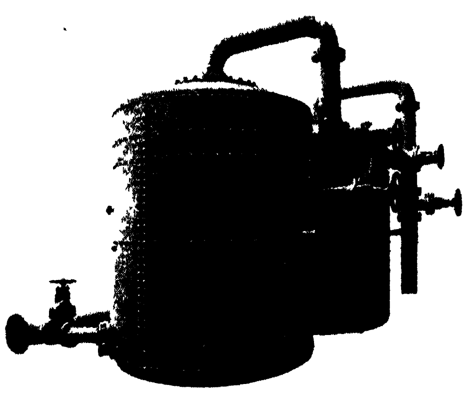


8. SECTION OF DESRUMANX WATER SOFTENER

Attention was called in the "Public Health Engineer" for September, 1905, to an apparatus for softening water called the Desrumanx, which deserves mention.

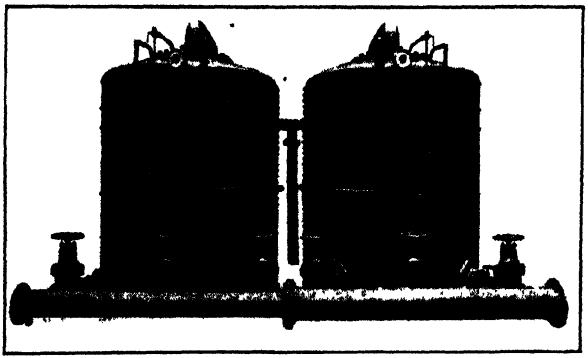
This apparatus, as will be seen from the section shown in 8, consists of two cylindrical tanks, the one on the left-hand side of illustration being the lime saturator for making lime-water, and that on the right-hand side being the decanter, in which the reagents are mixed with the water to be softened, and the clear soft water decanted and filtered ready for use.

Filtering. For filtering water on a large scale for public supply the form of filter employed in the past consists of a layer of clean, sharp sand, about $\frac{1}{30}$ in. average size, from two to four feet in thickness, beneath which is a thinner layer, about six inches, of fine gravel, with a layer of coarse gravel underneath. A series of small drain-pipes at the bottom carries the water, which passes downwards, to the main collecting outlet drain or drains. At the farthest ends of these, drains from the outlet pipes are carried up the walls of the filter-bed to the surface, to enable the air in the bed to escape when the filter is being filled. The usual rate of filtration varies with the conditions of supply and demand, but that which has been adopted for the supply of London is about 400 gallons to 500 gallons per sq. yd, per 24 hours, the rate being measured by a meter, either at the inlet or outlet. The head of water on the top of the filtering material is regulated to about two feet. The clear water is conveyed to a tank, which should be roofed in if it is in the open, and placed at a level to enable it to receive the water from the filter-bed. When the cistern is quite full and the bed emptied for clearing purposes, the head can force water upwards through the bed to remove impurities. To obtain a uniform rate of filtration through the whole of the bed, which is an important matter, the length, number, and size of the drains have to be arranged to meet the variation in pressure in the drains, which is least towards the outlet.



9. CANDY'S WATER FILTER AT HASTINGS

The rate of percolation through the bed should be regulated to prevent its being waterlogged, as the removal of organic matter in the water is not by mechanical but by bacterial agency, and the micro-organisms that accomplish this are aerobic, requiring air. The foregoing system of filtration has been termed the *slow sand* method.



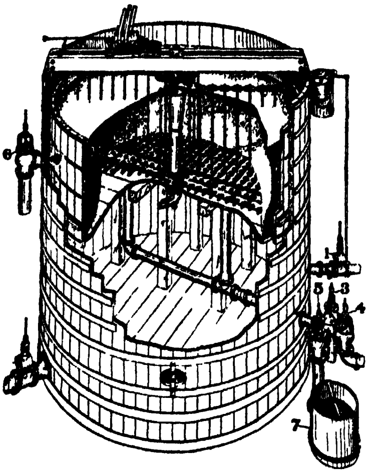
10. FRONT VIEW OF CANDY FILTERS

It was at one time thought that the efficiency of a sand filter, as regards the removal of bacteria from the water, depended on the maintenance of the surface film, which is formed by the collection of vegetable and organic matters floating in the water before it is passed over the filter. This view has been shown to be incorrect by the observations which were made by Mr. Clark, the chief chemist to the Massachusetts Board of Health, and communicated in 1901 to the Institution of Civil Engineers by Mr Rutter, who was connected with one of the large stations for the supply of London. He carried out a plan by which the surface film was systematically disturbed on a large area of open filters dealing with 25,000,000 gallons of water per day.

Candy's Water Filter. Candy's system of water purification consists in forcing air under pressure into the water, and subsequently passing the aerated water through a filtering medium in which "polarite" plays a part in conjunction with sand. The combined effects of aeration and filtration have been found to yield an excellent water at Hastings and St. Leonards. It has been characterised by the waterworks' engineer there as being "colourless, sparkling, and of the highest organic purity," and he states that the system is "a most satisfactory and economical method of purification." The material called *polarite* is an artificial one, prepared specially for use in sewage and water filters, and being insoluble, and having an oxidising property, has been found useful in this connection.

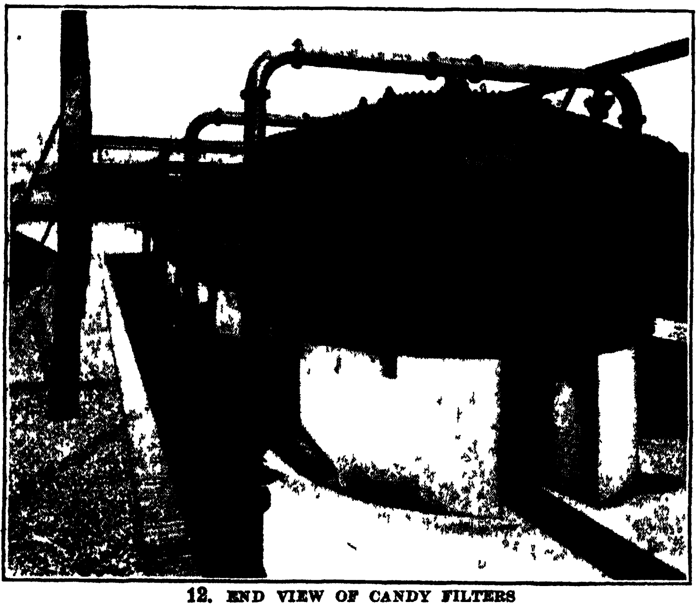
Fig. 9 shows filters, 15 ft in diameter, at the Hastings Waterworks, for dealing with 2,000,000 gallons a day. Figures 10 and 11 show a front and end view of two out of a battery at Cardiff. The cost of cleansing and working, including upkeep, is stated to be about 1d. per 50,000 gallons for a town's supply of over 1,000,000 gallons a day.

Sterilisation of Water. The sterilisation of water in the field was the subject of an inspection by Mr Arnold-Forster (then Secretary of State for War), at Millbank Barracks, in August, 1905, of several apparatus for that purpose. They were classed under three heads First, chemical methods of sterilisation by the employment of permanganate of potash, bisulphate of soda, alum, sulphate of copper, bromine, iodine, and chlorine The second class of apparatus employed filtration, and the third class relied upon boiling the water. The last is advocated by some authorities for army purposes, as the rough treatment to which filters would inevitably be exposed in the field might lead to the unnoticed breakage of a candle, whereby the water passing through it would be unfiltered, and the consumers would suffer accordingly



11 JEWEL GRAVITY FILTER

The "Jewel" Filter. The system of water purification that has been introduced by the Jewel Export Filter Company (of America) has been so successful that it deserves mention It is based on the application of some harmless soluble salt, such as sulphate of alumina, as a coagulant to the water, after which sedimentation and filtration is effected in specially arranged tanks, either open, when they are termed *gravity* filters, or closed, when they are called *pressure* filters. The writer has before him the results of many investigations of the treatment of water by these filters, and it appears that they possess advantages over the ordinary sand filters, called by the Americans the *slow sand* system, while the Jewel filter is termed the *quick sand* filter.



12. END VIEW OF CANDY FILTERS

In comparison with slow sand filters, it is claimed that rapid filters possess, among other advantages, the capacity to treat very turbid waters and to remove a large percentage of colour.

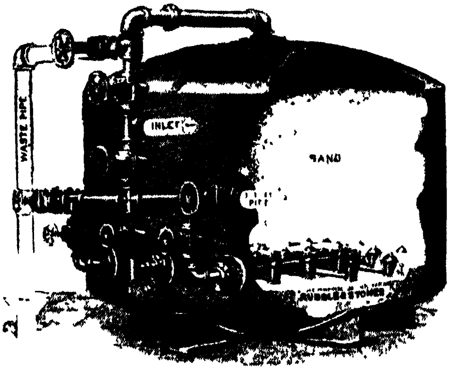
Figs 11 and 15 show a Jewel "gravity" filter with and without a subsidence basin, and 13 shows a "pressure" filter.

The addition of sulphate of alumina to the water results in the formation of a gelatinous insoluble coagulum of considerable bulk, and of greater specific gravity than the suspended particles present in the water The natural precipitation of this coagulum brings about the aggregation and deposit of the greater part of the suspended matter By this means from 40 to 75 per cent of both suspended matter and bacteria can be removed from the water before it reaches the filter bed

The filters consist of wood, iron, steel, or concrete tanks, containing a bed of carefully graded and selected sand of uniform size, supported by a special screen system To these are connected the necessary influent, effluent, wash water, and sewer-pipes

The rate of filtration may be varied from 1,600 imperial gallons to 3,200 imperial gallons per foot per diem, or from 70,000,000 gallons to 140,000,000 gallons per acre per diem The maintenance of this rate of flow requires a large filtering head, varying from 6 ft. to 14 ft. A relatively small head of water is carried over the sand bed, as it has been found that a negative head gives better results. This relatively high filtering head results in the compacting of the sand bed. On this bed the precipitation and straining out of the coagulated material causes the rapid formation of a gelatinous and sticky film. This film retains the greater part of the bacteria and suspended matter.

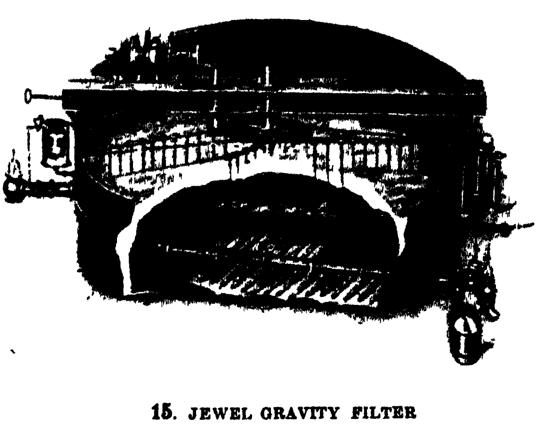
When the filtering film has become too thick and dirty for filtration to be economically continued the sand bed is washed. This is done by reversing the flow of water ; a current, preferably of filtered water, is forced upwards with



13. JEWEL PRESSURE FILTER

considerable velocity through the screen system and sand bed, wholly removing the deposited film and accumulated dirt, and restoring the sand bed throughout its entire depth to a state of purity. All sand grains coming into contact with water containing organic matter will, in course of time, collect an organic coating, particularly if the water passing through them carries with it any oil or greasy matter. The grains then become smooth and slippery, and deteriorate in filtering efficiency. This shiny organic coating surrounding the filtering sand is easily removed in a few hours without removing the sand from the filter tanks.

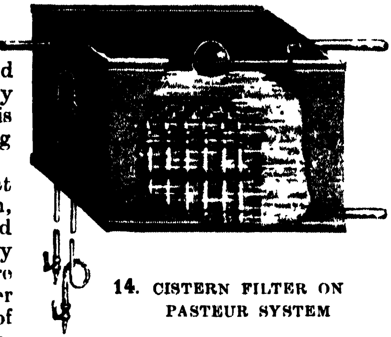
As in slow sand filters, it is most important that the rate of filtration should be perfectly uniform, and that the pressure should be gradually and uniformly increased as the bed becomes dirty and less porous. To secure this, all filters are provided with a patent automatic controller that maintains a perfectly uniform rate of flow under all conditions. They are also provided with loss of head gauges, that show at once the regularity of the increase of the filtering head. Each filter is also fitted with a valve connected to the waste-water main, so that, if desired, the first filtered water can be run to waste. Special sample draw-off cocks are provided, and the operator has at all times control of each individual filter and a knowledge of its condition.



15. JEWEL GRAVITY FILTER

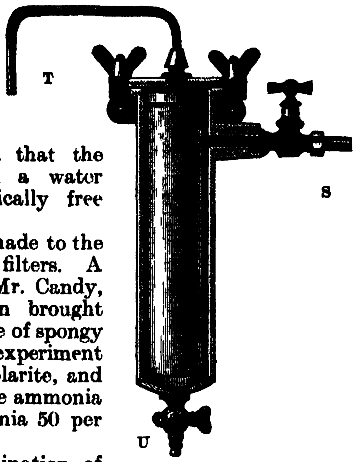
Pressure Filters. For domestic and manufacturing purposes, and in some cases for municipal supplies, the pressure type of filter will be frequently found to be more convenient than the gravity type. It requires no machinery for agitating the sand bed. It occupies less space, and is sometimes more economical, as in many cases it is possible, by using a pressure filter, to avoid double pumping. It also saves the additional pumping of water for washing the filters. Many patterns of pressure filters have been constructed, but the New York pattern, as shown in the illustration [13], has been proved to be the most satisfactory and convenient. The filter bed consists of carefully graded sand, supported by a screen system, as in the gravity type ; but the whole is enclosed in an iron or steel cylinder tested to 100 lb. pressure. The bed is washed by a reversal of the flow, and, as in the gravity pattern, the full volume of wash water can be directed into either the whole or separate sections of the filter bed.

The Jewel system of filtering water was adopted in connection with the Alexandria waterworks, and the completion of the filters was inaugurated by the Khedive in October, 1905. Before the system was introduced a most exhaustive series of experiments was made, and the chief engineer and the sanitary inspector reported to the municipal council in July, 1905, the completion of the entire works. Their report states that in the case of the bacterial efficiency of the new filters, from numerous analyses which have been made, it is especially shown that the removal of the microbes from the raw water by the process of subsidence and filtration has always been very satisfactory. Even during the most difficult periods of filtration, when the efficiency was at its worst—that is to say, during the first half hour after the washing of the filter—it was never below 99 per cent. It takes but five minutes to wash a filter, and yet within fifteen to twenty minutes after the beginning of a new period of work the filter again acquires its normal efficiency. It should be especially noted that the filters have worked under very difficult conditions owing



14. CISTERN FILTER ON PASTEUR SYSTEM

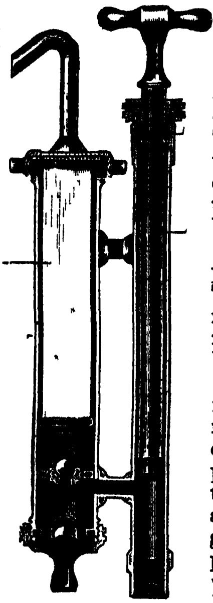
to the presence of numerous algæ in the raw water (season of green water). Notwithstanding this the results of filtration continued to be satisfactory. To cite but one example, the number of bacteria, always entirely harmless in the filtered water, was on July 8th but 22 per cent., while the raw water contained about 8,000 per cent. Upon the whole it is stated that the new process of filtration produced a water perfectly limpid, clear, and practically free from the microbes of the raw water.



16 BERKEFELD DOMESTIC FILTER

Oxidium. Reference has been made to the results obtained by using polarite in filters. A new filtering material employed by Mr. Candy, called "Oxidium," has recently been brought out, having properties similar to those of spongy platinum. It has been the subject of experiment by Dr. Thresh in comparison with polarite, and he states that oxidium reduced the free ammonia 90 per cent., and the organic ammonia 50 per cent, more than polarite.

Domestic Filters. The examination of water that had been passed through the various forms of domestic filters that were much in vogue years ago was confined to chemical analysis only, and the dangers attending the employment of a filter that had become foul with use were not realised. When bacteriological tests enabled the presence of micro-organisms to be detected the whole aspect of the matter became changed. Filters which had previously been used for a long time, until some discoloration of the water, bad odour, or unsatisfactory chemical analysis caused them to be sent back to the makers to be cleaned, were no longer regarded as affording safety. Many distinguished bacteriologists examined domestic filters, and their published opinions showed that the majority of the old types of filters cultivated, rather than destroyed, disease germs.



17. BERKEFELD PUMP FILTER

There are a variety of filters made on the principle discovered by Pasteur and Chamberland of employing particular earths which arrest disease germs. Fig. 14 shows a cistern filter exposed through the broken side of the cistern.

It consists of a galvanised iron frame with one or more rows of filter-tubes, connected by strong elastic collectors, and carried in a galvanised wrought-iron cage. The collectors are connected with a main collector, of which the end projects through the cistern, and is connected to a syphon pipe furnished with cocks for permitting the flow of filtered water and for expelling the air on starting. The quantity delivered varies from 100 gallons to 400 gallons a day, according to the number of rows of tubes. If a single tube only is used, as shown by the illustration of the service filter [16], about 8 gallons a day would be the supply, with a water pressure of 30 lb. per sq. in.

The Berkefeld Filter. The Berkefeld Filter is an excellent one, effecting the destruction of disease germs. The filtering medium is in the form of porous hollow cylinders of various sizes, made of what is described as kieselguhr, an infusorial or silicious earth, consisting of the fossilised skeletons of diatoms. The makers prefer the filter to be used with water under pressure. Fig. 16 shows a filter of the H type, for ordinary house use. S is the inlet tap, T is the filtered water outlet, and U is the flushing tap

A combination of the Berkefeld filter and pump is shown in 17, called the N type. This has been largely used by travellers, military men, and others who have to obtain their water from sources which, if used unfiltered, would be dangerous to health.

The filtering cylinders require periodical cleaning and sterilising in order to restore their original filtering capacity. As all the impurities are collected on the outside of the cylinder, gradually producing a slimy coating, all that is required is to remove the cylinder carefully from the casing, and while holding it under a tap to brush it gently with a piece of loofah, supplied for this purpose with each filter, or with a clean brush, which must not be too hard. Great care must be taken that no soap or other greasy matter comes into contact with the filtering cylinders. Complete sterilisation can be obtained by placing the cylinder, after been cleansed by brushing, in a clean vessel with cold or tepid water, and then boiling for an hour. After having been boiled the cylinder must be allowed to cool again.

FRANCE IN THE MIDDLE AGES

An Important Epoch in the History of France. Louis IX. and England. The Famous Reign of Francis I. St. Bartholomew's Day

By JUSTIN McCARTHY

MEANTIME, continental Europe was dividing and subdividing, distributing and redistributing itself into distinct states, which were at this time settling down into something like the lines of demarcation they have since maintained. Many of those lines were afterwards broken into and confused, and realms which were then formed afterwards became blended by circumstances with realms of superior strength. But even at the time when the Wars of the Roses came to an end the peoples of the European continent were beginning to form themselves into those states, monarchical or republican—for the most part monarchical—in which they are represented in the maps of the present time.

The principle of nationality counted for little in the formation of these early kingdoms and republics. Every rising state in Europe, and in many other parts of the world, went in for a policy of conquest and annexation, and did not trouble to ascertain whether the newly-annexed region could be made a contented and adhering part of the power that had conquered it. Even in Europe many different nationalities were now made part of one state, and, again, part of another; continued for generations and even for centuries to be parts of the dominions of each successive conqueror; then at length broke away, and, by the force of victorious resistance, established themselves as independent nations.

The House of Capet. With the reign of Hugh Capet began the monarchy of France as it lasted until the French Revolution. Louis le Gros, who reigned from 1108 to 1137, did much to improve the condition of the country; he regulated the feudal system, abolished serfdom on his own estates, and founded the free burgher class. Philipe Auguste, who came to the throne in 1180, took an active part in the Crusades. There were many wars in his reign; he recovered Normandy, Maine, Touraine, and Poitou from King John of England, and defeated the Germans in the famous battle of Bouvines. He made many improvements in the administration of the laws, created a Chamber of Peers (six ecclesiastical and six secular), and from his reign date the University of Paris, the Louvre, and other famous institutions. Many of the improvements in civil government initiated by him were continued by his son Louis VIII., and in 1226 his grandson Louis IX. succeeded.

Louis IX., known as St. Louis, was born on April 25th, 1215. He became a powerful sovereign, and by his victories compelled Henry III. of England to recognise French sovereignty in some parts of France which had, up to that time, been under foreign rule. He suffered from a very dangerous illness, and during the malady made a vow that in the event of his restoration to health he would go out to the East as a Crusader.

Louis IX. and His Reign. He recovered, and appointing his mother, Blanche of Castile, regent of the kingdom in his absence, led an army of 40,000 men to Egypt. There at first he met with success and captured Damietta, but it was not long before he suffered a defeat. He was himself taken prisoner, and only released upon paying a large ransom. He did not, however, give up his crusading task, but went with the remains of his army to Acre in Palestine, and remained in that region until the death of his mother compelled him to return to France. There he showed himself an able and enlightened ruler, and by the "Pragmatic Sanction" determined the relations of the French Church with the Papal authority.

The Pragmatic Sanction was the title given to the ordinances of the Kings of France which arranged the settlement of Church and State affairs. Louis authorised the founding of the Sorbonne, a society of ecclesiastics at Paris formed by Robert de Sorbonne, devoted to teaching the poor and the study of theology. He instituted throughout the French provinces Royal Courts of Justice, or Parliaments, for the administration of the laws, and was the author of an entirely new system designed to introduce equal legislation for all classes. In 1270 he started on a fresh crusade in the East which cost him his life; he died in the August of that year of the plague at Tunis. In 1297 Louis was canonised by Pope Boniface VIII. He was unquestionably a man of noble purpose, of great ability, with views of equitable government much in advance of his age, and his reign marks an important epoch in the history of France.

The States General Instituted. His son, Philip III., who succeeded him in 1270, was the first to issue titles of nobility conferred by letters patent. He also restored Valois and other parts of France to the French Crown. Philip IV., called Le Bel, who came to the throne in 1285, tried to secure support for himself against the prelates and the territorial nobility by giving prominence to the burgher section of the community. Under him the "States General" was instituted, a representative assembly in which the farming and trading classes held a place and became the "Tiers Etat" of the nation, the nobles and the clergy representing the other two classes. In his reign the transfer of the Papal Chair to Avignon brought the Popes under the influence of the French Court for many years. By his three sons and successors—Louis X., Philip V., and Charles IV.—the rule of the French sovereigns was extended and also much strengthened. Philip VI., the first king of the House of Valois, succeeded in 1328 by right of the Salic Law, which forbade women to inherit the crown in France.

In his reign and those of his successors, John and Charles V., Le Sage, France was much engaged in wars with England, which were productive to France of nothing but disorder, enormous taxation, and wide-spreading arbitrary conscription. The final defeat by the English at the Battle of Agincourt, in 1415, occurred during the reign of Charles VI., who came to the throne in 1380. This king became insane and was succeeded by his son Charles VII., Le Victorieux, the Dauphin who was crowned at Rheims by Joan of Arc in 1422. The only remarkable event of his reign, apart from this, was that he obtained from the States General a regular allotment of taxes for the maintenance of a paid army to keep in check the mercenaries and marauders who pillaged the country.

The Founder of Three Universities. Louis XI., the eldest son of Charles VII., who had made efforts to obtain the throne during the lifetime of his father and had then escaped for a time into Burgundy, succeeded in 1461. His reign was full of struggles with Charles the Bold, Duke of Burgundy, and Louis finally made a treaty by means of which some portions of Burgundy were given over to France. During his reign there were wars between France and Austria, and Louis also recovered Maine, Anjou, and Provence. Louis XI. had some good qualities as a man, but few indeed as a sovereign. He loved art, letters, and science, and was the founder of three universities. He increased the number and the power of the Parliaments, not from any enlightened appreciation of the representative principle, but to secure for himself a better defence against some of his feudal vassals. He passed his later years in abject misery caused by his morbid terror of death, and he died at last on August 30th, 1483.

The direct succession of the House of Valois came to an end with the reign of his successor, Charles VIII., who by his marriage with Anne of Brittany secured that powerful state to the Crown of France.

Louis XII., called Le Père du Peuple, was the only representative of the Valois-Orleans family. His reign on the whole tended to strengthen the position of the Crown in France, while it also helped to promote the improvement in the condition of the people.

Francis I. Louis was succeeded in 1515 by Francis I., of the Valois-Angoulême branch, who, as well as Charles VIII., wasted the resources of the state in vain attempts to establish a claim to Lombardy. He had four wars with Charles V. of Spain for the possession of Burgundy and Italy. He was made prisoner at the Battle of Pavia and taken to Madrid. In 1544 he made good his claim to Burgundy, but had to renounce Italy. His reign is famous for the beginning of the Renaissance and of the Protestant Reformation. He strengthened the power of the monarchy and subordinated the power of the clergy to that of the Crown. An ally of the Protestant Princes of Germany and of Henry VIII. of England, he was himself a Catholic.

He was succeeded in 1547 by Henry II., who regained Calais for France. In the reign of Francis II.—1559 to 1560—the House of Guise, a great Catholic family, became the most powerful in the State.

St. Bartholomew's Day. The history of France during the reigns of Charles IX. and Henry III. was little more than a continuation of the struggles between the Catholics and the Protestants. These amounted to civil wars, fierce and furious, and into them were imported the services of Spaniards, sent by the Duke of Alva, of Catholic Germans and Italian troops from Rome. August 24th, 1572, will always be remembered as the date of the Massacre of Protestants on St. Bartholomew's Day, which was generally believed to have been instigated, if not actually ordered, by Charles IX. Many thousands of Protestants were put to death. The King received a letter from Philip II. of Spain assuring him that "in furthering thus the affairs of God, you are furthering your own still more." The massacre had not, however, any of the consequences that Philip anticipated. The Calvinist party, then strong in France, was made stronger by persecution, and at once took up arms. A new civil war began, and was only brought to an end by the settlement at La Rochelle.

The Holy League. Charles IX. was succeeded by his brother, Henry III., who was born on September 19th, 1551. He contributed to the efforts to suppress the Huguenots by military force, and he even took a share in the Massacre of St. Bartholomew. Henry was, both in public and private life, a man of fickle and uncertain temper. He was not even a genuine fanatic, for he was ready to support the Huguenots, or to persecute them, according as advantage to himself could come from either course. His character was weak and dissolute, and he was, like his brother Charles IX., much under the influence of his mother, Catherine de Medici. The Duke of Guise, one of the most powerful nobles of that time, formed a league, known as the Holy League, to maintain the supremacy of the Catholics in France, and also to support the claims of the Guise family to the succession to the throne. Guise, while besieging Orleans, was assassinated by a Huguenot fanatic. This aroused the Catholic party to fury against the Huguenots, whom they regarded as instigators, or at least abettors, of the crime. Henry III. became an ally of Henry of Navarre, and they joined in leading an army on Paris.

Henry III., the last of the House of Valois, was stabbed on August 1st, 1589, by Jacques Clement, a Dominican friar, and he died the following day, after having designated Henry of Navarre as his successor. Henry of Navarre thus became King of France and of Navarre.

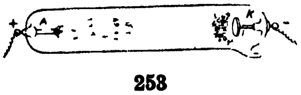
Group 10
ELECTRICITY
29

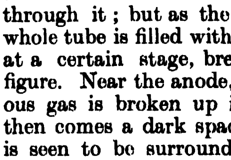
Continued from page 4023

By Professor SILVANUS P. THOMPSON

Electrons in Gaseous Discharges. In the last article some elementary facts were given in substantiation of the modern view that electricity itself consists of definite atomic quantities called *electrons*. The greater part of modern knowledge of electrons has, however, been acquired by the study of electric discharges in gases, particularly in vacuum tubes from which the air has been more or less pumped out. Suppose a glass tube [253] to have a pair of platinum electrodes sealed into its ends, and to be partially exhausted by means of an air pump. Let an electric discharge be sent through it by means of an influence machine or an induction coil. At first thin sparks flash through it; but as the exhaustion proceeds the whole tube is filled with a luminous cloud which, at a certain stage, breaks up, as shown in the figure. Near the anode, A, the column of luminous gas is broken up into flickering striations, then comes a dark space, while the kathode, K, is seen to be surrounded by another luminous cloud, chiefly in front of its surface, but separated from it by a second dark space or non-luminous layer. If a mercurial air pump is used so as to produce a very high vacuum, this effect is further modified as follows. The positive cloud retreats towards the anode and disappears. The dark layer around the kathode widens and drives the surrounding cloud away. With still higher exhaustion the dark space expands until it reaches the glass walls of the tube, which then shine with a yellow-green phosphorescent light. It was found by Crookes that this dark beam consists of something which he called *radiant matter*, shot off in straight lines from the surface of the kathode; and that if this dark beam of radiant matter is intercepted by any obstacle, a shadow of that obstacle will be cast on the glass wall of the tube at the opposite end. Fig. 254 shows a Crookes tube, in which a metal cross, J, has been erected. The anode, A, may be set anywhere in the tube. From the kathode, K, are shot out these *kathode rays*, or flights of radiant matter.

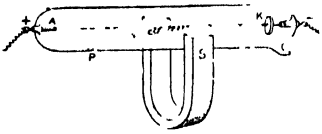


253



254

Kathode Rays. We now know that these rays consist of negatively-electrified corpuscles, or electrons, driven with an immense velocity. They bombard the walls of the tube and make it shine. If they are concentrated (by making the kathode surface concave) on a bit of metal, they heat it. They can drive around the vanes of a little mill if such be placed in the tube. Kathode rays can be acted upon by a magnet. If, as in 255, a narrow stream of radiant matter from a kathode is allowed to pass through a hole in a diaphragm, and a magnet is placed near the tube, the stream is observed to be deflected in a curve by the magnetic field, and causes a bright phosphorescent patch to appear when it touches the glass at P. The direction of the deflection shows the stream to be negatively electrified; for negative corpuscles flying from K towards P are electrically the equivalent of a (positive) current flowing from P towards K. According to the researches of Professor J. J. Thomson and others these flying negative electrons move with a velocity somewhat less than that of light, and act as though they were bodies having each a mass about $\frac{1}{1000}$ part as great as that of the atom of hydrogen. They cannot possibly be atoms or ions, because their energy is far smaller than that of atoms would be if flying at the same enormous speed. Moreover, it makes no difference to them what kind of gas was in the tube to begin with, or what metal is used as kathode; the kathode rays are independent of the kind of matter present. The kathode rays possess peculiar penetrating powers. Though they are stopped by a thin wall of glass, they can pass through a thin sheet of aluminium which is quite opaque to light. There are several other kinds of rays produced in vacuum tubes. One of these, known as diakathode rays or canal rays, consists of positive electrons moving much more slowly, and having each a mass about the same as that of a hydrogen atom. They are slightly deflected by a magnet, and in the opposite direction from the kathode rays. They produce a different kind of phosphorescence, and can cast shadows.



255

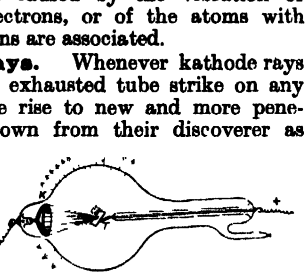
Gaseous Conductivity. All gases in their ordinary state are non-conductors. To send any electricity at all through ordinary air, even across a gap of $\frac{1}{1000}$ in., requires an electromotive force of several hundred volts, and then, when a spark takes place, this is a disruptive discharge through the medium, not a conduction by it. The air does not conduct, so the discharge pierces a hole through it, just as it might through a layer of oil or a thin sheet of glass. But it was found by Schuster that even a low electromotive force, such as 1 or 2 volts, will send a current through air, if at some other part of the containing vessel, or even in another vessel opening into the first, spark-discharges are being made. The explanation of this is that when a series of spark-discharges are made through air or other gas, some of the molecules of the gas become *ionised*, so that a number of free ions are present moving about amongst the neutral molecules; and as these free ions carry charges they can serve as carriers of electricity from the anode to the kathode, by a sort of electrolysis. Gases can be ionised in several ways—by the effect of disruptive discharges, as we have seen; by contact with red-hot metal surfaces; by being shone upon with ultra-violet light; by molecular impact between the gas molecules; and, as we shall see, by the influence of Röntgen rays and of radium.

Electrons and Molecules. One conception of electrons is that they are minute electric corpuscles which dance attendance on atoms, as though they were satellites attendant upon some planet. If an electron (negative) is separated from an atom of a gas, that atom becomes a positive ion, and it is probable that in ordinary gases, when ionised, the electron joins itself to a neutral atom, thus transforming it into a negative ion. In an ionised gas any electrified body loses its charge, for it attracts to itself the oppositely electrified ions, and they neutralise its charge. A neutral molecule will consist of a positive ion and a negative ion in conjunction.

Electrons in Movement. The conclusion is forced upon us by the observed facts that electrons in movement, whether flying free or carrying atoms of matter with them, as in electrolysis, are an electric current. Whenever they are moving along in any direction they set up a magnetic field around them, and the presence of this surrounding magnetic field, which is the essential thing in the phenomenon of the self-induction of a current, acts as an inertia. This has led Lodge and others to speculate whether the ordinary inertia of matter is not really due to the self-inductive effect of the electrons which accompany the atoms. The electrons in the kathode rays travel with a speed a hundred thousand times greater than the speed of a rifle-bullet. Their inertia is proved by the mechanical impact they exert upon the vanes of a mill as mentioned above.

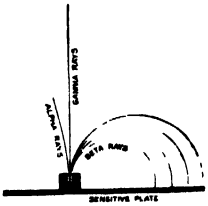
So long as the movement of the electrons is uniform and in a straight line, their inertia and their surrounding magnetic effect is constant; but if their speed changes, as when they are suddenly stopped or suddenly started, a new effect appears. During the period of change of speed the electron sets up waves in the surrounding ether, which travel off from the source with the speed of light. The more sudden the starting or stopping, the more violent will be the etheric pulse. If the electron vibrates, or oscillates, or revolves rapidly around an orbit, it will send off regular trains of minute waves, and these constitute the ordinary waves of light. Radiation, in fact, is caused by the vibration or revolution of electrons, or of the atoms with which the electrons are associated.

Röntgen Rays. Whenever kathode rays in a very highly exhausted tube strike on any surface they give rise to new and more penetrating rays, known from their discoverer as Röntgen rays, or X-rays. A special form of Röntgen-ray tube is depicted in 256. Here a cup-shaped kathode, K, concentrates the radiant matter that is shot off from it upon a little platinum plate, T, which serves as a target or *antikathode*. From this target are emitted the Röntgen rays, which are observed by the light they excite upon a fluorescent screen, or by their action on a photographic plate. It is these rays by which the bones of the hand or in the living body can be seen and photographed. They are, like the waves of light, movements in the ether; but sudden, irregular pulses, not periodic waves. They travel with the same speed as light. They render electrically conductive the air through which they pass, by ionising it. If they fall on a charged electroscope it is discharged; and the rate at which the instrument loses its charge can be used to measure the intensity of the rays.

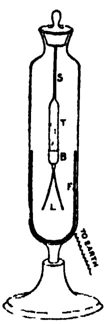


256

Radium and its Rays. The discovery of the Röntgen rays stirred up other investigations, and led to the discovery of the emission by the metal uranium and its compounds of some highly penetrative rays, known as *Becquerel rays*, from the discovery having been first published by Becquerel, though independently discovered by the writer. It was then found by Madame Curie that one of the ores of uranium, called pitchblende, was more powerful than uranium itself. This led M. and Mme. Curie to discover in uranium residues the wonderful and excessively rare metal *radium*. By patient and laborious chemical analysis they succeeded in separating a nearly pure salt of radium. But each ton of the mineral furnishes only a few grains of radium, and each grain of radium costs about £60, which is at the rate of £26,000 per ounce. The rays emitted by uranium and by radium have the property of causing a charged electroscope to discharge itself. If a piece of either of these substances is placed near an electroscope, like 250 [page 4022], the gold leaves fall together, the time taken for the discharge depending on the activity of the specimen. Samples of radium have been produced which are a million times more powerful than an equal piece of uranium. Radium has been found to emit three different kinds of rays, known as the alpha, beta, and gamma rays. The *alpha* rays are believed to be identical with the diakathode or canal rays, and consist of atoms positively charged. The *beta* rays are practically the same as the kathode rays, and consist of flights of negative electrons. The *gamma* rays are practically identical with Röntgen rays. They are extremely penetrating and will pass through a steel plate an inch thick. If a small piece of radium is put into a hole drilled in a block of lead, placed upon a sensitive photographic plate, and subjected to a magnetic field, the *beta* rays are deflected in circular paths by the magnetic influence, and act on the photographic plate at one side, while the *alpha* rays are slightly deflected in the opposite direction. The *gamma* rays are not deflected by the action of the magnet. This is illustrated in **257**, where the direction of the magnetic field is perpendicular to the plane of the paper. The *alpha* rays have very little penetrative power, and are stopped by even a thin sheet of paper. If a fluorescent screen made of sulphide of zinc is held close to a minute speck of radium, it is noticed that a luminous spot appears, due to the action of the *alpha* particles. Examining this spot in a microscope, Crookes observed it to present the appearance of a shower of sparks. Strutt has devised a most ingenious perpetual clock [**258**], consisting of a gold leaf electroscope, L, suspended on an insulating support, S, with a milligram of radium enclosed in the tube, T, ending in a brass box, B. The *beta* rays emitted from the radium carry away negative electricity, leaving the electroscope positively charged. So its gold leaves gradually diverge until one of them touches against a plate of foil, F, connected to the earth. This contact discharges the electroscope, and the leaves drop down; but they slowly open again until they again discharge; and so on, indefinitely, at perfectly regular intervals of time. This "clock" will go on until the radium loses its activity—a process probably requiring thousands of years.



257



258

Energy of Radium. Beside these rays, radium and its compounds—for example, the solution of chloride of radium—slowly give off a heavy vapour, called the *emanation*, which forms deposits on the surrounding surfaces and makes them also radio-active. More surprising still, radium is found to be always slightly warmer than its surroundings, and is therefore continually giving out energy. To account for this apparently perpetual supply of energy, Rutherford has suggested that the atoms of radium are themselves slowly disintegrating, this disintegration being accompanied by an evolution of their intrinsic energy. In fact, the emanation slowly changes and evolves the gas helium. Radium appears to undergo a series of transformations, some rapid, some slow. The atom of radium, when it parts with an alpha particle, becomes an atom of the emanation; the atom of emanation, when it disintegrates, parts with another alpha particle, and becomes a solid called "radium A." "Radium A" rapidly gives off another alpha particle, and becomes "radium B." "Radium B" is transformed into "radium C," without any emission; but "radium C" gives off not only alpha particles, but also beta and gamma rays, and changes to "radium D." This is a very stable product, but it is slowly transformed without emission into "radium E," which gives off beta and gamma rays only, and quickly changes into "radium F." The final result of all these transformations is yet uncertain, but apparently the original radium itself changes so slowly that in 1,300 years it would be only half transformed. The rapidity of these changes is examined principally by aid of the electroscope [**250**, page **4022**]. It is charged, and the radio-active substance to be examined is brought near it, the rate of the discharge so produced being noted.

Besides uranium and radium, another heavy metal, thorium, possesses radio-active properties and emits rays.

According to Ramsay, when an atom of a metal loses an electron it is transformed into some other element, but may go through a series of transformations. No atom can lose or gain an electron without experiencing a change in its properties.

Matter and Electricity. It is then seen that electricity, though usually associated with the molecules and atoms of matter, can—at least, in the negative state—be recognised as existing in minute quantities or corpuscles having apparently a mass 1,000 times smaller than the atoms of matter. Moreover, it has been shown that when incandescent bodies are emitting light, that which sets up the light waves in the ether is the movements of the negative electrons in vibration. What the precise relation of the electron to the ether itself may be is a matter for speculation. A further speculation is that all mass — that is, all matter — may consist of systems of electrons. Professor J. J. Thomson has suggested that the atoms of the ordinary elements as known to the chemist may consist of systems of negative corpuscles grouped about a central mass of positive electricity, some such groupings being stable, others unstable. Any unstable groups might readily emit some of their corpuscles and change to other more stable forms of lower atomic weight. This might account for the singular transformations of radium and the electric phenomena accompanying the emanations and rays which it emits. We may be yet very far from having arrived at any final knowledge of these relations; but this is at least clear, that a great deal more is now known about the nature of electricity itself than was known ten years ago.

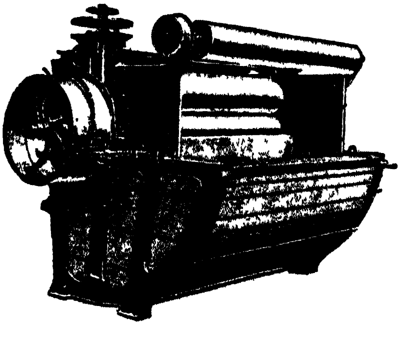
WOOL FINISHING

Scouring, Burling, Darning, Felting, Teasling, Cropping, Brushing and Steaming. The Machines and their Operations

By W. S. MURPHY

SOME classes of cloth are finished in the factory; others are handed over to outside specialists, such as bleachers, dyers, and calenderers. We cannot lay down any invariable rule, however, because practice varies indefinitely. It can only be said with certainty that the separate finishing operations may be studied to best advantage under specialised conditions. We purpose, therefore, considering the textile finishing operations in two divisions: first, as a factory process, directly succeeding the weaving; secondly, as a special process, carried on in establishments wholly separate from the spinning and weaving factories. Even this division may involve us in repetition; but theoretic consistency is not esteemed a virtue in practical industry.



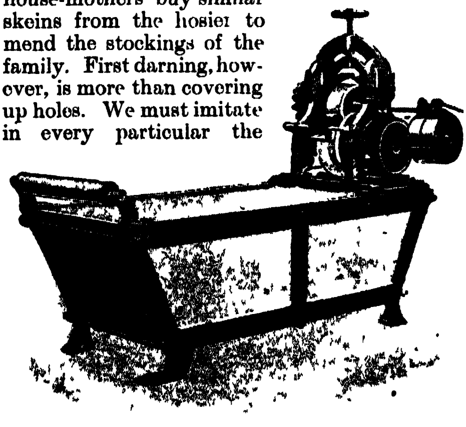
188. SCOURING MACHINE

Course of Operations. Our aim in this finishing process is to produce a cloth of solid body, unshrinkable under water and changes of temperature, with a fine nap lying evenly on the surface, which does not spot or allow dust to penetrate the fibres. We want, in short, a cloth which wears well, and keeps its fresh appearance after a considerable amount of use. The means adopted to accomplish these objects vary a good deal; but the following operations are generally employed: *Braying* or *scouring*, *burling*, *first darning*, *fulling*, *milling*, *second darning*, *scouring*, *stentering*, *teasling*, *cropping*, *brushing*, *steaming*, *darning*, *damping*, and *pressing*. Some manufacturers repeat these operations, or some of them, several times; others go straight through, relying on the efficacy of the one operation.

Braying or Scouring. When the cloth is taken off the loom it is full of size and oil. Having served the purposes for which they were employed, these substances must be got rid of by the operation we name *braying* or *scouring*. Any machine which will hold the detergent liquid, and carry the cloth through it, serves our purpose. A solution of 2 lb. of soda to 1 lb. of soap forms a good scouring liquid. After being run through the scouring machine [188] for 20 minutes or so, the cloth should be rinsed in water and cleared of soap. On the end of the rinsing machine a pair of squeezing rollers take away the superfluous water, and then the cloths are laid in the centrifugal drying machines, or *whizzers*, as they are called. These and the other finishing machines illustrated are made by Messrs. Wm. Whiteley & Sons, Ltd., Lockwood.

Burling. Scouring should have cleared away the size and grease and left the cloth bare. Our object is to detect and remedy any defects which may be in the cloth, such as knots, scobs, flying threads, flecks, and breaks in weft or warp. Over the roller hung in a good light the cloth is run, while we watch its surface for faults. The light penetrates the cloth and shows up every flaw; here appears the glittering point of a burr, there the soft cloud of a scob, and there the flying end of a loose thread. As each flaw comes into sight it must be picked out, or marked for the first darners. The work of burling requires quick eyes, a good knowledge of cloth, and deft hands.

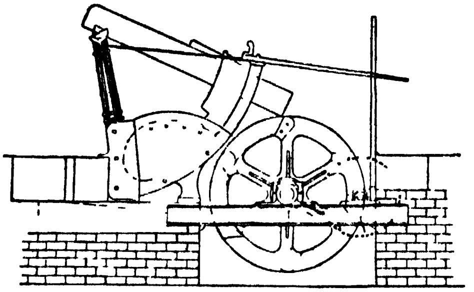
First Darning. Sometimes very serious defects occur in the cloth. Warp and weft may have broken at one point, or the tied knot of the mended thread may have slipped, leaving a hole. As each fault of that kind is detected in the burling, it is marked, and the cloth is handed on to the darner. On the darning table we find several rows of skeins of woollen or worsted thread wound on cards. Curiously enough, this device of the factory has become domestic, and house-mothers buy similar skeins from the hosier to mend the stockings of the family. First darning, however, is more than covering up holes. We must imitate in every particular the



189. FULLING TROUGH

weaving of the warp and weft so as to make the darn imperceptible.

Felting Cloth. Few operations in the woollen trade have been the occasion of so much speculation and controversy as this one of felting. Everyone agrees that woollen cloth has a felting property, greater in some wools than in others ; but there are wide differences of opinion as to what constitutes the felting property. Yet the facts are plain and simple. The woollen thread, as we have noted often, is loose and open ; wetted wool becomes flaccid and tends to cling. Wool fibres have serrated edges. Suppose the wool fibres have been soaked, and they are clinging together for mutual support, by bringing pressure to bear on them we can confirm the cohesion. But the fibres may tend to return to their former relations when dry. Some other factor must be brought in, and that factor is the serrated character of the wool. The scales of the outer skin of the fibres lie over each other like little plates of armour. When the wool is dry, the scales stand out, and under water tend to lie flat. Moreover, the scales are elastic, and spread out under a sharp blow or sudden pressure. Our factors are all gathered, and we shall try how they work out the theory. Fill up the cloth with a greasy substance easily discharged and of watery consistency; put the fabric under pressure at once elastic and firm. The fibres cling ; the pressure brings the loose thread close ; the serrations grip into and hold on to each other with a thousand little teeth—the cloth is felted.

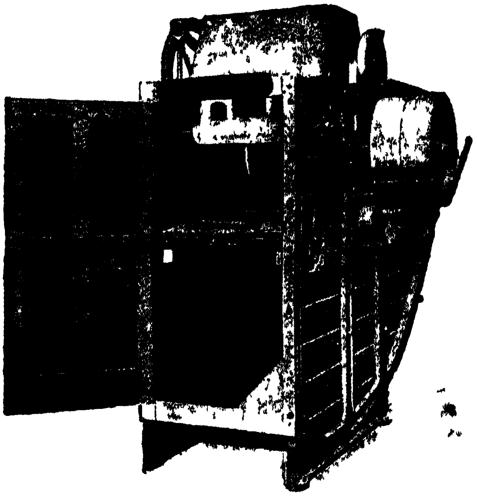


190 MILLING STOCKS

Fulling. Soft soap is the greasy substance used for fulling out the cloth for the felting machine. The soap greases the fibres, making them slip easily over one another, acts as a kind of protecting pad to the threads under pressure, or the blows of the milling stocks, and is easily discharged. The web of cloth is joined in an endless band, and stretched on the rollers over the fulling trough [189], where it is filled with the soft soap. Being so easily discharged, the soap requires to be renewed several times during the felting process.

Milling Stocks. The oldest form of felting machine still in use is the milling stocks. A pair of wooden slabs, with large heads, are geared on a frame above a sloping, narrow trough [190]. The heads of the stocks rest on the bottom of the trough, and the function of the gearing is to pull down and let go the end of each stock alternately. By this action the heads of the stocks fall by their own weight on the sloping bottom. When the cloth has been filled with soap it is laid on the fore-end of the trough, and as the stocks beat alternately upon it, it is slowly drawn to the other end. Here we have all the requisites of felting—the soap, the water, and the elastic beating of the fibres into close union.

Milling Machines. The stocks have failed to satisfy the needs of woollen manufacturers in a variety of ways. Probably the most serious objection to them is that they are slow in action New forms of milling machines have been placed at our disposal, very similar in structure though differing in minor details Examining one we obtain an idea of the whole class. On the fore end of the machine [191] is a slotted guide board, with stop motion ; above it is the guide roller, beyond which extends the contracting tube ; the felting rollers are geared behind, forming the end of the machine. Two kinds of felting rollers may be used in the same machine if desired. Most commonly the under roller is flanged at the sides, while the upper roller is plain. But, to harden the grip on the cloth, one roller is sometimes made convex and the other concave. When working, the soaped web is laid on the guide board and led up over the guide roller, through the contracting tube, and between the felting rollers, which draw and felt the cloth, drawing the fibres closer and closer. On this machine the soaping must be frequently renewed and carefully watched so as to prevent friction.



191. MILLING MACHINE

Shrinkage. The degree of felting depends a good deal on the character of the cloth. The amount of shrinkage generally aimed at is from 5 in. to 7 in. on the width of narrow cloth, and from 10 in. to 12 in. on broad cloths. Fine twills and fancy woollens are seldom more than half milled. When a heavy cloth comes out of the felting machine neither warp nor weft should show a single open thread.

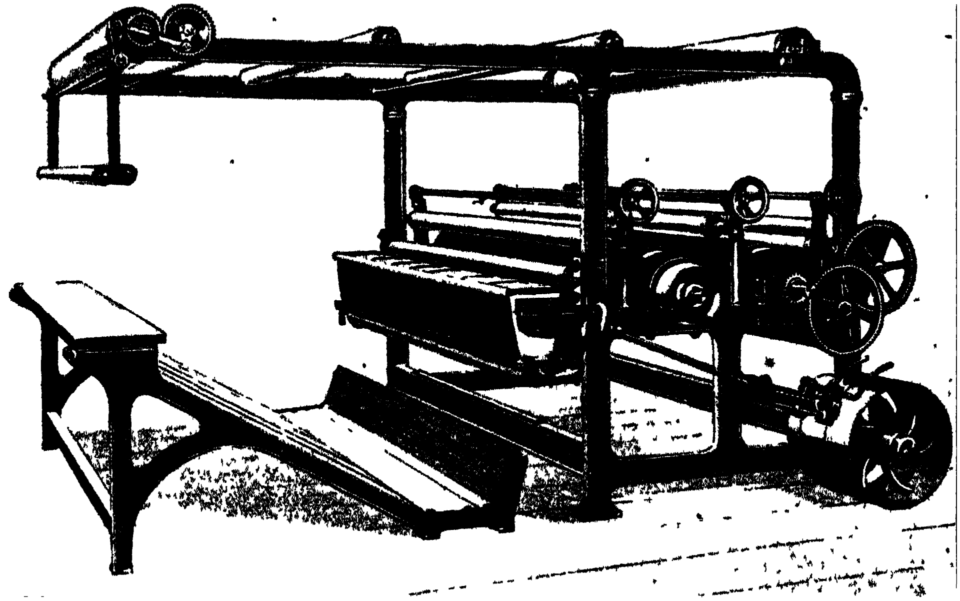
Milling Felt Cloths and Carpets. Felt cloths and felted carpets of all kinds require to be severely milled. Milling is an indispensable part of the manufacturing process of felt, not a mere finishing operation. When the felts come from the sulphurising-room, they are rough, harsh, and dry. On the fulling rollers the pieces are literally filled with soap, to endow them with the needed elasticity and to soften the fibres. As a rule, felts are milled on the stocks, because the heavy mallets work slowly over every fibre of the fabric. It is absolutely imperative that the milling of fine felts should be repeated over and over again till not a loose hair is visible. Fine felt should be indistinguishable, in outward appearance, from the finest superfine cloth. We have additional means of putting on a good finish, which shall be noted in time, but nothing can compensate for weak milling on the stocks.

Scouring and Stentering. At this point the departures in practice are so numerous as to call for notice. We may combine scouring with milling, and many combined milling and scouring machines are in use. Again, some cloths are sent direct from the scouring to a drying and stentering, or *tentering*, machine, while others require more elaborate and careful treatment. One very common practice is to scour, half-dry, and then *cuttle*, or *age*. To cuttle, is to fold the cloth up in a damp condition, and let it lie for a few days. In any case we come to the stentering.

This machine is used in many departments of the textile industry, and is worth detailed attention. The main object of all stentering machines, of whatever model, is to stretch the fabric to its utmost breadth and width, and to confirm its form. The main structure of the stentering machine is two parallel lines of framing, fitted with hooks or clips to grip the sides of the cloth. When the cloth is introduced, the ends of the framing are so near to each other as to allow the cloth to be easily clipped in. But the mechanism is designed to draw the frames apart whenever the machine is started. While the cloth is being drawn in on the long frame, it is being stretched to its utmost width and length, and the relation of every thread kept true to every other.

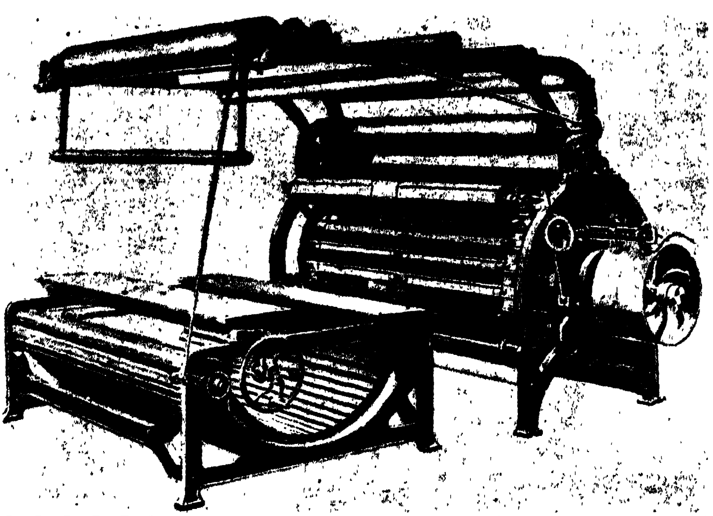
192. TEASLE

Teasling, or Nap-raising The cloth yet lacks that smoothness of texture which is characteristic of a well-finished cloth. Viewed through a magnifying glass, it presents the appearance of a rain-swathed and unshorn meadow. It must be shorn level; but if that were attempted without due preparation the result would be very unsatisfactory. To make sure that all the inequalities shall be removed, it is necessary to raise them all up. This operation



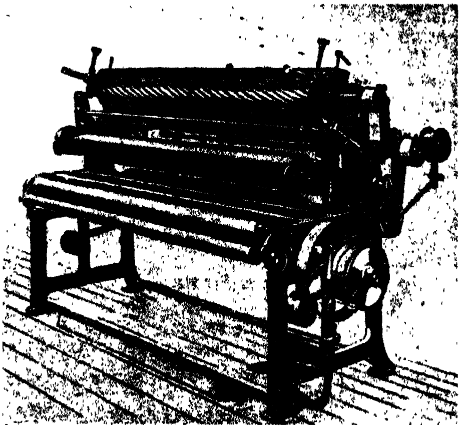
193. BRUSHING AND STEAMING MACHINE

is accomplished by the aid of a cone-shaped burr, spiked like the head of a thistle [**192**]. The plant on which the burrs, or teasles, are grown, named *Dipsacus Fullorum*, is cultivated in France and England solely for the woollen industry. Yorkshire teasles are highly esteemed. Looking into the cones, we see that the spines are sharply hooked, and pointing downwards from the top. Smooth and elastic, the spines are evenly set, forming an exquisitely proportioned teaser which we have vainly sought to supersede by mechanical arts. The teasles are fastened in horizontal rows, two deep, on the frames of the gig cylinder. The raising gig is a simple machine [**195**]. The teasle frames are mounted on a wide cylinder composed of staves fixed on the spokes of a driving shaft. Close to the cylinder hangs the cloth beam, and extending over like a canopy is the frame which, in conjunction with a driven scray in front, holds the web taut, and sends it round upon the gig cylinder. The cloth frame and beam run in the direction opposite from the motion of the gig cylinder, thus working the surface of the cloth against the teasles.

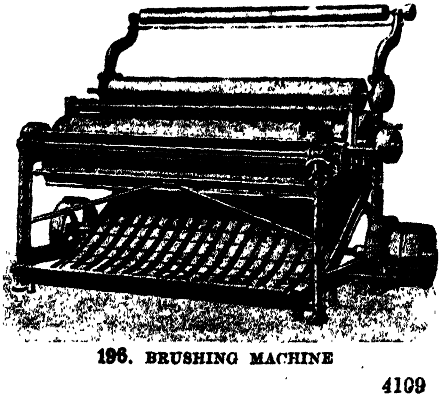


195. RAISING GIG

Cropping. Looking along the surface of the raised cloth, we see the fibres standing up irregularly, some long and floating, others stiff and short, and all mingled with fluff. To free the fibres and make them stand clear we employ what are called setting-up brushes. This may be done either on a separate machine [**196**], or by brushes on the cropping machine [**194**]. For the latter, which is the most up-to-date method, good machines, resembling in framework the teasling gig, have been devised. The setting-up brushes occupy the position of the teasling cylinder, and beyond these is the spiral cutting roller. Knife-blades form spirals round this roller, which revolves on a cutting bed. Some of the simpler machines have ledger blades for setting the nap against the cutter; but the best and newest machines are different. Makers of cropping machines undertake to supply any form of rest or bed, from the fixed solid to the elastic rubber rest [**197**]. Hard, heavy cloths can best be cut on the solid bed or ledger blades; but the greater variety of cloths require an adjustment more delicate. To obtain a smooth surface, the cloth may be passed twice, thrice, or oftener, through the machine.

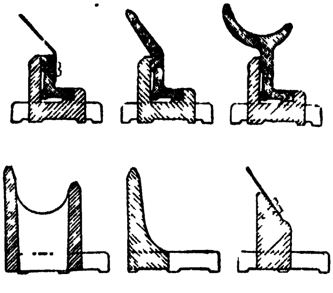


Brushing and Steaming. This is the beginning of another stage in the finishing process. The fabric is smooth, but two special qualities are yet wanted. The surface should be lustrous and resist the spotting of rain. In general structure the brushing and steaming machine [**193**]



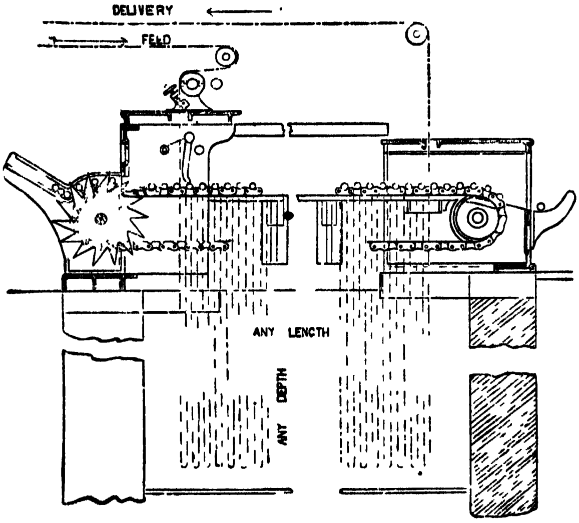
196. BRUSHING MACHINE

closely resembles the teasling gig. The steam-box is placed in front of the main body of the machine, and the brushing rollers revolve behind it. A scray before, and a canopied frame, with rollers, above, carry the cloth round, bringing it over the steaming-box and through the brushing rollers. When it emerges from this machine the cloth has a superficial finish, which is to be deepened and confirmed.



197. CROPPING MACHINE CUTTING BEDS

Repeated Operations. After brushing and steaming, the cloth is handed on to the burlers, who make a second inspection and take away the small knots and loose threads recent operations have brought to light. Next, the fine darners repair any little holes which may have shown themselves. Then the cloth is pressed in one or other of the many kinds of pressing appliances at the disposal of the trade. In former days, the cloths were folded over thin and glossy sheets of pasteboard, a board between each fold, and laid in the press, which was screwed down by strength of arm; but that fashion has almost gone, and now the pressing is done on a variety of machines, ranging from the simple hydraulic to the complex rotary pressing machine. A second steaming follows. The object of this is to impart lustre to the fabric, and one very good method is to wind the cloth round a perforated roller, or tube, one end of the tube being sealed, while the other is threaded for a screw joint. A steam-pipe is screwed on to the roller, and the steam blown through the cloth. Given another brush the cloth is again pressed, care being taken that the folds of the first pressing are not repeated. When brought out of the press, in which it should be kept for a day, the cloth needs but a little brushing to make it fit for the outside market.



198. SHRINKING MACHINE

Cloth Character. It cannot be too strongly emphasised that the finishing process is not, and never can be, a rigid system. Before the cloths arrive at the finishing department they have taken on a distinctive character, which requires to be considered. Every class of cloth has to be finished according to its own nature.

Worsteds. Except in one particular worsteds are finished by the same process as woollens. But this has to be specially noted. Worsteds are not felted; the beauty of many worsted cloths largely consists in the patterns which the threads form on the surface; if felting were resorted to all the weaver's trouble would be thrown away. But, as we have seen, all kinds of cloths composed of wool fibres have a tendency to shrink in water and under changes of temperature. Though woven of threads finely spun, a cloth, unless otherwise prepared, would be certain to shrink in water, and the shrinkage would be very readily confirmed by the merest pressure.

Shrinking. The only way to prevent irregular shrinking of worsted cloths is to shrink them thoroughly in the factory. After being scoured and dried, the cloth is damped and hung up on the shrinking machine. Shrinking machines are various, but we shall examine a very efficient and typical one [198]. In the shrinking-room, an endless chain extends between two wheels, fixed at opposite sides of the apartment; the chain supports the rods which hold the cloth suspended. The fore wheel has star points which bring the rods in one by one, and let them on to the chain. From the feed rollers above the machine the cloth comes down on the far side of the rod, being brought in by the star wheel, and when the cloth has gone down the required depth, a projection from the frame automatically holds the cloth against the rod, while the chain goes forward the breadth of a link. Being held, and so prevented from falling further, the cloth naturally makes a fold and turns upward, falling over the next rod on the chain, which gives it another point of descent. In this way the long length of the web is suspended in fold after fold. When the cloth has shrunk and dried the apparatus is reversed, and the cloth is re-delivered to the beam.

With the difference we have seen, worsted cloths are finished in the same way as woollens. Scoured, burled, darned, brushed, steamed, pressed, steamed, and again pressed, the woven fabrics are carefully finished.

BOX AND BALK JOINTS

Joints Used in Box-like Constructions. Butt, Rebated, Mitred, and Dovetailed Joints. Fished and Scarfed Joints

By WILLIAM J. HORNER

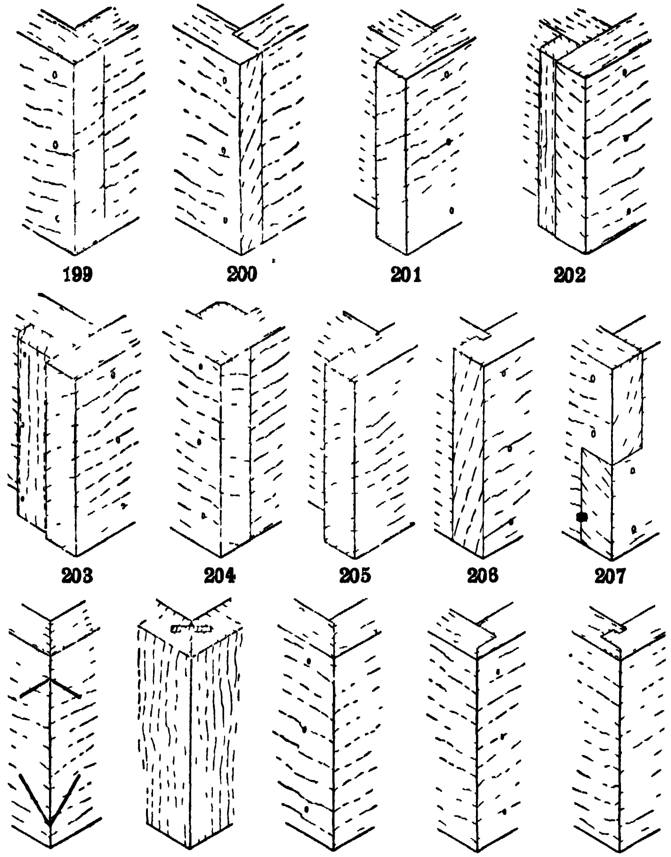
Joints Not in the Same Plane. We now come to a class of joints employed more in small work than in large, and consequently more used in joinery and cabinet-making than in carpentry. The weaker and more refined forms, such as the secret dovetail and mitre joints, are scarcely used at all in carpentry, but the rougher and stronger ones are necessarily employed a good deal in all woodworking trades, and as we are dealing with joints in general it would be difficult to select some and omit others that are in use, though only occasionally adopted in carpenters' work. The class of joints about to be described are those employed in uniting wide and comparatively thin pieces of wood at right or other angles—as, for instance, in boxes and cases of all kinds, drawers, etc.

As in the earlier joints described, we have first the simple butt joint [**199**] held together by nails or screws. Glue is of no use for holding such a joint, though on rare occasions it might be employed as a slight reinforcement to nails and screws. In such a case the pores of the end grain must be stopped by a preliminary coat of glue, which is allowed to dry before applying fresh glue to unite the parts. This, however, does not make a strong glue joint, for that is impossible where end grain is concerned. The ordinary butt joint, nailed or screwed, is commonly employed for all kinds of rough work where ends meet at right or other angles. Ordinary boxes, packing cases, etc., are usually nailed together with butt joints, as shown in **199**, the piece which laps over the end grain being usually the longer way of the box or other structure, and the piece between the shorter. If the box measures the same each way, of course this rule cannot apply; but sides and ends are always kept uniform—that is, ends always fit between and sides lap over.

Improved Butt Joints. An improvement on the plain butt joint is to rebate the end [**200**], thus forming a shoulder, which prevents the end piece from being knocked or forced inwards; and as the side abuts against the end, both pieces are able to resist external pressure without injury to the joint. If the rebate be cut as in **201**, an inch or so of wood extending beyond the end piece, the latter will be able to resist also a great deal more internal pressure than if simply depending on nails or screws, as in the two previous examples. Another advantage of the extended end is that the nails are less likely to split the wood or break out of it. In many cases, however, there are serious objections to having such an extension. Another joint with extended ends but without a rebate is shown in **202**. In this case a batten is nailed across the extension for the end piece to bear against. This practically forms a rebate on the outside which enables the end to withstand outward pressure—just the reverse of **200**, in fact. This is useful in work that is frequently taken apart, because the batten strengthens and keeps the side from warping or splitting. Fig. **203** shows a batten on the end piece instead of on the side. This is a method commonly adopted in making packing cases, the end being thus strengthened and the lap of the joint increased. It is simply a repetition of the butt joint, but with the end thickened and fortified. Another variation of this is shown in **204**, in which the joint is strengthened by a batten or block inside. Fig. **205** is a method of making a corner joint with extended end so that it will stand either tension or compression in any direction. It is done by making a veed or dovetailed rebate, into which the end must be slipped sideways. This involves more work in making than any of the preceding joints, and for some purposes the extended ends would be objectionable. It may be simplified by dovetailing only one side of the rebate. Fig. **206** shows another form of rebated joint, in which the rebate is made very narrow, extending from the inner face of the end piece to only about one quarter or a third of the thickness of the end, the latter being cut to fit it. This allows end grain beyond the rebate without any extension beyond the outer face of the end piece, thus forming a very neat and satisfactory joint not greatly inferior in strength to a full-width rebate like **201**. Another form of joint not very often employed and suitable only for rough work is that shown in **207**. It is a simple half-lap joint, almost unrecognisable as such because of the great depth of the members compared with their thickness.

Mitre Joints. Next in simplicity to square butt joints come *mitre joints*. As far as neatness goes, a plain mitre joint, like that shown in **208**, is an ideal method of uniting two pieces of wood meeting at an angle. In joining mouldings there is practically no choice but a mitre joint, or the more troublesome method of cutting the end of one piece to fit the contour of the other. This latter method is sometimes adopted, and is called a scribed joint.

Weakness of Mitre Joints. Unfortunately, however, the mitre is too weak to be employed for anything where strength is essential. Like the butt joint it always depends entirely on something else as a means of holding it together, while at the same time it is a much more difficult joint to hold than a square butt. Nails or screws can be used,



VARIOUS FORMS OF BUTT, REBATED, AND MITRED JOINTS UNITING PIECES AT RIGHT ANGLES

but, owing to the inclination of the surfaces, they are troublesome to insert, and the joint is not strong when they are in. Moreover, as mitre joints are used chiefly when appearance is the first consideration, nail or screw holes are objectionable. Glue holds slightly better on grain cut at this angle than on direct end grain, and it is generally used in a mitre joint, but always in conjunction with other fastenings. Fine nails are often used to hold mitre joints, and are driven in the same way as they would be into a square joint, the nail being entered at right angles with the face of the first piece and running into the other parallel with its grain. The mitred parts are held in position in a mitre cramp, or one is held in an ordinary vice and the other carefully kept in position by the hand while nailing. When screws are used they are generally inserted to go through the joint at right angles to its surface.

A very common method of uniting a mitre joint is shown in **208**. It consists in running sawcuts at an angle across the joint while the parts are clamped together, or after the joint has been glued, and gluing slips of wood of the same thickness as the sawcut into them. In cabinet-maker's shops veneer is handy for this purpose. The grain of the inserted pieces must run transversely to the joint, otherwise they would be of little value. After the glue is set they are trimmed off flush with the outside surface. Another more troublesome method less frequently employed is to cut slots across the joint for the reception of dovetail-shaped keys which are glued in similarly to the thin slips and trimmed off after. These methods are rather unsightly and are adopted only because something is necessary to hold the joint together. In the comparatively few cases where the mitre joint runs with the grain of the wood [**209**], glue may be sufficient to hold it, or it may be strengthened by wood blocking in the interior angle, as shown in the square butt [**204**], provided, of course, that there is no objection to the blocking. In an end grain mitre, like that shown in **208**, the joint might be strengthened by nailing or screwing a block in the angle; but it would not be advisable to glue it, because, as the grain would cross, unequal shrinkage would be almost certain to break the hold of the glue. Frequently a tongue is inserted, as in **209**, but in end grain especially this is troublesome to do without a circular saw and fixtures for holding and guiding the wood. Fig. **210** is a mitre joint which differs from the foregoing two in having a square shoulder or stop formed at the interior angle of one of the pieces, the chief reason for it being that the piece with the stop is thicker than the other, and it is desired to keep the mitre angle at 45 degrees. It also makes a joint slightly stronger and more convenient for nailing than a plain mitre. Fig. **211** is a more complicated form, eminently suitable for nailing, and very strong. In this case the joint is mitred only for a short distance back from its outer angle, the remainder being a rebate. Fig. **212** is a still more complicated form, often held together by glue only.

All these joints are marked out with square and bevel, scribed lines being made, or if the dimensions of the work that is to be mitred together are unimportant, plain mitres may be sawn against a mitre block [**97**, page 3755] or in a mitre box [**213**] or cut with a mitre machine; and usually are planed after to an accurate fit on a mitre shoot [**214**], of which

JOINTS IN WOOD

213. Mitre box **214.** Mitre shoot **215.** Lock corners **216.** Ordinary dovetails **217.** Cistern dovetails **218.** Method of marking out **219** and **220.** Marking pins from dovetails **221.** Lap dovetails **222.** Secret dovetails **223-227.** Ornamental corner joints **228** and **229.** Joints not at right angles there are several forms, 214 not being suitable for long joints like 208 and 209. The more complicated forms have to be carefully marked out, and sawn and worked to the lines with chisels and rebate planes.

Lock Corner Joints. We now come to an important variety of joints differing from all the foregoing in being fitted to each other by a series of projections and corresponding recesses, instead of a continuous projection, as in the case of a tongue and groove and others of similar character, or joints in which there are only one or two projections, as in tenons and laps. The simplest form of this class is the lock corner [215]. This is an excellent joint which, held by glue alone, is strong enough for almost any purpose. It is, however, not often made by hand because there is as much work in it as in dovetailing, and hand workers prefer the latter if a first-class joint is to be made. Lock corners, therefore, are almost invariably cut by machinery, but owing to the prejudice against their appearance they are employed only for a rough class of work.

Dovetail Joints. Very closely allied to the lock corner is the *dovetailed joint*, which is considered the best possible for uniting ends of wood at right angles. Fig. 216 shows the ordinary form and proportions of dovetails, the two pieces being separated. Fig. 217 shows a form in which *pins*, and spaces or *sockets* are of equal width. This is sometimes called a *cistern* dovetail, because it is used for wood cisterns and large heavy boxes. It is rather stronger than 216, but the appearance of the latter is considered better, and so it is almost universally employed for light and small work. The ideal shape is considered to be dovetails, with the narrowest possible spaces between —that is, a space no wider at its narrowest part than the thickness of the saw; and where appearance is of more importance than strength, this proportion is often adopted. But the usual proportion in ordinary work is that shown in 216, in which the dovetails are about four times the width of the spaces between them, the measurement being taken on a line half-way between roots and points [A, B, 218]. The angle of the dovetails is about 80 degrees with the ends of the wood. A more acute angle renders that portion of the wood liable to shear away in line with the grain. As in the putting together of ordinary butt ends, like 199, so in dovetailed ends; if the box or frame be longer in one direction than in the other, the dovetails are cut on the longest sides, and the pins which fit between them on the shortest. A gauge is set to the thickness of the wood that is to be dovetailed. In most cases, of course, sides and ends are of similar thickness, and the gauge is set to that dimension and used on the ends of all the pieces alike, gauge lines being marked on both sides of each end where dovetails are to be cut, and also continued over the edges, so that a line goes completely round each end, indicating the length of the dovetails.

Marking Dovetail Joints. As one part is marked and cut first and the part which has to fit it is marked directly from it, it is not essential that the marking out of pins or sockets should be done other than roughly by the eye, but usually it is done accurately by measurement. Some men start by marking out the dovetails or socketed portions, while others are in the habit of marking the pins first. It is not a matter of any importance, but the first method is preferable when a quantity of parts are being done, and it is desired to cramp and saw a number together.

To begin by marking out the socketed part, the line A B [218] should be gauged or pencil-marked half-way between the roots of the dovetails and the end of the wood. This is the line on which the divisions are made, the inclined lines of the sockets cutting through the divisions on this line and extending to the roots and tops of the sockets where the divisions to mark from could not be so conveniently made. To proportion them roughly one-third of the thickness of the wood may be taken as a suitable width for the sockets and four times that amount for the intervening dovetails. These divisions are made on the line A B, and modified to suit the width of the wood. At the edges of the wood, half dovetails are formed, or, if desirable, more than half, in order to give a reasonable thickness of material on the outside. A bevel is set to the angle of 80 degrees, and used against the end of the wood to scribe the lines in the same way that a square would be used for marking right angles. When, as is usually the case, two sides have to be marked and cut they are clamped or screwed together and treated as one piece, thus saving time. The bevelled lines of the sockets are next cut with a dovetail saw, or if large, with a tenon saw, the wood being held end upwards in the vice, and the cuts being made down to the gauged line which marks the roots of the sockets.

Dovetails are usually put together a sawn fit, only the end grain at the roots being finished with a chisel. When sawn down there is a choice of two methods of procedure. One is to clear the sockets out first. This would be done with a bandsaw if one were available, but by hand they are either partially cut with a bow saw or else by mallet and chisel, working from each face of the wood in turn. In any case a chisel must be used for finishing exactly to the gauge line. For this purpose a chisel with sides bevelled to the angle of 80 degrees or more is more convenient than a square-sided one. Then, the end to be fitted to it is placed in the vice and scribed from it, as shown in 219. The other method is to mark the end with a saw inserted in the saw cuts before the spaces are cleared out [220]. This method would be decidedly better if the saw mark represented exactly the cut, but to make the pins and sockets a close fit the saw must afterwards be kept a shade to one side to allow for the thickness of the cut. Either method may be adopted, marking with the saw generally being preferred. The parts are numbered or marked to show how they go, and then sawn down and cleared out with a chisel, and are ready to go together.

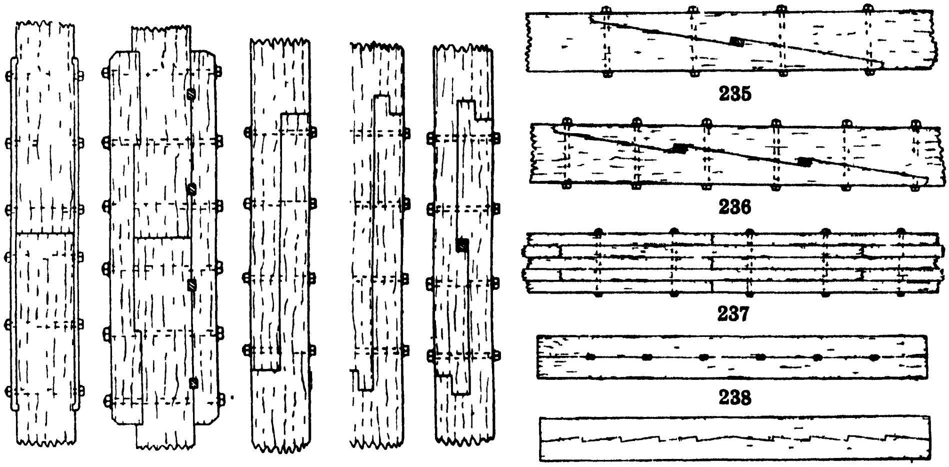
Lap Dovetails. Lap dovetails [221] are used chiefly for drawer fronts, the front being made to lap over and conceal the ends of the dovetails so that the latter are visible only in the sides when the drawer is open. The thickness of the lapping or covering portion on the front is usually the difference in thickness between front and sides, generally about ¼ in. or so. This does not materially affect the method of marking out and cutting them already described, except that the saw cannot be run through in cutting the front.

Secret Dovetails. Secret dovetails [222] are concealed within what appears from the exterior to be a plain mitre joint. They are employed only in high-class work for the sake of appearance, the joint being weaker than ordinary dovetailing, and more troublesome to make. The dovetails are simply gauged back short of the ends of the stuff, and otherwise marked and worked in the ordinary way, except that they have to be cut out, chiefly by the chisel alone, because the saw cannot go through. The wood extending beyond the ends and sides of the dovetails is then bevelled to form a mitre joint. Another method frequently adopted, but not so strictly a secret dovetail as the preceding, is to mitre only the front and leave the ends square, which gives the joint an exterior appearance like **211**. It is, in fact, a double lap, instead of a single lap like **221**, the corner being mitred to permit the laps to come together. In another form the lap is not mitred, but appears on the exterior as a plain lapped joint like **200**.

Dovetailed joints are usually held together by glue alone, though it adds to their strength if they are nailed as well. Before gluing, the parts should be tried together to see that they fit properly. Then plenty of glue should be applied to the end grain of the pin spaces, and a little to all parts that come in contact, using a small brush or thin slip of wood in the sockets. In finally driving together, the wood is not struck directly with a mallet, for fear of bruising or splitting it if the pins do not go down regularly, but a large block of wood is laid on the surface, and blows with a mallet or heavy hammer delivered on this, changing the locality of the blows as required. The fit, of course, must not be so tight as to necessitate very heavy hammering, or there will be a risk of splitting.

Ornamental Angle Joints. Figs. **223** to **227** illustrate methods of ornamenting and concealing joints in wood meeting at right angles, the forms of the actual joints not differing in principle from those previously shown in **199** to **212**.

Joints at Other than Right Angles. These are frequently necessary, and there are two main varieties. One, in which the pieces meet at right angles in one plane but not so in the other, **228** being an example; and the other, in which they meet either at an obtuse or acute angle, **229** being an example of an obtuse angle. In either of these cases most of the joints already described are applicable, making the necessary allowance for the different angle. This in most cases gives more trouble in making them, especially the dovetail. The pins and sockets in this case should be parallel with the sides of the wood and not marked from the ends unless two bevels set to different angles are used, for the angle of 80 degrees, sloping alternate ways from the end, would tilt the dovetails out of parallel with the sides. Such a joint would go together and is sometimes employed, but it is not the usual method. The extra difficulty, however, in all points of this kind is more in the marking out than anywhere else. The square generally has to be discarded and a bevel used in its place. Even in a simple butt joint [**228**], the fitting is considerably complicated by the slope of the sides and ends, which throw at an angle everything which in ordinary work would be cut square. This necessitates the use of the bevel, and careful marking out.



230 231 232 233 234 235 236 237 238 239

JOINTS IN BALKS

Fished and Scarfed Joints. These are joints used in lengthening balks and timbers of large section in heavy carpentry. In these, as in all others, the kind of joint adopted depends on the nature of the stress it has to sustain, or whether it is for temporary work or permanent service. There are two main varieties of joint used for uniting large timbers end to end, each well adapted for resisting corresponding stresses. These are joints to resist compression, and those to resist bending and shearing and some amount of tension. The former are required for posts and vertical timbers, the latter for horizontal beams.

Timbers which stand vertically and have to resist compression endwise should always have square joints, never scarfed, veed, or sloping surfaces. The simplest way to joint for this purpose is to butt the square ends together and bolt fish-plates to the sides, as shown in 230. Fish-plates may be either of iron or wood. In the latter case, to make the joint equal in strength to a solid timber, the combined thickness of the plates should be equal to the thickness of the timbers joined. Iron plates are usually preferred, sometimes laid flat on the surface, and sometimes with their ends turned in [230].

Fish-plates are generally made in length equal to about six times the thickness of the timber, hard wood requiring less length than soft. Fig. 231 is a joint connected by wood plates. The plates might be bolted flat on the surfaces without the indentations shown, but the latter enable it to better resist bending and tension. Two methods of indenting are shown in this illustration. That on the left, where the plate is fitted into the beam, is known as tabling, and that on the right, where separate keys are used, as cogging or joggling or keying. These greatly relieve strain on the bolts. A half-lap joint like 232 is neater than either of the preceding, and in many cases would be sufficiently strong in itself without the addition of fish-plates.

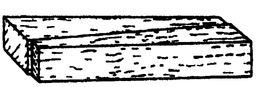
Improved Fish Joints. A still better form would be to cut the lapping ends in a series of steps, which leave each timber thick where its reduction starts, and thin at its extremity. Fig. 233 is a more complicated joint of the half-lap class, quite as strong in compression, but able also to resist more transverse stress than either of the preceding. It may therefore be considered superior in every way, but is more troublesome to make. A further improvement on this is shown in 234, the joint in this case being tightened by driving a key through the slot cut in the centre. The advantage of this is that the joint can be more easily fitted together, and can be keyed to a tighter fit than would be possible if the parts had to be driven together sideways and left at that. When a beam has to be fortified against side strains as well as downward pressure, the joint is often indented longitudinally at each end of the lap instead of being cut straight across.

Scarfed Joints. All the examples so far have been suitable for vertical timbers, but we now come to scarfed joints for tension and bending rather than compression.

A scarf is a bevelled or sloping joint [235 and 236]. In its simplest form, which is not very strong, it is a plain, flat surface at an angle. In compression the surfaces of such a joint would tend to slide over each other and so break the joint; and even in more complicated form, with the surfaces veed, as at the lower side of 235 and 236, there would be a tendency to split the recessed part out. But these joints are well adapted for beams which are subjected to combined tension and bending. As the upper part of a beam is in compression and the lower part in tension, the extremities of the scarf are generally formed, as in 235 and 236, to suit this, the square shoulder on the upper side being much better for compression. Often short fish-plates are bolted across the under sides to assist in keeping the joint together, and sometimes also across the top joint to stiffen the beam. Sometimes fish-plates the full length of the scarf are employed. Joints in beams should always be arranged to come on or near supports. Fig. 235 is tightened by one key, and 236 by two keys, its form being complicated thereby. For rough temporary work, timbers in tension are often lapped side by side for several feet and bolted.

The tabled and cogged joint [231] is adapted for resisting tension. Deeper notches might be employed if it were a joint for tension only, but this would make it weak laterally, and if carried too far, weak in every way. Generally, direct tension in a joint is so slight that the bolts alone can be relied on to resist it. In fished and scarfed joints bolt holes should be bored small enough for the bolts to be driven in a tight fit; and, as in all other woodwork, the nuts should be tightened at intervals as the timber shrinks and accommodates itself to the compressive force of the bolts.

Other Joints. When great lengths have to be made up, a number of deals are often bolted together, breaking joint with each other [237]. A very strong timber of unlimited length can be built up in this way. When a great number of deals are employed in this way in forming a single timber, the end joints would not be arranged symmetrically as in 237, but so that not even alternate ones came opposite each other. The building up of a long timber is only one example out of innumerable instances in which the principle of breaking joint is employed in constructions of wood.



240. KEY FOR BEAMS

Beams may be increased in depth by jointing, as in 238 and 239, the cogged or serrated joint being necessary to prevent sliding. Iron plates may be employed as in fished joints to increase the strength of a beam. Generally one plate only, called a *flitch plate*, is employed, the beam being split down the middle and the plate bolted between. Steel girders or trussed beams are usually preferred to these methods.

Fig. 240 shows the form of key employed in beams. It consists of a pair of folding wedges which, driven in opposite directions, tighten themselves in a parallel slot.

ART IN GERMANY, FRANCE & SPAIN

Dürer and Holbein. The Fêtes Galantes. Watteau, Boucher, Fragonard, and Greuze. Hidalgo and Inquisition. Velasquez and Goya

By P. G. KONODY

German Painters. German painting of the fifteenth century has been admirably summed up by M. Reinach: "Italian art dreamed of beauty and realised its dream. Flemish art was in love with truth and held the mirror up to Nature. German art rarely achieved either truth or beauty. But it succeeded in rendering, with a fidelity that was often brutal, the character of the German people immediately before and after the Reformation." Local schools were flourishing already in the fourteenth century in the various cities and districts, but comparatively few of the artists' names have been handed down to us, and modern research has had to be content in many cases with identifying the painters as "the master of such and such a picture." The schools of Prague, Cologne, Augsburg, the Upper and the Lower Rhine abound in such anonymous masters, who generally contented themselves with setting their angular figures, which in movement and expression often verge on caricature, against a flat golden background, without an attempt at landscape backgrounds, and without much concern for orderly composition. Yet there is an undeniable naive charm in the sincerity of many of these works, though they have neither the beautiful colour, nor the tender sentiment, nor the delicate execution of the contemporary Flemish works.

Dürer. Even Albrecht Dürer (A.D. 1471-1528), the greatest German master, is no exception to the rule, and of pure beauty such as we have met in the works of his contemporaries in Italy but little is to be found in his pictures. He is intensely dramatic and serious, simple and direct, and combines to the highest degree all the qualities that are characteristic of the German Renaissance, a movement which was intellectual and moral rather than artistic [81]. Few, if any, artists could rival Dürer in the rendering of textures, and this refers as much to his line engravings as to his paintings; few could invest every detail and accessory introduced in a picture with more interest; few there are that could depict a simple story with more homely, touching directness.

81. A PORTRAIT, BY DURER *Mansell*
(The Prado, Madrid)

Holbein. The second of the great masters produced by Germany was Hans Holbein (1497-1543), the greatest of the Augsburg School, as Dürer had been the greatest of that of Nüremberg. Holbein is one of the few early Germans who is exempt from the charge of lacking the sense of beauty. He benefited by the lesson taught by the Italians as regards pictorial composition, and developed a noble free style which had none of the taint of German ugliness. At the same time he retained the typical German quality of careful, minute observation, tempered by sympathetic insight into character. His portrait drawings, of which a vast number are preserved at Windsor Castle—Holbein was Court painter to Henry VIII.—show his unrivalled sureness of touch and expressiveness of line. Like most northerners, he loved to introduce a great variety of detail into his pictures, but he always knew how to subordinate it to the main theme, which it emphasises rather than detracts from. In such pictures as "The Ambassadors" at the National Gallery [82], or the merchant "George Gyze" at the Berlin Gallery, all the accessories are fraught with meaning, but do not draw our interest from the personages depicted. And for perfect craftsmanship Holbein may be held up to every student as an example worthy of emulation.

Janet. In France the chief representative of autochthonous painting in the fifteenth century was the illuminator Jean Fouquet, but the history of French painting may be said to begin with François Clouet (A.D. 1510-1572), better known as Janet, an artist considerably influenced by the Van Eycks, and one of the world's greatest miniature painters. His portraits often bear a close resemblance to Holbein's. His contemporary, Jehan Cousin, owed nothing to foreign teaching and acquired great fame as a painter of glass.

Francis I., in A.D. 1531, called Primaticcio and a few other second-rate Italian painters to his country to decorate his castle at Fontainebleau, and this led to the founding of the school of Fontainebleau, from which issued a number of pseudo-Italian mannerists whose pretentious work only delayed the development of national French art. Only, the early seventeenth century brought forth a few native artists of decided originality, notably the brothers Le Nain, painters of homely scenes and of camp life, who had distinct affinity with the Dutchmen of the time, though their sombre colouring connects them with the Spanish school.

82. THE AMBASSADORS, BY HOLBEIN *Mansell*
(National Gallery, London)

The French Classicists. Nicolas Poussin (A.D. 1594-1665) studied in Rome, then considered the fountain-head of all art, and learnt the lessons taught by Raphael and Michelangelo, and even more by the antique. He was more classic than any of the Italian classicists, and his figure paintings are antique reliefs translated into terms of colour. His eclecticism debarred him from seeing life, movement, and emotion in Nature, which, in his pictures, are merely superficial adjuncts to classic poses. But he was a master of the "heroic" landscape, a landscape that is based on noble arrangement and linear perspective, and not on colour and atmosphere. Gaspard Poussin, his brother-in-law, was inspired by Nicolas in his landscapes, though the younger master was a little more concerned with light and air, and not so uncompromisingly severe. The same influence produced the style of Claude Lorrain (A.D. 1600-1682), who is considered in the article on landscape art, and who was an artistic progenitor of the great Turner.

Watteau and the "Rococo" Period. Another pupil of Poussin, Charles Lebrun (A.D. 1619-1690), became Court painter to Louis XIV., and ruled as a veritable autocrat over the art of his country, which degenerated into mere theatrical pathos. He was not only entrusted with all official commissions for paintings, but was made Director of the Gobelins Tapestry Works, and supplied designs for sculptors, cabinetmakers, and metal-workers. His paintings belong entirely to the literary order, and have little to do with art. The real national tradition was perpetuated to a certain extent by the portrait painters Mignard and Rigaud, and, above all, by Antoine Watteau (A.D. 1684-1721), the great painter of the "Fêtes galantes," the typical artist of the "Rococo" period. His arcadian scenes—French courtiers and amorous dames masquerading as harlequins and shepherdesses in delicious gardens—have not a trace of cold classicism, and hold up a faithful mirror to the idle, gallant life of eighteenth-century society. The life he depicts is essentially artificial, but there is nothing artificial in his style. With all their beauty of arrangement, his scenes do not appear to be constructed according to a formula, but have a convincing air of reality; and, above all, he is a painter who revels in the precious quality of the pigment and who allows air and atmosphere to enter into his landscapes. His followers, Lancret and Pater, degenerate into a coarse suggestiveness which is quite in accordance with the immorality of the Court of Louis XV.

Immorality in Art. This tendency reaches a climax in François Boucher (A.D. 1704-1770), the "Painter of the Graces," who is the typical child of a period of degeneracy, though his works, however objectionable they may appear from the moral point of view, have undeniable decorative charm and superficial beauty. His pupil, Fragonard (A.D. 1732-1806), is a brilliant delineator of the nude, an artist of great esprit, who connects the period of untrammelled lasciviousness with the downfall of the old régime brought about by the Revolution. Parallel with this current of art, which is essentially at the service of the Court, is another little stream which reflects the healthier life of the people. Chardin (A.D. 1699-1779) is a painter whose tendency is as decidedly moral and sermonising as Boucher and his school are immoral and seductive. And just as the latter are offshoots of the Italianising classicists, so Chardin is connected with Le Nain and with the Dutch small masters. Even more marked is the moral tendency of some of Greuze's genre pictures [83], though in other works he appears to cater for the sensuality of the ruling classes. But neither of the two was the founder of a school, and the Revolution directed the art of France into new channels.

French Sculpture. The progress of sculpture in France during these two centuries was very much on the same lines as that of painting. The master who dominates the seventeenth century, Pierre Puget (A.D. 1622–1694), did not receive official recognition, since he would not submit to the autocratic rule of Lebrun. His art was based on the study of the antique and of Michelangelo. The hold of the latter master over Puget appears most strongly in the "Milo of Crotona" at the Louvre. To the eighteenth century belongs Falconet, the author of the very academic equestrian statue of Peter the Great, at St. Petersburg; Clodion, a boudoir sculptor, who expressed in marble and terra-cotta what Boucher and Fragonard expressed in paint; Houdon, a brilliant modeller of portrait busts, and Pigalle, who continued to follow the antique with exaggerated elegance of form. His noblest work is the tomb of the Maréchal de Saxe, in Strasburg. What marks all French sculpture of this period is the striving after grace and elegance and decorative effect, which frequently results in limbs of exaggerated length and a certain dainty affectation, which is far from displeasing. The character of the period is certainly reflected in its sculpture as well as in its painting. But with the advent of the Italian Canova, at the turn of the century, all character was lost in a soulless, cold imitation of all that is merely formal in the antique. The fame of this uninspired marble-carver spread over the whole of Europe, and acted as an effective check to all individual expression. In every country his fatal example was emulated—in Denmark by Thorwaldsen, in England by Flaxman, in Germany by Danneker, and in France by numerous sculptors whose fame has been obliterated by the great men who followed in the second half of the last century.

Mansell

83. THE LISTENING GIRL, BY GREUZE
(Wallace Collection, London)

Spanish Painting. The history of Spanish painting may be said to begin about the time when Granada was captured from the Moors, in A.D 1492. In no other country was the individual expression so severely handicapped as in this country, where for centuries the Inquisition exercised a censorship which not only forbade the study of the nude and all other "worldliness," but interfered even in matters of detail. The slightest deviation from Scriptural truth or from Catholic dogma was treated as heresy. Thus in painting a "Crucifixion" every artist had to adhere strictly to the measurements of the cross, which had to be in the proportion of 15 ft. by 8 ft.; and the Italian sculptor Torrigiano, who was working in Spain, was actually imprisoned by the Inquisition for having, in a fit of passion, broken up a "Virgin and Child" wrought by his own hands!

Art Under a Shadow. This strict supervision by the Church, together with the serious, proud character of the Spanish race, produced an art of great sombreness and reserve, inspired by a passionate love of reality, an art which has dramatic intensity, boldness, and strength, but never sounds a note of gaiety and joy, and is rarely occupied with beauty and grace. It reflects the proud, hidalgic attitude to life, the grandeza and strict ceremonial of the silent Court, the iron rule of the Church and Inquisition. And through all the influences from abroad—from Flanders in the fifteenth century (the Gothic period), from Italy in the sixteenth century, and from France at the close of the glorious period which culminated with Velasquez—can be detected the sombre glow of these national traits.

Juan de Borgoña and Pedro Berreguete, both of whom worked in Castile at the end of the fifteenth century, were among the first to introduce Italian methods, which took firmer root when Charles V. and Philip II. induced a whole band of Italian painters to settle in Spain. Among the prominent Spanish masters of the early sixteenth century are Luis de Morales, Pedro Campaña, and Luis de Vargas, but their works, like those of innumerable other meritorious painters of the period, are practically unknown outside their native country.

The Rise of the Spanish School. What might be called the "historical" period of Spanish art rises with the school of Sevilla, towards the end of the sixteenth century. Pacheco, from whom Velasquez received his early training, was scarcely more than an able Italian mannerist; but Juan de las Roélas (A.D. 1558–1625) and Herrera the Elder (A.D. 1576–1656) introduced something of the sumptuousness of Venetian colouring into the sadness and dark shadows of the Spanish palette. Francisco Zurbaran (A.D. 1598–1662) was a painter of great emotional power, almost ecstatic in his dramatic intensity, with a sense of pleasing form and line.

An extraordinary genius, weird and passionate, was El Greco (1548–1614), who, in his endeavours to escape from the convention and imitation which fettered his precursors, arrived at a frenzied, extravagant style, with figures whose limbs are twisted into extraordinary contortions and of inordinate length, seen in a patchy light that never was on sea or land. He was a restless spirit, but endowed with a noble sense of colour and with the gift of seeing the dreams of his almost insane imagination as a homogeneous whole.

Velasquez, King of Painters. With Velasquez (A.D. 1599–1660) we reach the apogee of Spanish art. He was not only the greatest master of his time, but opened a new vision to modern art, a vision in which the greatest painters of our own day find salvation. No one has ever more completely realised the truth of the saying that the greatest art is to conceal art. Painted with an astounding sureness and simplicity of means—his palette is said to have consisted of only four colours—his pictures produce an amazing effect of reality. His tone values are perfect, and there is a unity of vision which places before one just what could in real life be taken in by one glance, leaving out such detail as would detract from the general impression, and yet never slurring over anything that is really essential. In his portraits his sitters seem to live in the atmosphere in which they are placed, and their life is not only that of their body, but of the very soul. His psychological insight is the more marvellous, as he painted at a Court where everybody wore habitually a mask of cold dignity to conceal his real character. The realism of Velasquez is of a kind that never stoops to an indiscriminate recording of Nature's accidental blemishes. If his pictures appear to be the spontaneous result of direct observation, and have little in common with the studied arrangement of academic compositions, he is so perfect a master of selection that there is never a touch which would in the slightest degree disturb their quiet harmony and decorative spacing. [See illustrations of paintings by Velasquez on pages 182 and 723.]

84. THE HOLY FAMILY, BY MURILLO
(National Gallery, London)

Murillo and Ribera. The other name that is inscribed in letters of gold on the tablets of Spanish art is that of Murillo (A.D. 1617–1682), whose pictures have been aptly called the embodied expression of Spanish Catholicism. A charming colourist and accomplished draughtsman, he is wholly lacking in inspiration and depth of thought. He clothed the holy legends in the garments of his period, using the types of the people by whom he was daily surrounded, and thus translated the teaching of the Catholic Church into the vulgar tongue. One of his most familiar paintings is "The Holy Family" at the National Gallery, London [84] But fascinating as he is at times, he has little to add to the history of the artistic development of his country, or of the world at large Contemporary with Velasquez and Murillo was Ribera (A D. 1588-1656), who, trained by the Italian naturalists, became in his turn the paramount influence in the school of Naples. In spite of all that he derived from Italian sources, he always retained the ecstatic passion and the sombre shadows so characteristic of Spain. His favourite subjects were scenes of martyrdom and physical pain.

Goya the Satirist. With the death of Velasquez and Murillo, Spanish art collapsed as suddenly and completely as it had arisen under their dual star. A brief renaissance of the ancient splendour was, however, brought about by Goya (A.D. 1746–1828), an artist of immense versatility and great genius, though frequently hasty and slovenly in execution. In his best work he almost rivalled Velasquez—in fact, he is the one link that connects this great master with Manet and the later nineteenth century. He must be counted among the greatest etchers and lithographers of all times, as he was one of the greatest satirists; who defied Government and Inquisition with his merciless exposure of the vice, ignorance, corruption, and immorality of his period.

HERBERT SPENCER & SOCIETY

The Master-Book of Sociology. The Bias of Patriotism. The Sociological Society and Its Work. The Universities and Sociology. Science and Social Life.

Continued from page 3989

By Dr. C. W. SALEEBY

THE book to which we referred at the close of the last article is entitled "The Study of Sociology," and was written by Spencer as an introduction to the whole subject. It constitutes Vol. V. of the International Scientific Series—that magnificent enterprise which Spencer himself had some share in starting—and has been by far the most popular of all its noteworthy successes.

A Book that Must be Read. It is comparatively a small book, and costs only 3s. 9d. Anyone capable of reading anything worth reading can read it. Excepting the little treatise on education it is by far the most popular and readable and attractive of all Spencer's works Just as no one could regard himself as a serious student of organic evolution unless he had read the "Origin of Species," so no one could regard himself as having made a beginning with sociology who had not read this book. If the reader has time to follow further sections of this course, it follows, *a fortiori*, that he has time to read this book, and we shall assume that he will do so. Our indications of its substance may therefore be brief.

The author begins by showing that we are in need of sociology—an easy task most convincingly performed. He then asks whether there is such a thing as sociology, refuting those who, insisting upon the difficulties of the science, the mutual contradictions of its professors, the incalculable part played in human affairs by the will of man, declare that sociology is impracticable and vain. Among the parallels which he employs he makes good use of that of meteorology. He then proceeds to discuss the nature of sociology and the various difficulties which beset it.

Difficulties of Sociology. The illustrations employed in the course of these chapters will be found the most delightful reading. After thirty years, we may say, perhaps, that the discussion of the intellectual difficulties in the study of sociology will meet, as it did not meet in 1873, with the immediate assent of the great majority of readers. Still more impressive is the discussion of the emotional difficulties which beset us—a discussion which includes a noble and terrible indictment of those who worship the incomparable criminal whom men call Napoleon the Great. Here we may note that Spencer refers to the estimate that "one vile man's lust of power was gratified through the deaths of two millions." The recent estimate made by a great living Frenchman, however, places the figure at eight millions. The present writer would be only too pleased if he could send to each of his readers a copy of this volume containing all the annotations that he has made in his own copy; but this one, at least, he cannot forbear quoting.

Morality and Patriotism. Spencer then goes on to discuss the difficulties which may all be classed as bias. He describes the educational bias which, alas! is as bad to-day as it was a generation ago, and which continues effectively to blind our legislators. Then follows a chapter on the bias of patriotism, which distorts so many of our views and which often expresses itself in the abominably immoral sentiment, "my country, right or wrong." This chapter concludes with many admirable pages upon the bias of anti-patriotism, which, of course, is not nearly so common nor yet so dangerous, but unfortunately vitiates the social and political judgments of some of the finest souls in our midst. We recommend this chapter to every reader who thinks, or thinks there is any chance of his ever thinking, about things that matter. Equally important is the chapter on the class bias, which, like the whole book, is filled with such admirable sayings as these: "It will become a matter of wonder that there should ever have existed those who thought it admirable to enjoy without working at the expense of others who worked without enjoying." Next comes political bias, quite the least excusable of all forms of bias, and then a great chapter on theological bias and anti-theological bias, the wisdom of which, if listened to, would wipe out the columns of imbecilities that constitute reports of speeches on the Education question.

The Sociologist's Intellectual Training. Not with reference to sociology alone, but with reference to all objects of study and belief, we will venture to say that the reading of these pages (178 to 313) on bias must establish an epoch in the development of any mind that is a living thing and not a mere sensitive plate. They will make fair-minded, or as fair-minded as one may be, any one who tries to be fair-minded, and they will at least make ashamed of himself in his heart of hearts anyone who does not.

Lastly, the author considers the intellectual discipline necessary for the sensible and worthy study of sociology. Previously, as the reader will observe, he has considered the moral discipline which will make the student's mind fair and worthy—the author rightly regarding the importance of this discipline as prior to that of any merely intellectual training. The author shows how this intellectual training must include an acquaintance with the principles and practices of the fundamental sciences, ever strengthening in the mind the ideas of relation and cause and effect. Subsequent sciences, such as biology, will prepare the student's idea of causation for the demands which will be made upon it by sociology, in which causation is not only *continuous* but almost appallingly *complex*, and *contingent* upon so many factors. There follow important chapters upon special preparation in biology and psychology—such, it may be hoped, as the reader has had—and then the work is brought to a conclusion.

The Sociological Habit of Mind. Our estimate of the book is that which is commonly entertained by sociologists in all countries, and we earnestly hope that what we have said will compel our readers to acquaint themselves with it. Having done so they will find themselves not only far more interested in sociology than they were before, but also able without effort to look at things from the sociological standpoint. In short, to read this book is to acquire the sociological habit of mind; nor is there any other means by which this may be so readily or so well acquired. Having read this book the student will welcome a brief account of its illustrious author—an account which we shall try to make consonant with his own conception of the value of personalities and of the right kind of biography.

It would be fair to say, perhaps, that the modern rational view of history in general regards it as a combination of descriptive sociology and scientific biography. Thus, to choose extremes, the geographical view of history and the great-man theory of history may take their due places in that comprehensive view which will be completely true.

The author of the doctrine of universal evolution was born in Derby in 1820 and died at Brighton in 1903. In his voluminous autobiography he discusses, in scientific fashion, all the facts of his ancestors which could throw a light upon his own mental characters. It is quite plain that he belonged to an exceptional stock, the most noteworthy character of which was independence of thought.

Herbert Spencer's Greatest Achievement. Spencer, of course, was predestined to be a thinker from the first, but it was not until he was forty that the great work of his life was begun. Before that time he had written some remarkable essays, including the famous short paper in which he upheld the nebular theory against all the astronomical authority of the time, and the essay called "The Development Hypothesis," in which, in 1852, seven years before the publication of the "Origin of Species," the young author argued for the truth of the doctrine of organic evolution. Reference has already been made to the epoch-making "Principles of Psychology," which appeared in 1855. The great achievement of Spencer's life was, of course, the Synthetic Philosophy. This is not merely the only philosophic system that any Englishman has given to the world, but—which is immeasurably more important—it is regarded as substantially true by those competent critics who are acquainted with it.

The doctrine of the synthetic philosophy is that the principle of evolution—this word having been introduced by Spencer in 1857—is the key to the problems of all phenomena. The Synthetic Philosophy consists of "First Principles" (recently published in a cheap edition by Williams & Norgate); "Principles of Biology"; "Principles of Psychology"; "Principles of Sociology"; "Principles of Ethics." The aim of the entire system was to establish the truths of morality upon the "solid ground of Nature," and, as the author became an old man, he feared that he would never reach the "Principles of Ethics" if he wrote his work in the logical order. He therefore passed at once to this final subject, but fortunately lived to return to the "Principles of Sociology," the last volume of which was published in 1896—thirty-six years after the inception of this magnificent enterprise.

What We Owe to Spencer's Inspiration. Spencer is undoubtedly greater as a biologist, a psychologist and a moralist than as a sociologist. This, however, is not to say that his sociological work is not of the utmost importance. Many of his conclusions, however, like those of his predecessors, are invalidated by the inadequacy of the facts upon which they were based.

If the history of science proves anything it is that there is no royal road to generalisations, and sociology was yet too young for Spencer and his contemporaries to do the work which they attempted. This we must recognise, even though we admit that the main lines of his conclusions were sound, and, pre-eminently, that his method and his conception of sociology, as dependent upon biology and psychology, were true and fruitful. Lastly, sociologists must pay him tribute as having done far more than anyone else in his time to disseminate the idea of sociology, to teach thinking people that there is or may be such a thing, to arouse their interest, and to inspire the labours of thousands. Largely to such inspiration do we owe the fact that the sociological material at the disposal of the student is multiplying manifold with every decade and that the voice of trained thinkers is beginning to be heard even where politicians most do congregate.

The Sociological Society. During the last few months of Spencer's life a few ardent students determined to form a Sociological Society in this country. Owing to the generosity of many persons, and especially of Mr. Martin White, whose name is well worthy of honour, this project was realised, and on November 20th, 1903, there was founded, less than three weeks before the death of the great philosopher, the Sociological Society, which is beginning to count for something in English thought and has already done much for two great complementary studies of the first importance—Eugenics and Civics—which we shall afterwards have to consider. Some interest attaches to the fact that the first president of this society, the Rt. Hon. James Bryce, is now a Cabinet Minister. One wonders what some Cabinet Ministers of the past, such as Palmerston, with his "damned professors" and his ignorant hatred of anything like knowledge or learning, or the philosophic temper, would have made of a meeting of the Sociological Society. Mr. Bryce has been succeeded by Lord Avebury. To the sociologist who approaches the science, as we are doing, from the more fundamental sciences, especial interest attaches to the presence of Lord Avebury in the presidential chair of this society. In the first place, it is significant that sociology should demand the services of a historian like Mr. Bryce on the one hand, and a biologist like Lord Avebury on the other. But it is particularly noteworthy that Lord Avebury symbolises the existence of the science which we may here venture to call *Comparative Sociology*. To this subject we must devote at least a brief study.

Human and other Societies. The use of the term *comparative* is well recognised in all departments of the sciences that deal with living things. Comparative anatomy takes a wider view of anatomy than mere human anatomy. It deals with the anatomy of all animals, with a special eye to discovering the comparisons between the body of man and the bodies of the lower animals. If the doctrine of evolution means anything at all it must certainly mean that one cannot truly understand human anatomy without studying comparative anatomy. The same is, of course, true of comparative physiology. We are just discovering that it is most conspicuously true of pathology and comparative pathology. A whole host of the most important diseases, which the study of man alone would never have elucidated, has already yielded or is rapidly yielding to the science which compares disease processes in man, monkey, and mouse. Yet, again, the importance of the comparative method is demonstrated in the case of psychology. Spencer, as we have seen elsewhere, was the first comparative psychologist, the first thinker to abandon the false and proud attitude which assumed not merely that the psychical characters of the lower animals had no relation to, and no bearing upon, the mind of man, but even that the minds of savages, the minds of children, the minds of Orientals, the minds of women, needed no study and, presumably, had nothing to do with the particular mental characters of the adult Caucasian man—characters to which all psychologists hitherto had been complacent enough to attribute the magnificent term *Mind*.

Social Instinct in Animals. Nor does the comparative method fail us when we come to sociology. When we speak of a school of whales, a shoal of fishes, a herd of deer, when we see the flight of birds across the sky, each bird falling into its own place in rank or file—in all such cases we recognise, though we may never have thought about it, that the social instinct is not peculiar to man. We shall afterwards see that the unit of society—or at least of all the higher forms of societies—is the family, and wherever there is the family there is at least the germ of a society. Now, the lower animals also show the existence of the family in many cases. Furthermore, there may be suggested the generalisation, which the present writer is prepared to uphold, that the form of the family—the word being here used in its widest sense—will determine the form and the fate of the society. Where there is no family, as in the case of nearly all the fishes, the society can never reach any but the most rudimentary form. Where the family is that dependent upon polygamy, a human society—for instance—will differ in form and fate from that the unit of which is the monogamic family. Again, where the family—if family it can be called—is so vastly different, as in the case of the hive bees, there the resulting society will be totally different in form and in potentiality.

The "Sub-Human" Societies. The comparative study of societies, then, or the comparative study of the family, must be of the greatest interest to the sociologist. And of all the sub-human societies which interest him none can for a moment approach in interest, in complexity of organisation, in wonder, in strangeness, and in significance, as well as in respect of the immeasurable gap which separates them from us, *the societies of the social insects.*

Now, of these Lord Avebury is, as everyone knows, not only the greatest living authority, but the greatest authority of any time, and thus a very especial interest attaches to the official connection of the greatest student of sub-human society with the society that exists to study human society. It is now earnestly to be hoped that Lord Avebury may consider the desirability of adding a volume of "Comparative Sociology" to his already great record of literary work. It would be a pity if some student of the subject whose knowledge is less profound is compelled to do this piece of work, which, it seems to the present writer, urgently demands doing.

Sociology and the Universities. Though there are six official teachers of sociology in such a place as Chicago, and though Brussels, for instance, has its magnificent Institut Solvay, founded by a man of wealth and wisdom, it was not until the end of the year 1904 that sociology obtained its first recognition in any university in the land of Spencer. The recent recognition of sociology as an academic subject by the University of London—which has hitherto been followed by no other university—is due to the work of the Sociological Society and the generosity of Mr. Martin White. Since that first step was taken there has also been removed the reproach that there was not a single recognised teacher of sociology in this country. It is true that this mighty and dominating science is yet unrepresented by a Chair in any of our universities, including even the recent provincial universities, from which such great work will surely spring, and including even the University of London, which is at last beginning to become a reality and not a name. But, at any rate, the University of London has instituted a lectureship—one solitary lectureship—in sociology, and has appointed to it one of the very greatest of living thinkers—Dr. Westermarck. It is significant that the first official teacher of sociology in this country should be a foreigner. Dr. Westermarck is known throughout the civilised world as the greatest authority upon marriage—perhaps the only social institution that is worthy of the title fundamental. Since leaving his native Finland for this country, Dr. Westermarck has been at work upon an aspect of the evolution of ethics which is entirely new, and quite distinct from the wider conception of the evolution of ethics, which we owe, of course, to the apostle of evolution himself.

Moral Ideas. In his book on "The Development of Moral Ideas," Dr. Westermarck concerns himself not with the gradual evolution of morality from parentage and from sympathy, but with the actual history, so far as it can be ascertained, of the production and growth of moral ideas among the lower races of man—many or most of which, of course, when judged by true ethics, are immoral ideas; and he is continuing his study of this subject up to the highest places. The moral ideas with which he is concerned are, of course, quite distinct from the true morality, which is grounded in love alone, but conforms more to the derivation of the word morals, which, of course, means merely customs. These ideas, and the customs based upon them, have, however, played a gigantic part in the history of society, and very notably in the history of religions. It is something that this great work is being done, though not by an Englishman, at any rate by the first academic sociologist in this country, and on English soil.

The different standpoints from which sociology may be looked at are many and various. It is unique amongst the sciences in this respect. Every man's conception of sociology differs from his neighbour's conception. The ecclesiastic, the psychologist, the physician,, the biologist, the social reformer, the moralist, and the detached student of the sciences in general—all these have their own points of view. Again, a man and a woman cannot possibly look upon sociology with the same eyes. Here, however, we have no space in which to discuss "the relations of sociology to the social sciences," or, indeed, what may be called the philosophy of sociology.

There are two leading considerations, however, which it is impossible to omit from our introduction to the subject. In the first place, we must refer briefly to the relations of sociology to the sciences that are beneath it, and then we must consider its relations to the one supreme science which is above and beyond it.

The Foundation of the Sciences. There is an aspect of sociology on which it is well that we should insist. The science has often been described as the crown of all the other sciences, and so, of course, it is. One readily understands how a complete sociology would include within its substance the whole tissue of, say, physics, biology and politics alike; but, on the other hand, the present writer is coming more and more to be impressed by the significance of another view of sociology—that which regards it as not so much the crown as the foundation of the sciences. Instances may easily be adduced. For some years the writer has thought, written, and spoken about infant mortality as if it were a medical problem. He has sought to eliminate heredity from its causation in any marked degree, and to attribute it to bad feeding and the like. It is only after reading Dr. Newman's recent book on the subject, which he describes as a *social problem*, that the present writer has realised how partial his analysis of the matter has been. It now seems self-evident to him that this is not a medical problem, but a social problem.

Drink is Society's Problem. Or, again, take the question of alcohol. In this case, as in the last, the medical sciences have done their work. The alcohol question was once, perhaps, a medical problem; it is so no longer. On the contrary, medicine can hand it over to sociology, and say: "This is your affair; what are you going to do about it?" Or, yet again, take the question of the provision of meals for school-children. Here, again, the medical problem is easy, soluble, and solved. The medical man knows how minute are the sums on which a child may be adequately fed. He knows how constantly these and larger sums are spent on that which is not bread.

The working-class family in this country spends on the average one-sixth of its total income on alcohol, as Messrs. Rowntree and Sherwell have proved. The problem of the physical state of these school-children is not to-day one for physiology or medicine, and is not to be solved once and for all either by medical inspection or by the most scrupulous obedience to the science of dietetics in the provision of school meals. In reality it is a question for the sociologist, and its solution will depend, the present writer believes, upon the answer which is returned to the question: "What is the unit of society—the family or the school?"

"The Causes of the Causes." These instances are typical. It is evident that the subordinate sciences, such as medicine and biology, have their place. It might also be proved readily enough that these sciences must be incorporate in a perfect sociology; but it is also evident that these sciences alone are impotent to cope with the questions which at one stage have to be referred to them. Faced, for instance, with "physical deterioration," they are able to analyse it, define it, and indicate its "causes"; but—and this is the essential thing—*the causes are only proximate causes.* We who believe that the universe is a universe know that causation is universal and eternal, and that of any causes of anything the philosopher must ask: "What are the causes of these causes?" For years the writer has contented himself with asserting and animadverting upon the merely proximate and medical causes of infant mortality. He thought that one had merely to make these causes generally known to abolish the evil. Now, however, Dr. Newman has taught him, what he should not have needed to be taught, that these causes, though valid and essential, are only links in a chain which is endless, but the most essential links of which are not medical, but *social.*

Continued from page 3942

By A. H. HIORNS

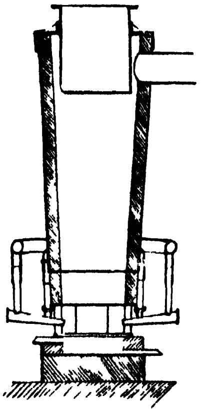
A HEARTH, forge, or furnace is a structure in which ores and metals are submitted to high temperatures. A furnace is usually constructed of refractory material on the inside, and of iron or ordinary brick on the outside. Furnaces may be divided into three classes: (1) those without an independent fireplace, such as a blast furnace and a hearth; (2) those with an independent fireplace, such as a reverberatory furnace; (3) those in which the material is separated both from the fuel and from the products of combustion, such as a zinc retort. They may be used with a natural draught, the air being aspirated by means of a chimney, or the air may be forced in by means of a blowing apparatus. In both cases the heat developed depends on the calorific power and weight of fuel burnt in a given time; also on the mode of combustion, for if the combustion be complete, the whole of the heat may be utilised.

Hearths. A hearth is a low furnace in which the material to be operated upon is mixed with the fuel and flux. The heaps, stalls, and certain kilns for roasting ores are included under this title, as the fuel and ore are mixed, and the action is the same. The smith's hearth is a familiar example of this type.

Shaft Furnaces. A shaft furnace, commonly called a *blast furnace*, is a structure with the long axis vertical, and contains one common receptacle for the materials employed. Certain of them, as the kilns in which limestone or ore is calcined, are worked by a natural current of air, the furnace forming a large chimney. The forms of blast furnaces are very varied, according to the nature of the ore and fuel used. They may be egg-shaped, cylindrical, or conical. In roasting iron ores, for example, where a large mass of material has to be expeditiously treated and where only a moderate temperature is needed, the diameter is greater in proportion to the height than in furnaces used for the reduction of ores, in which case the height may be from three to five times the diameter, because it is necessary to have a high temperature in the region where the fuel is largely consumed, and the more fuel there is burnt in a given space in a given time, the higher will be the temperature. The fuel employed may be coal, coke or charcoal, because oxides or materials which have been oxidised by roasting are generally treated in this furnace.

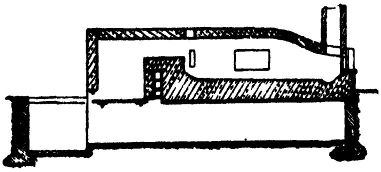
In the case of raw coal, it is decomposed in the upper portions of the furnace, so that by the time it reaches the zone of combustion it is in the form of coke.

Shaft furnaces for reducing ores are supplied with a forced blast, and may be theoretically divided into three parts: (1) the upper portion, where the ore is partly reduced without melting, the volatile matter is expelled, and raw coal is converted into coke; (2) the middle portion, which may be considered neutral, because the carbon dioxide formed by the reduction of metallic oxides in the lower part of the furnace neutralises the reducing gases; (3) the lower portion, where the temperature is very high and the atmosphere completely reducing. In the last, flux and earthy matters unite to form a fusible slag; the metal is liquefied and falls to the bottom of the furnace, the slag floating on the top. Fig. 26 is an example of a blast furnace used for lead smelting. It is formed of two independent parts—the *body* or *stack*, which is supported on iron pillars, and the *hearth* or *crucible*, which is surrounded by a double iron casing, through which water is made to flow in order to keep it cool. The blast is supplied through six or eight twyers. The throat is closed, except while charging, by a cylinder, and the waste gases are carried off by a side pipe.



26. BLAST FURNACE FOR LEAD SMELTING

Reverberatory Furnaces. A reverberatory furnace is distinguished from the former types in being arranged with the long axis horizontal, and in having an independent receptacle for the fuel. The fireplace is separated from the bed, or *laboratory*, as it has been conveniently called, by a fire-bridge, which is simply a wall of refractory brick, usually furnished with an air channel to keep it cool, and sometimes provided with orifices which admit air into the furnace. At the chimney end there is generally another bridge, termed the *flue-bridge*. The chimney is connected with the laboratory by a flue of varying length, and more or less horizontal. The chimney serves the double purpose of producing the draught and of carrying off the waste gases. The roof generally slopes downwards from the fireplace to the chimney, so that the flame may be reverberated on to the material on the bed. The size of a reverberatory furnace is determined by the kind of material to be operated upon. When ores are simply roasted, the length may be many times that of the fireplace, but when a high local temperature is desired, as in the case of puddling iron, the bed is not more than two to three times the area of the fireplace.

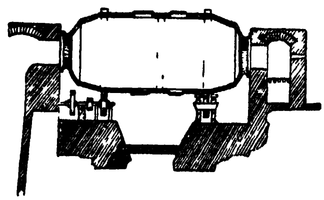


27. REVERBERATORY FURNACE FOR REFINING COPPER

Fig. 27 is an illustration of a reverberatory furnace used for refining copper.

Types of Reverberatory Furnaces. In cases where the temperature need not be very high, as in the calcination of ores, the bed is built of common firebricks; but in copper-smelting furnaces the bed is formed of two feet of sand rammed in tightly, and in puddling iron the bed is coated with a thick layer of oxide of iron and iron slag rich in oxide of iron. The most important reverberatory furnace in which gaseous fuel is used is the regenerative open-hearth furnace of Siemens. The great advantage of this type of furnace is that a reducing, neutral, or oxidising atmosphere may be obtained at will by regulating the supply of air.

The Bruckner Calciner [28] is a special type of reverbetraory furnace used for roasting silver and copper ores. It consists of an iron revolving cylinder, lined with firebrick, about 8 ft. in diameter and 15 to 20 ft. long. At one end is the fireplace and at the other end is a dust chamber connected with the flue and chimney. The cylinder rests on friction rollers and is rotated by gearing placed on the exterior.



28. BRUCKNER CALCINER

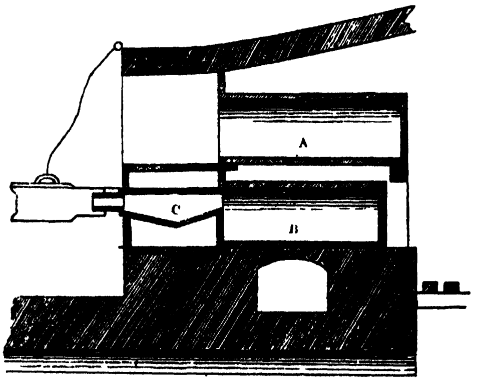
Closed Vessel Furnaces. In this class of furnace the material to be heated is separated from the fuel by an envelope, in the form of a closed vessel. The vessel is heated by being in contact with the fuel or with the flame developed by the combustion of fuel. The form of the vessel is determined by the work to be done. Thus, for simple heating, the muffle is employed, while for fusion, crucibles are used. For distillation and sublimation a retort is used. The ordinary brassfounders' furnace may be taken as a type of crucible furnaces, and the zinc retort as a type of retort furnaces. Fig. 29 is a section of a Belgo-Silesian zinc furnace. Two retorts (A, B) are shown one above the other; in these the zinc ore and carbon are placed, and the flame playing round them produces the necessary heat for the reduction of the ore. The vaporised zinc is condensed in the receivers, C, placed in front and attached to the retorts.

Production of Draught. Natural draught is produced by means of a chimney, which may be regarded as a vertical pipe containing heated and expanded gaseous products of combustion. The column of air in the chimney is lighter than the air of the same height at the ordinary temperature. Hence, there is an upward movement owing to the difference of weight, and as the air has to pass through the furnace, the draught will depend on the temperature of the fire in the fireplace, because the higher the temperature the more rapidly will the gases pass through the chimney, and a greater weight of air will be required to replace these gases per second.

Forced draught in small hearths is produced by bellows, but for smelting furnaces, blowing cylinders are generally used. In the simple melting of metals and in some small blast furnaces a rotatory fan or blower is largely used.

Hot Air. When hot air instead of cold air is supplied to a furnace the temperature of combustion is considerably increased, and as the waste heat of a furnace may be utilised in heating the air a great economy is effected by its use. A description of arrangements for heating the blast of air supplied to blast furnaces is given in the course on Iron Manufacture.

Copper. The metal copper has been known from the earliest times, because it is found in the earth in the metallic state, and its oxides are easily reduced. It has a red colour and brilliant lustre; it is highly malleable and ductile, so that it can be rolled into thin sheets and drawn into fine wire. At temperatures near its melting point it is brittle, and may be readily powdered. The tenacity of cast copper is about 8·5 tons per sq. in It melts at a temperature of 1,080° C., and is not sensibly volatile. Its specific gravity is 8·82. The fractured surface of pure copper is of a fine salmon-red colour and finely granular, but after hammering it exhibits a somewhat fibrous fracture, with a silky lustre. The conductivity of copper is very high, but is considerably reduced by small quantities of certain impurities. Of the impurities likely to be present, bismuth is the most injurious; antimony, arsenic, iron, tin, phosphorus, and manganese, also largely interfere with this property.



29. BELGO-SILESIAN ZINC FURNACE

Copper is unacted on in dry air at ordinary temperatures, but rapidly oxidises at a red heat. In moist air it acquires a coating of carbonate. It forms with oxygen both cuprous and cupric oxides.

Native Copper. The ores of copper are: Native copper, of varying degrees of purity; *cuprite* or red oxide (Cu_2O); black oxide (CuO); copper glance (Cu_2S); copper pyrites ($Cu_2S\ Fe_2S_3$). Grey copper ore is a mixture of the sulphides of copper, arsenic, antimony, and iron. Blue and green carbonates, known as *malachite* and *azurite*, are composed of $CuCO_3$ and CuH_2O_2 For smelting purposes, copper ores may be classified as oxides and sulphides. The most abundant and poorest ore of copper is pyrites, since the iron and copper occur in almost all proportions from a trace of copper up to 56 per cent., as in peacock ore. Copper is extracted by both dry and wet methods. The dry method is further classified into *reverberatory* and *blast* furnace processes, although the main principle is the same in each case.

Copper Extraction The Welsh or reverberatory method was formerly conducted in six or eight stages, according to the richness of the ore, which is chiefly pyrites. The process consists of alternate roastings and meltings in order to oxidise the impurities and pass them into the slag, while the copper is concentrated as a regulus or sulphide. When this concentration is considered sufficient, the copper sulphide is partially roasted, so as to form a mixture of oxide and sulphide. Then these are allowed to react on each other at a higher temperature, and liberate the copper in an approximately pure condition. This reduced copper is refined in a special reverberatory furnace [27]. The cakes of copper are gradually melted, during which oxides are formed, including the impurities. These oxides unite with silica (sand), and form a rich slag. The metallic copper is covered with anthracite and a pole of wood is inserted. The carbon and gases from the wood reduce the oxides of copper, and bring the impurities to the surface. If the poling is insufficient, the copper is dry in appearance and brittle. When the right degree of poling is attained, the copper is said to be at "tough pitch." If the poling is carried too far, the oxides of the impurities are also reduced and pass into the copper, making it brittle. Another method of refining copper, largely practised in America, is by means of electrolysis. It is cast into slabs, placed in a copper sulphate solution, and a current of electricity passed through until the copper is deposited. Such copper is remarkably pure.

Copper Reduction. In the blast furnace methods, the roasting is often done in heaps or kilns, but the more modern plan is to use large revolving cylinders or large fixed chambers, in which the charge of ore, or regulus, is automatically stirred and carried forward by mechanical arrangements. The blast furnace for copper extraction is generally built of iron, tapering slightly, so that the top is wider than the bottom. The iron casing is double, with a space between, so that water can circulate through in order to keep down the temperature. The regulus collects in a special receptacle called a *fore-hearth*, and is withdrawn when desired. Brick furnaces are also extensively used. The regulus, or matte, is again roasted, so as to form oxide, and the oxide is reduced by carbon in a second blast furnace treatment. The refining is the same as in the Welsh method. The blast furnace process differs, therefore, from the reverberatory process in that the oxide is finally reduced by carbon, and not by reaction between oxide and sulphide.

The Bessemer converter is now largely used for obtaining copper from regulus (sulphide). The blast of air oxidises the sulphur, forming sulphur dioxide gas, which escapes, and partially oxidises the regulus. The oxide and sulphide then react on each other, producing metallic copper, as in the Welsh method. The *wet* process of copper reaction depends upon the principle that a solvent first dissolves the ore, which passes into solution, and the copper is then precipitated by means of iron. The precipitate is finally refined.

Electrolytic Copper. The application of electrolysis to the refining of crude copper, referred to above, has greatly increased of late years. If a current of electricity pass between two copper plates immersed in a solution of sulphate of copper, the anode rapidly dissolves, while an equivalent weight of copper is deposited on the cathode. If, then, an impure plate of copper be used as an anode, the copper will be dissolved, and with it some of the impurities, but so long as there is a good excess of copper present, and the right strength of current is employed, the copper alone will be deposited. Bismuth, tin, antimony, and arsenic remain in part insoluble; platinum, gold, and silver are left on the anode as a slimy deposit. The crude copper is cast into slabs, which are suspended one behind the other in lead-lined vats, all of them being connected with the positive pole of the generating dynamo. Alternately with them are hung thin sheets of pure copper, which are connected with the negative pole and on which the pure copper is deposited.

The varieties of commercial copper are: Cement copper, Japan copper, cake and ingot copper, bean short and feathered shot copper, electrolytic copper, and best selected copper.

CHEMISTRY AND THE WORLD

The Chemists and the Great World-Problems. The "Beginning" of the Universe. Can We Make Radium? "All Flesh is Grass." Our Universal Ancestor

By Dr. C. W. SALEEBY

THERE is absolutely no limit to the variety or the number of organic compounds. We are acquainted with merely a fraction of those that occur in Nature, and we are capable of making as many more as we please of compounds which we have every reason to believe do not occur in Nature at all. To these latter products we can make no detailed allusion here, but it is necessary, at least, to point out their importance and to convince the reader of it, though he hears little about them in this place.

Most Fascinating Branch of Chemistry. Synthetic chemistry, which is now, with the exception of radio-activity, the most fascinating branch of the science, is daily making very rapid strides, notably under the influence of Professor Emil Fischer, of Berlin. Its difficulty can only faintly be imagined by the elementary student. If we were to discuss it here in proportion to its importance, we should need scarcely less space than this course has hitherto occupied. Here, however, we must try to gain clear notions as to the two distinct and equally important directions in which synthetic chemistry is advancing. When these have been discussed, we must also consider a third direction in which as yet no advance whatever has been made, but which in time may overshadow both the others.

One definite direction in which synthetic chemistry is advancing, so fast that even those who devote their whole lives to this particular branch of our subject can scarcely keep abreast of it, is the manufacture by synthesis of entirely new chemical compounds of carbon. The object of this branch of synthetic chemistry is largely theoretical, but perhaps mainly practical. In the first place, let us consider its theoretical interests.

The Achievements of Synthetic Chemistry. The chemist believes that law governs the behaviour and properties of all chemical compounds. He is acquainted in Nature with a number of organic series, such as the paraffins and their derivatives. It is thus one interest of his to see whether he cannot form artificial series which still display the serial quality. Furthermore, he tries to elucidate the relations of one series with another; and he tries to account for the properties of various series, and for the variations in the properties of the successive members of any series, in terms of molecular constitution. It need hardly be said that the facts which he thus discovers—having first, in a sense, made them—are of the very greatest importance in the study of the compounds which occur in Nature.

The second interest of this branch of synthetic chemistry is practical. We have already seen one of its practical issues, with which the name of Sir William Perkin, the great Englishman who has enriched the wise Germans, will always be associated. But we may venture to say that the manufacture of artificial colours is one of the least of the practical results of this branch of chemistry. Far more important in these days are various developments which more directly concern human life. Of these the best instance is furnished by the modern synthesis of drugs, which has already achieved the most remarkable successes. This subject can be dealt with here only by means of one illustration.

The Search for an Ideal Hypnotic. We have already seen in our study of the alkaloids two powerful substances which are capable of causing sleep, and to these many more might be added; but hyoscine, though irresistible, is an extremely dangerous drug. The patient will certainly sleep, but there is the risk that he will never waken. Morphine, again, though it is still absolutely indispensable, is attended with many grave disadvantages, as the reader knows. Now synthetic chemistry has turned its attention to this question of the production of an ideal hypnotic. It is doing the same with respect to the ideal antiseptic, the ideal anæsthetic, the ideal antipyretic, or febrifuge, not to mention many other kinds of drugs. In the case of the hypnotics, its efforts have been very successful, and for some time past every few years have seen a definite advance. This advance becomes the faster because the chemist is aided by the study of the molecular constitution of his previous products. He finds, for instance, that a certain compound will cause sleep, but has very little effect in relieving pain. On the other hand, he is acquainted with another compound, perhaps, which does not cause sleep, but will markedly relieve neuralgia, and thus, of course, may indirectly cause sleep. He compares these drugs with each other and with many of their fellows, and is more or less able to recognise the particular part of a given molecule that has a particular action upon sleep or pain or fever, or whatever it may be. He then tries, so to speak, to piece these various parts together in various combinations for various purposes. Let us briefly glance at some of the results.

The Survival of the Fittest. The chemist has added the substance called *paraldehyde* to the list of hypnotics, this being a polymer of acetic aldehyde. Again, we have already referred to chloral, and now we may note the existence of a really valuable hypnotic called *chloralamide*, which is a compound of chloral and formic acid. These, however, are not to be called synthetic products, perhaps, in the same sense as a number of other hypnotics, of which the best known is called *sulphonal*. This substance has a well recognised formula, and may be regarded as methane, the hydrogen atoms of which have been replaced by ethyl groups and methyl groups, together with an oxide of sulphur. For some time sulphonal ranked as one of the best of all hypnotics for certain purposes. It was very widely used, and sometimes unfortunately abused. Then it was found that a modification might be made in sulphonal by the insertion of three ethyl groups instead of two in the molecule ; or four ethyl groups might be inserted. The substances thus formed are known as *trional* and *tetronal* respectively. Of these the first, trional, is in every respect without exception markedly superior to sulphonal. If trional had been discovered first and sulphonal later, no one would dream of employing sulphonal to-day. In course of time the diethyl compound will be entirely superseded by the triethyl compound. The tetraethyl compound, *tetronal*, is dangerous, and should not be used.

And now it appears that, directly in consequence of a research initiated by Fischer, trional itself will have to be superseded and replaced by a new synthetic product called *veronal*, which, for a very large number of cases, may be looked upon as, at any rate, all but the ideal hypnotic. This last drug is, so to speak, an instance of the survival of the fittest. During the last ten years the number of possible hypnotics of synthetic origin must have reached scores. As each new one comes out its effects have to be tried, and it is only now and again that one is found capable of replacing the drugs already known.

What the Chemists are Learning. Both in this case, however, and in the case of the production of artificial scents, colours, and other products, the purely experimental method is yielding to something of a higher scientific order. At one time the chemist worked almost in the dark ; he began with some suitable substance, such as benzene, perhaps, and then tried to fit various atoms or combinations of atoms on to it in the hope that "something would turn up." Now, however, this purely empirical method is being superseded. Chemists are learning, as we have seen, not merely that there is a necessary relation between molecular constitution and physical action, but also what the exact relation is in a number of cases, and so now the work can be done more methodically. Time need not be wasted by the mere manufacture of one compound after another—its novelty being the first consideration, but the chemist can work in definite directions, keeping firm hold, so to speak, of molecules or radicles which he knows to be valuable, and aiming only at the production of new molecules in which those properties will be retained.

So much by way of illustration; but we try to number ourselves, readers and writer, among those who, as Spencer puts it, "search for the wider meanings of facts," and we cannot leave this subject without reference to what we may call the philosophy of it. If we venture to employ such a daring term as *creative chemistry*, or to speak, as has elsewhere been done, of "the chemist as creator," we must inquire into the meaning of that term.

Nature is Commanded by being Obeyed. In a great epigram which we have quoted more than once, Bacon has summed up all the facts of the case and more. "Nature is to be commanded only by obeying her." Now, words like creative and creator may legitimately be applied to man in many of his acts. A great musical composition—such as, let us say, the third or fifth or seventh symphonies of Beethoven, or even a simple folk-song, may properly be called a human creation ; so, also, is a chair, a house, or a football; so, also, is "Paradise Lost." Man may be looked upon as the creating animal.

Now what does the word mean ? We who are students of science clearly recognise what the word does not mean. First, the chemist or the poet does not make something out of nothing, and, in the second place, whatever he makes, does, or creates, he remains the servant of Nature, to use Bacon's phrase, as well as her commander. The greatest genius cannot modify by a hair's breadth the smallest of Nature's laws. Not in this sense can Nature be commanded, and not in this sense can man create ; but if man choses to observe Nature's laws, to obey Nature, then he can command her in this limited sense. Thus the synthetic chemist will fail, and continue to fail, if he tries to make compounds in defiance of Nature's laws. If it be a fact of Nature that carbon and oxygen have an affinity for each other, there will never be any making of a compound which depend for its existence upon an antagonism between those two elements. If, on the other hand, the chemist will accept Nature's laws, then his intelligence is capable of directing them to his own purpose, and so producing new compounds which Nature herself would not have made, but which yet are made in obedience to her. This saying of Bacon's is one of the profoundest that ever emerged from a mighty mind.

Natural Law and Creative Works. Or turn from chemistry to poetry, or music, or art in general. There are artists in all ages and in all kinds of art who have never had a glimmering of the truth which Bacon stated. They think that they can create works of art without any reference to Nature. They think that they can use pigments, or sounds, or human emotions—which are all natural products—and create works of art therefrom without any reference to the laws of chemistry, the laws of vision, the laws of acoustics, or the laws of psychology. Contemporary musicians might be named, and poets and painters, who think that because they did not defy Nature, Beethoven and Wordsworth and Velasquez were not great men and were not creators. But these mighty geniuses did not set up their puny wills against the laws of the Universe; they obeyed Nature ; they obeyed her so well, and loved her so well—Wordsworth says that "Nature never did betray the heart that loved her"—that she allowed them to command her, and so they produced works of creative art which can never die.

The same is strictly true of every kind of scientific invention and creation, as well as of the creations of synthetic chemistry. All the men, without one solitary exception, who have commanded Nature in the past—the man who made the wheel; the man who built the Forth Bridge; the creator of the steam engine; Pasteur, the conqueror of disease; Galileo, the inventor of the telescope; or Perkin, the creator of the coal-tar dyes—have commanded Nature by obeying her. Only in virtue of their obedience are they creators. The countless men who have failed and are forgotten, or are remembered with scorn or pity, alike in science and in art, are those who either were unconscious of the existence of Nature's laws, and so fought against them unknowingly, or those who thought that they themselves were superior to the mighty universe of which they formed a part, and so fell; for Nature never forgives and never forgets. She accepts no excuses, she makes no exceptions, and the mother of all wits has never yet been outwitted.

Chemistry and the Imitation of Nature. And now let us consider the second of the great directions in which synthetic chemistry is advancing. The writer is endeavouring to invent easily memorable names which will aid the reader, and perhaps the term *imitative chemistry* will form a useful contrast to *creative chemistry*. The very best that the most brilliant chemist can accomplish is very little compared with the achievements of the living cell, which is the supreme chemist. An insignificant red cell, one of five millions that are to be found in two pins' heads space of the blood of Professor Berthelot, or Professor Fischer, is capable of making the compound hæmoglobin which those two great creators, aided by all the other chemists in the world, could not begin to imitate. Nevertheless, the chemical synthesis of vital products is making rapid advance, as we have already seen, and it is by no means inconceivable that even hæmoglobin, which is believed to be the most complex chemical substance known, and to contain more than a thousand atoms in its molecule, may some day be manufactured on the laboratory table at perhaps a thousand times the difficulty and expense with which it is manufactured in the blood of the boy who dusts that table in the morning.

The Limit to Imitative Chemistry. As in the last case, any detailed discussion of the accomplishments of this imitative chemistry is out of the question. There is no need to refer the reader again to Professor Meldola's recent book on this subject, but we must ask him to turn back to the quotations from that book which have already been made and to our comments thereon.

For it has clearly to be recognised that imitative chemistry, as at present practised, is imitative only in so far as the results are concerned. The chemist can imitate alcohol and various carbohydrates, for instance, and his *products* are identical in many cases with those of the plant. But the chemist does not imitate the *processes* of the plant. His methods are the same as those employed in "creative chemistry." Now the many successes of imitative chemistry must not blind us to the fact that, despite them, this imitative chemistry is not the real thing. While Nature's results are obtained, her processes are ignored. Hence we may be certain that there must be a limit to the artificial synthesis of the vital products, and that limit may soon be reached.

Chemistry Must go "Back to Nature." Chemists may find that they can go a long way in the manufacture of a large number of compounds which are produced by living cells for their own purposes. But it is very likely that the imitation of the most essential compounds found in living matter, the compounds which most truly express and perhaps condition its life, may be found impossible so long as chemists continue to employ processes which are not, of course, properly speaking, *unnatural*, since the laws of chemistry are always observed in making them, but which, at any rate, are not the processes which Nature chooses to employ.

It seems probable, then, that if this branch of chemistry is to achieve its utmost it must go "back to Nature," and attempt to imitate the processes which she prefers, though they are evidently not the only processes she permits, for the making of these compounds. It might then be found—in fact, nothing else could be found—that the adoption of the processes employed by the living cell would enable imitative chemistry to do all that the living cell can do. But there is a great difficulty in our way.

What we are asking chemists to do is to imitate the unknown. No chemist in his senses would dream of employing high temperatures and powerful reagents for the manufacture of these compounds if he were able to employ the cell's own processes. He uses his own methods merely because he cannot imitate methods which he does not understand. Indeed, the supreme problem of chemistry at this hour is the understanding of the chemistry of life, and to this topic we must soon turn.

Can We Make Radium? But before we pass to this difficult and fascinating subject, allusion must be made to a new kind of synthetic chemistry, of which chemists are beginning, just in these last few months, to perceive the possibility. It need hardly be said that it is radium which has opened out this new prospect.

The synthetic chemistry of which we have been speaking is the synthesis of compounds, and, of course, anything which is the product of synthesis, or putting together, must necessarily be a compound. Only a few years ago, to speak of the synthesis of the elements would have been considered as foolish and meaningless as to speak of their analysis. The essential idea of an element was of a something which could neither be put together nor taken to pieces. But we now believe that the atom of any element is not really atomic or indivisible. It has been conclusively demonstrated that the atom of radium, for instance, is capable of analysing itself, so to speak, into smaller parts, among which in all probability five atoms of helium may be numbered. It seems to be impossible to control the analysis of the elements, but it is certainly possible to observe it.

Now, this necessarily suggests to the mind the possibility of the converse process. If radium be capable of analysis, may it not be possible to build it up by synthesis of its parts? This conceivable synthesis of the heavier elements is the new possibility which, like its predecessors, is certainly worthy of the name synthetic chemistry—far more worthy, indeed.

The Genesis of Radium. These words are fortunately written just late enough for reference to an extremely important controversy on this point, which was started by Lord Kelvin in a letter sent to the "Times" in August, 1906, and which called forth the most recent views of such distinguished workers in radio-activity as Sir Oliver Lodge, Mr. Frederick Soddy, and the Hon. R. J. Strutt. If the reader will recall what was said when we were discussing radium, or will turn back to those sections of our course, he will be able rightly to value the remarkable suggestion made by Lord Kelvin in his third and last letter.

Lord Kelvin accepts the statement that the life of the radium atom is finite (perhaps 1,800 years, which is Professor Rutherford's latest estimate), and yet he is inclined to question the belief of workers at the subject, that radium is an evolutionary product of uranium. Mr. Strutt, therefore, asked him what theory he held as to the origin of the radium now existing on the earth. No one would suggest that this radium was made by "special creation" 1,800 years ago, and if it is not derived from the uranium, with which it is always associated, whence comes it? In reply to this, Lord Kelvin suggests that the radium atom may be formed by a "concourse of atoms" crushed together, so to speak, in the course of the condensation of the nebula from which the solar system and all the parts thereof are formed.

Did the World Begin as One Huge Atom? In other words, Lord Kelvin suggests that the large compound atoms, as we know them, may have been formed by a process of natural synthesis, and this is a suggestion worthy of the most careful thought. The reader will remember that hitherto opinion has been inclined—accepting the view that large atoms, such as those of uranium and radium, break down into smaller ones—to suppose, as Professor J. J. Thomson puts it, that the known universe must have begun as one huge atom, of which all contemporary atoms are disintegrated parts.

The idea suggested by Lord Kelvin is that the process of atomic evolution has two phases, and may be, indeed, a balanced process. Without making any assertions as to Lord Kelvin's beliefs (which, it must be confessed, are somewhat difficult to define), we may, at any rate, realise the possibility that atomic synthesis as well as atomic analysis—building up as well as breaking down—is occurring at the present time. The idea that the whole history of the universe is a continuous process of the analysis and disintegration of one mighty atom is beset with a thousand difficulties, and yet we have seen that it has been suggested as the apparent inference from the facts of the natural analysis or breaking down of large atoms, which have lately been discovered.

Breaking Down and Building Up Atoms. It seems to the present writer that these difficulties disappear if we conceive that both processes may be in operation according to the conditions. On the one hand, there may be breaking down of large atoms into more numerous and smaller ones; but, on the other hand, there may be a reciprocal process of natural synthesis, or "concourse of atoms," to use Lord Kelvin's phrase, whereby numerous small atoms are merged into one another so as to form larger and more complex ones, such as the atom of radium. Indeed, to the present writer it seems that there is no warrant for the assumption that the atom of radium must either be formed by analysis of the larger atom of uranium, or else must have been formed by synthesis of, probably, one atom of lead and five atoms of helium. Lord Kelvin stated: "Radium (atomic weight, 225) may be a compound of five atoms of helium (atomic weight, 4 × 5) and one atom of lead (atomic weight, 205)." Why should we be asked to take one of these views as true and reject the other as false? There is nothing contrary to what is known in the belief that both views may be true. In the case of such a compound as carbonic acid we know perfectly well that it may be formed, on the one hand, by the decomposition or analysis of a carbonate, or, on the other hand, by synthesis of carbon and oxygen directly. Similarly, there is no reason why, under appropriate conditions, that complex compound which we call the atom of radium should not be formed by analysis of the still more complex compound called the atom of uranium; or why, under other conditions, it should not be formed by concourse or combination of atoms of lead and helium—which may, perhaps, be a synthesis as natural as the synthesis of oxygen and carbon to form carbonic acid.

An Artificial Concourse of Atoms. Though Lord Kelvin would seem to be the first to have suggested the natural synthesis of the elements, a year or two has now passed since Sir William Ramsay recognised the possibility of the artificial synthesis of heavier atoms by means of lighter ones. We already know that the transmutation of the elements under certain conditions is a fact, but the only transmutations we know are those of larger atoms into smaller ones, incredible quantities of energy being meanwhile evolved. We know no instance as yet of the new synthetic chemistry which would consist of the making of large atoms from small ones. There is a fundamental distinction between the two processes. In the former, energy is evolved; in the latter, which as yet we can only imagine, energy—and in enormous quantities—would have to be supplied.

Now, it looks as if the supplying of energy for the purpose of this "concourse of atoms," or atomic synthesis, whether natural, as Lord Kelvin supposes, or artificial, as Sir William Ramsay expects to achieve, must involve an infraction of that law of the *dissipation of energy* and its loss of availability, which Lord Kelvin himself first discovered, and which has been discussed in the course on Physics.

We cannot here expect, however, to anticipate all the discoveries and solutions of the future, and so we must now leave imperfect—like all other human knowledge—the study of synthetic chemistry in its various forms.

The Chemistry of Living Things. Two great subjects remain for brief treatment ere we conclude this course. Of these, the first is the chemistry of life and living processes. Incidental reference has often been made to vital chemistry in preceding pages, but here it will be well to state the main facts in a systematic way, and, first of all, as to what constitutes the peculiar character of vital chemistry.

The first proposition which must here be repeated is that all the known laws of general chemistry are strictly and rigidly observed by living matter. No form of living matter that we know is capable of annihilating or creating an atom out of nothing, or of destroying or creating energy. The law of the conservation of matter, with the reservation involved by the study of radio-activity—is observed in the chemical processes of living creatures, and so also is the law of the conservation of energy. Secondly, no element is found in living matter that is not found elsewhere. Thirdly, the elements found in living matter are in every respect identical with other specimens of the same elements occurring elsewhere. Fourthly, no processes are known to occur in living matter that cannot be imitated more or less successfully outside it. This is true even of the remarkable process called fermentation, which is very extensively employed by living matter for its own purposes.

Having insisted on the ultimate identity of the laws that govern all chemistry, including the chemistry of life, let us now state the general facts which the world of life displays to the chemist.

The Wonderful Cycle of Life. For a very long time the vegetable and animal kingdoms have been regarded as forming the two divergent limbs of the great V of life—both kingdoms having their origin, it was supposed, in some primitive organisms that were neither animal nor vegetable. This conception, however, which involves much confusion from the chemical point of view, must be modified not only for that reason but for other positive and final reasons which it is not our business to discuss in this course. On the contrary, we may be assured that the first living things were essentially vegetable and that the animal world is an offshoot from the vegetable world. If we clearly retain this idea, we shall be ready to understand the next paragraph.

In considering the chemistry of living things we must plainly begin with the plant, which is not only the ancestor of the animal, but is also the necessary source of its food; for, even if we are not vegetarians, what is the ox but transformed grass?

Let us consider, then, the typical plant. It displays in its vital functions that transformation of energy with which the student of physics is always familiar; but we have already stated that the plant, though a living thing, offers no exception to the law of the conservation of energy. Whence, then, is the energy which the plant transforms?

Transformed Sunlight. The sun is the source of the energies displayed by all living things, whether animal or vegetable. The motion of the eyelid which intermittently cleanses your eye-ball with a tear as you read is transformed sunlight. Now, let us see how this works out.

The energy which constitutes sunlight—including many rays which are invisible to our eyes—is focussed, so to speak, by the chlorophyll of the plant leaf. In virtue of this influx of energy, the living protoplasm of the cells of the leaf is enabled to effect that extraordinary dissociation of carbonic acid which we have already discussed. On the other hand, the plant elsewhere obtains water and inorganic salts, which include among their constituent elements nitrogen, sulphur, and phosphorus. The upshot of the plant's activities is the formation from these food materials—on which *we* should so soon starve—of the countless complex organic compounds, a few of which we have already discussed. In them the kinetic energy of the solar radiation is still conserved in the form of what we call potential chemical energy. The plant does not create energy, but it is an incomparable collector of it.

The Energy of the Plant. On the other hand, the plant, like every living thing, is also a dissipator of energy. Living protoplasm, whether found in the plant or in the animal, must breathe—must take in oxygen and give out carbonic acid and water. But the breathing of a plant, though necessary to its life, is a very much less rapid process than the breathing of an animal. The plant has not much occasion for the using up of energy. One great distinction between the plant and the animal is that the food of the former comes to it while the latter has to find its food. Thus, the plant is not under the necessity of using up much energy for purposes of locomotion, whereas the animal, which has muscles and uses them, must breathe extensively in order to obtain the oxygen which burns up its food within its body with the transformation of potential energy into kinetic energy.

Therefore, though we must never forget that a plant breathes and must breathe, we look upon the plant as, on the whole, a synthetic chemist —a converter or transformer of kinetic into potential energy.

The Ancestor of Us All. The sun shines upon animals as well as plants, but animals have no apparatus whereby they can transform the kinetic energy of sunlight into, for instance, the kinetic energy of muscular motion. The carbonic acid of the atmosphere and the nitrates and phosphates in the soil furnish no diet for the animal. *The animal world is absolutely dependent for its existence upon the vegetable world, not only because the vegetable world is its ancestor but because the vegetable world is its daily bread.* Now, just as the plant is typically a *synthetic* chemist so the animal is typically an *analytic* chemist, breaking down that which the plant built up. The potential chemical energy thus obtained, which, be it remembered, is transformed sunlight, is converted by the animal into kinetic energy which, in some cases (as, for instance, the light of the glow-worm) may be absolutely identical with part of the light which it originally was. But muscular motion is the most common form which this energy assumes. Lastly, the animal dies and returns to the dust. There its body is resolved by microbes or bacteria—the indispensable part played by which in the existence of man himself upon the earth must be discussed in the course on Bacteriology—into simple sulphates, phosphates, and nitrates which we call manure, in which form they are again taken up by the plant. So said Tennyson:

> " And from his ashes may be made
> The violet of his native land."

Perhaps the writer may be allowed to quote his own previous expression of the significance of this: " As we dwell, we living things, in this our ' Isle of terror,' each of us is inalienably bound to all the rest. So you may be selfish for a century, but at the last others will claim your dust. For altruism is the law of Nature."

The Chemistry of Food: A Life for a Life. Many a large volume might be written upon the chemistry of diet; here we are merely concerned with the principles, and must endeavour to reduce the multifarious diet of the many kinds of animals that inhabit earth and sky and sea to their simplest terms.

Every animal (as, for instance, a man or a sea-anemone) must have a supply of water and a supply of certain inorganic salts. In so far as these two items are concerned the needs of the whole living world are identical, for plants also must have water and salts. But if the plant has water, salts, and the ordinary gases of the air, it has enough or a feast. On the other hand, the animal, and this is true of all animals, must have some kind of proteid and, in the last resort, this proteid is invariably a vegetable product. The plant made it out of its raw materials—having easily solved the problem at which synthetic chemistry is still heavily labouring—and the animal uses it. For our present point of view it matters not a straw whether the animal be a cannibal who obtains his albumin by eating the muscles of a fellow man, or be a cow munching grasses. In the last resort, the vegetable world is the source of all proteids for all animals, and we are not here concerned with the appalling morel questions which arise in relation to Nature's apparent law, *a life for a life.*

Animal life can be sustained on water, salts and proteids. If the diet contain these three constituents alone the animal body will yet be found to contain *fats*, and *carbohydrates* such as sugar. Now, we know for certain that the animal is incapable of synthesising fats or sugars from their elements or from simpler compounds, and we have clear evidence that when proteids, salts, and water constitute the whole diet, the proteids supply the source of the carbohydrates and fats which the animal body displays and utilises. This one fact will give us some little idea of the almost incalculable complexity of the proteids, and the appalling nature of the task which the synthetic chemist essays when he attempts to synthesise an artificial proteid.

The Three Essentials to Life. But in actual practice it is found that the animal, including man, takes carbohydrates and fats *as such* in its diet, and so we have five distinct items constituting the food of a man: proteids, fats, carbohydrates, salts, and water. In certain cases the second may be dispensed with; in certain cases the third; life may continue if both second and third be omitted; but if either the first, fourth or fifth be withheld death necessarily follows.

The vegetable body requires food, partly for the accumulation of tissue and partly as a source of energy; but we have seen that the vegetable body spends scarcely any energy. The animal body also requires food for two purposes, and two alone—the making of tissue and the supply of energy. The water and the salts are necessary for life for a number of reasons, though they cannot clearly and definitely be included under either of these purposes. The animal's expenditure of energy is extremely high, and by far the greater part of its food is required for this purpose. The fats and carbohydrates are the principal sources of the potential chemical energy, most of which the animal will convert into motion. These failing, the proteids will be used, but when a suitable diet is employed the proteids are very little used for this purpose, their main concern being to replace waste of tissue. Proteids, indeed, are the chief constituent of all protoplasm. Vegetable protoplasm makes them and animal protoplasm snatches them, ready made, from the vegetable.

Proteins—the Principal Food Substances. We are using the term most commonly employed in this country for those extraordinarily complex compounds which, in certain varieties, are the chief constituents of all living things. At an important scientific meeting in Canada, in the autumn of 1906, some steps were taken, however, to obtain a greater uniformity in the nomenclature. At present, the words *proteid, albumin,* and *albuminoid,* are frequently used interchangeably, but the splendid work of Emil Fischer has necessitated a more precise nomenclature. It is therefore desired by those in authority that the term *protein* should be employed as the general name for all those substances. It is at present so used in America and to some extent in Germany. These proteins, then, as they will be commonly called before long, may be divided, largely in consequence of Fischer's work, into about seven groups, or sub-classes. It is possible to make artificially certain substances which belong, or all but belong, to the simplest of these sub-classes—the group known as the *protamines.* From these, which are relatively simple, we pass in increasing complexity through a special *albumin,* such as egg albumin, through such a substance as gelatin, which is rather more complex still, on to the *gluco-proteins,* such as mucin, the characteristic constituent of the stuff called *mucus,* which is produced by mucous membranes, on to the *nucleo-proteins,* and at last to the coloured or *chromo-proteins,* the most celebrated and complicated of which is hæmoglobin, the red colouring matter of the blood.

The Most Familiar Proteins. Of course, it will be some time yet before the term proteid is discarded. It is the generally recognised word in this country, and we have employed it everywhere except in the last paragraph. But we desire that the reader should not be confounded when he meets the word protein, as he certainly will do more frequently every succeeding year.

We may quote from Sir William Ramsay a very brief description of the most familiar sub-class of the proteins. It contains the main facts in very small space.

"Albumins are the chief constituents of animal organisms. They are soluble in water, but are precipitated by warming their solution, or by the addition of strong acids—copper sulphate, mercuric chloride, basic lead acetate, etc., and also by tannic acid or alcohol. They turn yellow when boiled with nitric acid; give a red colour with Millon's reagent (a solution of mercuric nitrate containing N_2O_3); and violet with caustic soda and a trace of copper sulphate. They combine with both acids and alkalies. They contain sulphur. When hydrolysed by boiling with baryta-water, the chief products are amido-acids, such as amidoacetic acid (glycocoll), amidocaproic acid (leucin), etc. They are converted by gastric juice (pepsin) into a soluble grey mass, named peptones, which are not coagulated on boiling."

Chemical Processes in Living Matter. Utilising the Greek word *Bios,* life, chemists now frequently speak of bio-chemistry in order to indicate the study of the chemical processes that occur in living matter. This term has the advantage that it is almost identical in all languages—an advantage common to words of Greek origin and largely explanatory of their wide use—and it has the further advantage that it avoids the term *vital;* which is apt to suggest the theory of Vitalism, unless that theory has been explicitly discussed and abandoned, as in our case.

The study of the proteins is the cardinal necessity for the bio-chemist, and in our brief discussion of the subject we shall utilise the volume just published by Mr. John Murray, under the title "Chemistry of the Albumins," by Dr. S. B. Schryver. This volume consists of lectures delivered before the University of London, and is one of the quite invaluable series of such volumes which have been issued under the auspices of that great institution since it became a teaching reality and not a mere examining body. It is necessary to add that Dr. Schryver uses the older terminology, and that what he calls albumins, for convenience, are now to be known as proteins.

We cannot here discuss the modern theories as to the constitution of the various albumins, the possibility of the crystallisation of some of them, as, for instance, hæmoglobin, or the extremely important question of the various degradation products of the albumins, recently studied with splendid results by Fischer and his pupils. Briefly, we merely note that among these degradation products are included fats and carbohydrates. These are demonstrated chemical observations, and are in strict correspondence with what was said above when we were discussing the dietary groups. Also, we can only refer the reader to these extremely valuable lectures for a discussion of the chemistry of hæmoglobin, with the importance of which the reader is already acquainted.

Three Fundamental Facts. Here, however, we must attend carefully to the theories of bio-chemical action, which the author discusses in his concluding lectures, and which are of transcendent interest on every ground. And first, as to definite facts. There are three which are obvious and fundamental:

1. *That the organism is in a state of constant change.* "To live is to change," says Cardinal Newman, somewhere; and this is true not only of the psychical life, but also of the physical. Ceaseless change in the molecules of living protein is a necessary condition of life wherever it is manifested.

2. *The molecule of the albumin,* which performs the normal chemical function necessary for the maintenance of life, compared with ordinary molecules, *is of enormous size and very unstable;* it loses many of its properties on the application of a very moderate amount of heat.

3. *The chemical reactions necessary for the maintenance of life take place within very narrow limits of temperature.* Furthermore, these temperatures are very much lower than those which are otherwise found necessary. For instance, a commonplace in bio-chemistry is the oxidation of fats and carbohydrates by means of the oxygen of the air at the temperature of the body. "Hence," says Dr. Schryver, "we are dealing with abnormally large molecules which are constantly bringing about chemical change at a temperature of about 37° C., which changes occur *in vitro* (that is, in a test-tube) only at higher temperatures, and with the use of energetic chemical reagents which do not exist in the body. We are forced, therefore, to seek for some special explanation of bio-chemical reaction."

Life "A Series of Fermentations." Now, it appears that the explanation of the possibility of these reactions under these conditions must ultimately be expressed in terms of what we know as *fermentation*—in short, putting the matter unphilosophically, crudely but memorably, "life *is a series of fermentations.*"

The technical term employed is *catalysis* or *catalytic action*. This term is rather wider than the term fermentation, but all fermentation comes under its heading.

A ferment is a substance which induces chemical change by its presence, without itself undergoing any change. The most familiar instance is the pepsin which Sir William Ramsay mentions in the quotation above. More powerful than the pepsin of the stomach is the trypsin which is produced by the pancreas or sweetbread. These substances, without themselves undergoing any change, are capable of breaking down the ordinary albumins of the food in such a fashion that they are afterwards capable of absorption into the blood.

Ferment Action. A ferment, or *enzyme*, as it is often called, is a product of the living cell, and is highly complex in composition, but it is possible to find outside the living body parallels to the action of a ferment. For instance, we know that the peroxide of hydrogen, in the presence of platinum black, is decomposed with the evolution of free oxygen, while the platinum remains unchanged at the end of the reaction. Various theories of ferment action have been advanced, but it suffices for us to note here that the reactions due to ferments in the body are rarely, if ever, much more complicated than this catalytic decomposition of peroxide of hydrogen ; indeed, we may say that oxidation, reduction, hydrolysis, and dehydration will include all, or practically all, the forms of ferment action. Furthermore, the chemical changes induced by ferments are usually such as would be apt to occur in any case though not at such a speed. This will explain the important definition of Professor Ostwald, who is one of the greatest living students of the subject : " a catalysor is a body which, without appearing as an end-product in a chemical reaction, alters its velocity."

Theories of Bio-chemical Action. The oldest theory of bio-chemical action contains as its essential part the proposition that the living molecule (as, for instance, in the contractile cell of a muscle) is capable of taking up oxygen into itself, which is thereby held at the disposal of the organism for the purpose of oxidation. The reader is familiar with this theory.

We have referred to the next theory, that of Pflüger, which assumes the truth of the theory of intra-molecular oxygen, and the special character of which is its insistence upon the potential energy in the cyanogen group assumed to occur in the living albuminous molecule. Many subsequent observers have restated this theory in various forms.

Later, we have the remarkable theory of Ehrlich, who conceives of the whole protein molecule as having a ferment-like action, part of it being specialised for the purpose of anchoring oxygen to the molecule, and another part being specialised for the purpose of anchoring various oxidisable substances, with obvious consequences. To Ehrlich we owe the idea of specialisation of function within the molecule. This is a very great advance. The theory is often known as the *side-chain theory*.

Then, only three years ago, Professor Verworn combined the side-chain theory of Ehrlich with the theory which assumes the existence of substances which can act as oxygen carriers, and with the theory of intra-molecular oxygen. This, which is known as the *biogen* theory, will undoubtedly require much modification, but at the present time it may be regarded as the best working hypothesis available.

The Chemistry of the Stars. Space does not here avail of the discussion of what is usually known as *physiological chemistry*, which discusses the particular chemistry of the various organs and tissues of the body ; we have preferred to discuss the more fundamental subject of bio-chemistry in general.

And now we must turn from the chemical discussion of life upon our little earth to a study of the chemistry of the illimitable heavens. This is a subject for volumes, and here we must merely state the main outstanding facts. Elsewhere in this course, and in the course on Physics, the reader has made acquaintance with the method by which many facts of the chemistry of sun, stars, comets, and nebulæ are as positively known as if portions of those heavenly bodies had been sent by celestial post to the chemist's laboratory. We know that there is no more certain evidence of the identity of the atoms of any substance than the characters of the light which those atoms give out when the substance becomes luminous. Thus, by means of the spectroscope and spectrum analysis, we have acquired knowledge which some of the wisest thinkers of not so long ago declared to be forever beyond the reach of the human mind.

Is Evolution Universal ? The first amazing, yet utterly natural, fact is that the elements of which our own bodies and our surroundings are composed also constitute the heavenly bodies. In the light of the most recent knowledge it is, perhaps, not possible to say without some qualification that we know of no elements in the heavens that are not found on the earth. We may undoubtedly believe that there is no kind of celestial stuff which is utterly distinct from terrestrial stuff ; but it is quite possible that there may be represented in the heavens, stages or forms of atomic evolution with which we do not happen to be familiar in this our little moment of time, and upon this our " lukewarm bullet," as Stevenson called it. In Sir Norman Lockyer's opinion there is, for instance, an element characteristic of the corona of the sun, and this element is known as *coronium*. But though this were so—and a thousand instances beside it—the fact would remain that there is a real identity of composition alike in heavens and earth. We may also remind ourselves of the celebrated case of helium, discovered about a quarter of a century ago in the sun, and named accordingly, but now known to occur upon the earth also.

The study of inorganic evolution in its widest sense includes the study of the evolution of atoms and the evolution of planets, suns, and stars. But we must not confine ourselves merely to atomic evolution as it has lately been recognised in the laboratories of earth. It is surely extremely probable that atomic evolution also occurs in the heavens. Our minds having been prepared by recent knowledge, we should think it very strange indeed if no case of atomic dissociation could be recognised in the sun.

Evolution in the Heavens. Now, Sir Norman Lockyer has devoted a great part of his life to the study of this subject. He has shown, what is now a commonplace, that the spectrum of an element alters with alterations of temperature; and no modern student of radium and its revelations can doubt that these changes are due to atomic changes within the luminous substance that is examined, and, in the upshot, that these atomic changes are due to atomic dissociation. Thus, in the case of iron, which is known to occur in the sun, there is reason to believe that such atomic dissociation occurs. Says Professor Duncan: "In one part of the sun, called the 'reversing layer,' the spectrum of iron is represented by nearly a thousand lines. In another part of the sun, called the 'chromosphere,' which is apparently at a much higher temperature, the spectrum of iron is reduced to two lines only. It is difficult to see what other explanation we can assign to this remarkable fact than that at the higher temperature of the chromosphere the atom of iron is decomposed or dissociated into some simpler constituent which appears at that point. This explanation is rendered additionally valid by the further fact that in sun-spots one set of iron lines is found, and in the chromosphere, quite another." These and other reasons lead us to suppose that in the sun, as Lockyer says, "we are not dealing with iron itself, but with primitive forms of matter contained in iron which are capable of withstanding the high temperature of the sun after the iron, observed as such, has broken up." Similar evidence can be adduced to show that other elements, such as magnesium and calcium, are also dissociated in parts of the sun.

A Constituent of the Hottest Stars. The stars also yield evidence of the same thing, not only in the case of these metals, but also in the case of many others, such as copper, chromium, and strontium. The term *proto* has been applied (until further knowledge) to the names of the dissociated constituents of the element as they are found in the sun and stars. Says Professor Duncan: "A very important proto-element is proto-hydrogen, discovered by Professor Pickering of Harvard University," in a certain star. "The spectral lines representing this substance Pickering at first supposed to signify a new element; but he was able to show later that they belonged to a new series of hydrogen lines constituting a form of hydrogen unknown on earth." This proto-hydrogen has since been discovered in other stars, and it is extremely noteworthy that the stars in which it occurs are the hottest stars known.

The Temperature of the Stars. Now, this last fact leads us to a brief discussion of the great theory of Lockyer, that atomic evolution in the heavens is an orderly and continuous process, dependent upon orderly and continuous changes of temperature in the stars. The study of the light given out by various stars seems to show quite clearly that they vary in temperature, and Sir Norman Lockyer has divided the stars into three groups: *gaseous stars*, *metallic stars*, and *carbon stars*, the first group being of the highest temperature and the last group of the lowest. We may say, in a word, that the evidence of comparative temperature depends, as in the case of a heated poker, upon the comparative lengths of the spectra given out by the stars.

Examining the stars in this fashion, Sir Norman Lockyer finds that the chemical composition of a star varies with its temperature. The hottest gaseous stars seem to consist of comparatively few gaseous elements; then it would appear that as the star cools there occurs some such "concourse of atoms" as Lord Kelvin has lately been writing of.

Fascinating though it be, chemistry is not the only subject needed to make an educated man, and we must bring our present study of it to a close. We have merely opened the door to endless wonders, and have peeped in for but a moment.

The Future of Chemistry. In arranging the proportions of our vast subject we have deliberately recognised the all but overwhelming importance of recent work in chemistry. We have not at all followed the orthodox lines of an elementary chemical textbook; but the truth is that those orthodox lines will very soon cease to be orthodox, and that a vast proportion of the reactions and technical processes, descriptions of salts, and so forth, which now occupy so much of the chemical textbooks, will be regarded as no more worthy of a place in a discussion on chemistry in general than, let us say, the minute details which distinguish the muscular anatomy of the tail of one kind of fish from that of another kind of fish will be deemed worthy of a place in a general textbook on biology. Though principles depend upon details, and though one little fact is quite sufficient to overthrow the greatest of generalisations, yet we must recognise that for the purposes of education the details are but means to an end, and that that end is the *knowledge of principles*.

The writer takes leave of his readers with the utmost regret and with the earnest hope that here and there he may have imparted to them some of the interest which his fresh review of the subject as a whole has excited in him. He can scarcely think that anyone has enjoyed reading this course as much as he has enjoyed writing it, but at least he hopes that the pleasure has not been all on one side. And we may hope, also, to meet again!

Chemistry concluded; followed by
APPLIED CHEMISTRY

For the Best Books on Chemistry the student should see the discussion at the end of PHYSICS.

THE SHOEMAKER AT HIS LAST

Top Boots. Shaping the Last. Lasting, Welting, Sewing and Stitching. Trimming. Shaping. Soling. Shaping and Paring. Finishing

continued from page 4018

By W. S. MURPHY

Top Boots. When it ceased to be the ambition of every respectable young man to possess a pair of fine top boots the bootmaking trade declined in its most artistic and profitable branch. A top boot is a big job, and calls for patient care, deft hands, and a good eye for effect. We do not refer to the coarse things that are made for ostlers and stable-boys, but to the boots of gentlemen. This trade is still the mainstay of many hand-working shoemakers. Riding, cavalry, and livery boots have all special models, and the civilian top boot differs from them all. What distinguishes tops from every other form of boot is the long leg and the plain front. Horsemen's boots of the lower class are simply plain-fronted boots with leather stove-pipes stuck on to them. But the best class tops are one piece of fine leather from head to toe, with side-seams joining backs and fronts, lined with fine chamois or morocco, and topped with a broad band of soft leather.

Making the Top Boot Upper. When measuring for top boots, the length and thickness of the leg must be taken as well as the proportion of the ankle. Every fraction of an inch in the limb has its graduation to be accounted for, if the boot is to fit properly. Cutting tops is anxious work, and can be safely undertaken only by skilled workmen. The best way of acquiring the requisite skill is study of good models and instructions from a practical man while he is at the work. Having got all your stuff gathered for the tops, the next business is to sew and shape it. The long side-seams, the stiffening of the backs, the shaping of the fronts, the fine adjustment of the linings, take much patience and skill. Then every seam must be flattened out to almost invisibility. But when all is done, the result is worth the pains; you have a splendid boot, fit to be worn by a king—that is, always provided that the soles and heels are worthy of the tops.

No matter how well it has been sewn, the boot top is rather an unshapely thing, but we have the remedy. Made of hard wood, and fashioned to the shape of the human foot, the last is the mould of the boot. The best kind of last [33] is in two parts, the lower half representing the body of the foot from the middle of the ankle, the upper part giving the front of the leg and the instep. Over this block the top is stretched and shaped.

Stock of Lasts. Lasts are cheap, and it pays to keep a large stock of them. In addition to a pair of lasts for every size, it is good policy to keep special lasts for particular customers. A first-class shoemaker generally has a large number of lasts rented or owned by customers, for whom they have been specially prepared and kept.

Shaping the Last. With the measure and notes in hand, we go to the last rack and take down the lasts required. If no size corresponds exactly with the measures, we take the nearest in size, and begin to work. For lengthening, put a neatly pared piece of leather on the heel, like a pad; lay a toe-cap on the toe. For a higher instep, cut a neat long patch and put it on the instep, and so on for all other peculiarities. The pieces must be finely graded or skived, so as to fall in with the general outline of the last, and pasted firmly on. The ideal last is flat on the heel and under the toe-joints, and finely tapered on the top of the toes.

Cutting Out. If a shape be not already in existence for this last, we have to cut one exactly the size and shape of the sole as a guide for finding the size of the insole. With this and our measures we go into the leather store. Insoles should be of good body, but thinner than soles, the leather from the shoulder of an average hide suiting well. Cut out to shape from the hide, reserving scraps for packing. From the same hide cut the stiffeners.

Sole Cutting. Next lay the hide of sole-leather on the cutting table and cut off right and left soles rough to measure. This leather should be stout, firm, yet flexible, of a brownish buff colour shading to dull white. Last are the welts. Some bootmakers buy these ready-made, of an oil tannage; but they may be cut from a well-tanned English shoulder that has been shaved evenly. Cut strips over ⅜ in. broad, the cross-way of the hide. Gather the stuff together, and fling it all into a tub of water, sousing well over. When all have been thoroughly soaked, take out everything but the welts, and lay out in an open place to dry free from water.

Blocking the Insole. While still damp, the insoles are scraped and lightly beaten smooth with the broad hammer, stretched on the lasts, tacked down, and left to dry in shape. As soon as they are firm, the insoles are cut neatly to the edge of the last, the sole lined across into three parts—the heel, the waist, and the fore part—and skived away finely at the waist. Keep the curve well within the sides of last, cutting deeper to the inside of the foot. The insole has to be sewn to the upper, and the operation is a delicate one. To make it as easy as possible, we hole the insole by itself. Round the edge of the insole make a bevel, or feather, about ½ in. broad, cut sharply half through the leather at the inside, and tapering to the edge, forming a corner all round the sides of the insole.

Take the awl and strike holes from the face of the insole to the surface created by the feathering. It is plain that if a thread is passed through those holes, a strong catch will be formed.

Lasting. Lace the top neatly with a strong leather lace up to the bend of the foot. Sit down on the bench, put the last between your knees, heel to the left, place the top evenly on the last, and pull it strongly down, drawing more to the toe than the heel. This done, turn the last sole upwards, and take the heel between your knees; pull the toe of the upper over the toe of the last and tack it into place. Watch carefully that the top is centred on the last, and then begin tacking all round. For pulling down the top we are provided with a pair of fine strong pincers. Begin round the toe and work evenly along both sides to the heel. Before fixing up the sides, however, we put the side linings in between the linings of the tops. When the top is being folded down on the last, wrinkles and pipings naturally form; these must be beaten out and tightened over, or unsightly work will be the result. Sometimes the last is hard to drive into the top, and we have many recipes for overcoming the difficulty easily; but we know of none like intelligent ingenuity and patience. The top has to be made smooth over the last, and the job can be done.

33. KNIFING A LAST

Welting. From lying in the tub all this time, the welts are soaked with water; strike the surplus liquid out by rubbing down with a hammer handle, or anything handy; then skive the inner edges on the grain side. Take the one you are going to work with, and fit it round the sole of the last, marking where the creases caused by the turnings are highest. Cut the creases out, taking care not to lessen the strength of the welt. A welt properly shaped lies as flat and keen as a knife blade. The welt should come up the sole to about the end of the waist, and no further. If too long, cut off the ends.

Sewing and Stitching. Our work up to this point has been preliminary; the serious and important business begins now. Have ready several threads, seven-ply, well waxed, and with strong bristles on the ends; put on the sewing-mittens—skeleton gloves that leave the fingers and thumb bare, and protect the palm and back of the hand; set the boot between the knees, heel outward, and bring the belt over the waist of the boot, tightening it with your left foot on the buckle. Start sewing on the side nearest the left hand; drive the long point of the awl through the hole in the insole, through the welt, and bring it out through the top or upper, and up through the welt. Send one end of the thread the same path, and draw till half is on one side and half on the other. Pierce with the awl again; put the bristle in the right hand through from above, and the bristle in the left hand through from below; grip the bristle coming up with the right hand, and the other going down with the left; draw firmly yet gently, winding the cords round your hands to get purchase, and then tug once, twice, thrice, with a swimming action, to drag the threads through [**34**], and give a last firm tug to tighten the stitch. For this operation strength and intelligence are required in equal proportions. Mere force will break the insole or tear open the path of the thread. After careful practice, the art comes naturally, and the skilled bootmaker mechanically forms the stitches firmly and accurately. In this way the whole welt is sewn, and the insole, top and welt, all firmly joined together.

Sewing Round the Heel. On the heel we have no welt, and the top must be joined in some way to the insole. Nothing could be simpler. Take a new thread, send the awl curving as before through insole and top, sew strongly round, and secure by a knot at the end.

Trimming. As stitch after stitch was made, the tacks holding the top to the last were taken out; but there are yet other trimmings to be done. Rough edges come up from the upper, and the welt protrudes over the waist. For hunting and other classes of heavy boots, the welts are left on; but in ordinary boots the welts are reduced at the waist. All the superfluous stuff on top and welt has to be finely pared off, but not so closely as to weaken the stitching. When this has been done, the seams should be hammered down smooth with the flat head of the broad hammer, care being taken to avoid bruising the stitches.

Soling. Between the surface of the insole and the level of the welt there is a difference which must be filled up. A padding of felt is favoured by many shoemakers, and for light boots it does very well; but soft felt cannot add anything to the strength of a sole, and our duty is to make it as strong as possible. Scraps of good leather, skived to a uniform thickness and neatly built to each other, form a strong packing.

Paste all over the insole with thick, strong paste, and lay in the packing, pressing down smooth Over this brush a coating of paste, and fix on the sole.

Beating the Sole. Before putting on the sole, however, we subject it to some hard treatment. Lift the heavy iron lapstone on to your thighs, smooth face upward; take the broad-faced hammer in your right, and the sole in your left hand; lay the leather, flesh side upward, on the lapstone, and hammer firmly and evenly from the centre of the sole outward. Our object in the operation is twofold—first, to weld the fibres of the leather together; second, to give the sole a smooth surface on both sides.

Shaping. Another point should be mentioned here. In heavy boots the sole is put on just as it is with, of course, the necessary paring; but light boots and those to be finely shaped have soles skived on the under side of the shank, a broad crescent on each side thinning the leather towards the edges.

Laying on the Sole. Laid evenly on, the sole is tacked down, a tack in the centre of the toe, one in the middle of the sole, and two at the end, near the seat of the heel, securing it firmly. Now brace the boot between the knees, and hammer smooth and flat all over the sole. Turn the boot top up, and take a cold iron and smooth down the welt, setting it at right angles with the upper.

Paring. Our boot begins to take shape, and the thought is an inspiration for the deft and delicate work of paring and shaping. All round, and at toe and waist especially, the sole stands out rough and rugged. Those rough edges and corners are to be cut off, but be sure you realise what is to be aimed at in the cutting. Many a million boots have been spoiled in the trimming. Mark lightly the outline of the sole with the back of the knife, and then, with wrist braced, and fingers steadily guiding the blade, cut away the rough edges round the sole, and show what a fine shape it was designed to be. That is good art and fine craft, and now we pass on to the art which conceals craft—make the channelling that conceals the sewing of the sole to the welt.

Channelling. This is not a simple matter of drawing a line round the edge of the sole; it must be graduated from $\frac{1}{16}$ in. at the sides to ¼ in. at the shank. Having drawn the lines with a pair of dividers, take the knife in the right hand like a pen, slant the point into the sole, and make a cut on the line that raises the surface of the leather. Deepen the channel with the slanting blade of the prick-stitch, and lift the flap wide, so as to be out of the way of the stitching awl. Turn over the boot, and run the fudge wheel along the welt, as a guide to stitching.

Stitching. If it be desired that the stitching should be shown up, make a thread of yellow flax, and wax it with white wax. The thread should, in any case, be formed of the finest hemp, and waxed sparingly. Set the boot, side up, between the knees, and bind firmly in position with the belt over the shank and under the foot. With the stitching awl, make a hole through welt and sole, bringing the point of the awl out in the channel cut in the sole, and so begin the work of stitching. The rest is obvious, and further detail is needless; but a hint or two may be of service. When about to make a stitch, set the curve of the awl against the upper and the point on the flat of the welt, drive the point quickly through the leather, bringing the elbow down with the stroke, lifting the elbow again to withdraw the awl. To aid the awl, the left thumb should push the sole at the moment of the stroke against the point. As the wax wears off the thread, always renew it on the side furthest from the boot, so that none of the wax may fall on the upper and spoil the work. After stitching, the channel is closed over the stitches.

Building the Heel. The leather for the heel must be hard, thick, and firm in fibre. For an ordinary square heel, we require a seat-piece, two pairs of lifts, and a sole-piece. Cut wide, so as to cover the heel-stitching, the seat-piece is pegged on and made square with the end of the sole. Next, the pair of split lifts have to be placed.

34. SEWING IN THE WELT IN A HAND-SEWN BOOT

Making Splits. Split lifts are formed out of a solid piece of butt leather, 1 in. broad, 7 in. long, split into two wedges by a simple process. Lay the leather flat, holding it down with the left thumb in the centre. Put the knife into the head of the strip near the outer edge, and make a slanting cut down almost to the other side; then draw the knife evenly down, and the leather will be split in equal wedges. Soak the splits in water, and bend the ends together vertically, and they will form a ring with the inner edge curling. Hammer down the raised edges, and a heel-piece will be formed.

on Split Lifts. Rasp the seat-piece roughly, and cover with paste ; lay on the split lift, and tap down with the hammer ; repeat the process, and put on the second split lift ; pack in the centre with leather. Now put on the solid lifts and top piece, pegging them down. Thus firmed, the heel is ready for sewing. Except that the heel is harder and deeper than the sole, there is no difference between welt sewing and heel sewing. The awl, of course, is straight.

Shapes of Heels. No one knows the variety of taste there is in regard to heels except a bootmaker with a good class of trade. Square heels, round heels, high heels, pegtop heels, and many modifications of these puzzle the bootmaker's wits. Let no one imagine that it is merely a question of a different form of heel ; the kind of heel frequently determines the whole character of the boot. A high heel makes a long angle which must be compensated for somehow, or the tips of the toes and edges of the heels are certain to get the whole weight to carry. The last must be modelled according to the height of the heel. There are various ways of doing this, the most common method of accommodating high heels being to shorten the arch of the foot and heighten the instep on the last. Other methods are adopted, but these are special to different makers.

Finishing the Heel. The heel is the last to be made, and the first to be finished. In spite of all our care, the edges of the lifts show, and the ideal heel is a solid block. First round off the top piece with the knife, and then cut the lower layers of leather to an even shape. This is called *knifing*, and the succeeding peening process is an apparent contradiction of it. With the peen, or

buffing knives—flat pieces of soft steel given a turned edge that scrapes the surface of the leather evenly.. Go over the sides of the sole and heel with the knife, making a clean, hard surface.

Sand-papering. We have done with the tools that cut, and take up the rubbers and smoothers and polishers. First of these is the sandpaper, a strong flexible paper covered with sand silicate. Take a bit of this paper about the size of your palm, clothe the tip of the thumb with it, and rub over sole and edges, imparting to the whole of the bottom of the boot a smooth, uniform colour.

Irons. Like our neighbours, the tailor and the shirtmaker, we have smoothing and polishing irons, but between our little irons and the tailor's goose the contrast is very great. Our irons are little metal blocks, an inch in depth, varying in breadth and thickness according to the purpose for which they are designed. The large glazing iron is 2 in. broad, dome-headed, and 1 in. thick ; on the other hand, some of the waist irons are about the dimensions of a common file. A gas burner or a spirit lamp should be near at hand, for heating the irons. Needless to say, the irons must never be made so hot as to scorch the leather, but the caution is one to be kept in mind. When brought to the proper heat, the irons are applied to the waist, the sides of the sole and the heel, and to the top of the welt, rubbing to a firm smoothness.

Inking. Before applying the blackening ink, rub over the parts to be blacked with a little weak ammonia, and then brush on the ink. Now is the time for using the glazing irons. Kept at a good heat, the irons are rigorously rubbed on the surface of the leather, bringing it to a high polish.

the

together, and when the rasp has been applied and has cleared away the dents, a smooth, solid surface remains.

Smoothing Edges. We leave the heel in that state for the present, and take up other parts of the boot. Apply the sharp knife to the shank and sole, clearing away the rough edges and stiff corners, till the outline of the boot runs clean and smooth from waist to toe. Now the edge of the sole has to be peened and rasped in the same style as the heel. Keep the stroke of the peen well in the centre of the sole, for the edges are tender and may be frayed. Similarly, in rasping hold the sole steady with the left hand and rub the rasp firmly along the centre, taking about 3 in. at a time. One side of the rasp is sharp-toothed, and the other is a fine file. With the file side go over all the rasped parts and smooth them down.

Buffing is the next process, and is designed to clear away whatever marks, scratches, or stains the leather may have taken on, as well as to give a new surface. Before the age of machinery, the buffing tool was a piece of glass ; now we have

tions. After the work of polishing and finishing has been done, a very important and troublesome job remains, and that is the taking out of the last. Perhaps the last comes out with little bother, but if it is stiff, get the last-hook. Having cut the laces that held the fronts together during soling, we put the last-hook down into the hole above the heel of the last. Lay the long double handle of the hook on the floor, and set the feet on it, one on each side of the stalk. Grip the boot firmly under the toe with the left hand, and with the right take hold of the back of the heel. Pull hard at the heel, working the toe up and down. In ordinary cases the last yields and comes out ; but sometimes we have long and sore work to get the boot clear, and the reason is not always obvious.

When you have put in the sock soles, blacked and polished the boots, and duly parcelled them for the customer, you are entitled to think that you have performed a service to the industrial world, and, it may be, the world of art as well, though the Royal Academy may not acknowledge it.

CYCLOPÆDIA OF SHOPKEEPING

OPTICIANS. Education of the Optician. Capital Required in the Business. Shop and Stock. Sight-testing Workshop

PAINTERS AND DECORATORS. Sale-shop, Showroom and Workshop Stock. Capital and Credit. Buying and Selling

OPTICIANS

The meaning of *optician* as defined by Johnson is "one skilled in optics," which includes not only the making and fitting of spectacles but sight-testing. The business is a very old one, as may be judged from the fact that the Spectacle Makers' Company was established by charter in London as early as 1629. This company still survives, and is one of the City Companies that is trying to retrieve the inaction of a couple of hundred years by devoting its energies to a scheme of optical examination.

Revival of the Business. Of late years a great revival has taken place in the optician's business, partly due to improved methods of sight-testing, and partly to the fact that the importance of correcting errors of the refraction of the eyes is more generally recognised. Formerly, the universal practice, when one wished to obtain spectacles, was to try on a number of pairs one after the other, and to choose the pair which seemed best to correct the failing or ailing sight. Now, however, the application of scientific principles to sight-testing has completely altered the routine. A Sight-testing Opticians' Bill was introduced into the House of Lords in 1906, and had for its object the registration of opticians in much the same way as dentists and pharmacists have been regulated. The Bill, which would probably have had to be much altered before it would have been accepted by the Legislature, was withdrawn but may be re-introduced when the dissensions in the optical industry have disappeared. We mention these points to show that the business of an optician is one which has good prospects of being an increasing one in the future.

Apprenticeship. There are comparatively few persons solely employed as sight testing opticians, the business being more often carried on in conjunction with other trades such as that of a chemist, jeweller, photographic apparatus dealer, or scientific instrument dealer. As a consequence, apprenticeship to a sight-testing optician is not at all general. The youth is usually apprenticed to a business in connection with which the sale of spectacles is a side line, and if his inclinations tend that way he studies and obtains one of the optical diplomas. The youth who desires to be an optician must have a natural taste for mathematics, and must see in figures more than a mere collection of apparently meaningless symbols. He should also have a taste for making models of small objects, and aptitude in mechanical manipulations. The parent should see that the business to which his son is to be apprenticed is a large one, in which not only is a retail trade done but, in addition, a certain amount of manufacturing, apart from the fitting up and repairing of spectacles. A premium of from £20 to £50 will be needed, and this is generally returned in the form of a small salary.

Education. Apart from the education imparted during the course of the apprenticeship, a youth should attend suitable science classes. If in London he will be able to take a course in technical and practical optics at the Northampton Institute, Clerkenwell, E.C. This institute was the first to establish classes in applied, visual, and physiological optics and optical instrument construction. Day and evening classes are arranged, and the fees, which are moderate, depend on the time devoted and the number of subjects studied. The day course extends over two years, the fees being £15 a year; but as such a course necessitates attendance daily from ten to five on five days of the week it cannot be taken by apprentices. The evening classes are, however, very convenient for those engaged during the day. Optical classes are also held by the Scottish Optical College in Glasgow and Edinburgh, and there are private instructors in London and some provincial towns.

Examinations. At the end of a course of study, it is advisable to sit for a diploma of one of the optical examining bodies. The two existing bodies are the British Optical Association and the Spectacle Makers' Company. The British Optical Association was established in 1895, and has its headquarters at 199, Piccadilly, London, W. It was the first to establish a complete examination for sight-testing opticians. There are two grades of examination, the dioptric and the fellowship grade, the fees being three and five guineas respectively. Each examination is divided into three sections. In the dioptric the sections are lenses and frames (occupying two hours), subjective sight-testing and dissection (half to one hour), physical optics, physiologic optics, anatomy and physiology, photometry and ethics (four to six hours). The fellowship examination can be taken only by holders of the dioptric certificate. The three sections are practical dissections or microscopic demonstrations (30 minutes), objective and subjective tests (two hours), physiologic optics, embryology and physiology, ethics and etymology, ophthalmoscopy, prismetry (five to seven and a half hours).

The examination scheme of the Spectacle Makers' Company was brought out and the first examinations held in 1898. The scheme was, in 1904, enlarged so as to embrace sight-testing. As at present constituted, there are three divisions of the company's examination: (1) the special examination; (2) general examination; and (3) sight-testing examination. The first, or arts division, is a written examination in elementary mathematics, light, optics, theory of optical instruments, and heat, with a *viva voce* examination in the use and adjustment of the camera and projection apparatus, the telescope and binocular, the microscope and sextant. Certain parts of this examination are excused to those holding Oxford or Cambridge Local Examination certificates and matriculation or similar certificate; and in the case of pharmacists the examination need not be taken, as they have already passed a more stringent test. The general examination is in three sections: (*a*) a written examination in general and visual optics; (*b*) *viva voce* in the same subjects; and (*c*) a practical examination in the optical analysis of lenses, knowledge of materials employed, and workmanship and frame fitting. The sight-testing examination deals with all sides of the subject of sight-testing and the instruments used. The fees for the three examinations are: (1) £2 2s.; (2) £3 3s.; (3) £2 12s. 6d. The headquarters of the Spectacle Makers' Company are Temple House, Temple Avenue, London, E.C. These examinations are the favourite ones with opticians as diplomates can take up the freedom of the company and of the City of London on payment of £4 4s. and £1 1s. respectively. A freeman may become a liveryman of the Company on payment of £22.

Capital. The ambition of every young optician is to have his own establishment; but before doing so he should take care to enlarge his experience in practical work as much as possible. It is advisable to serve as an assistant in at least two positions, and the modern tendency is to let at least one of these be with a large "store" so as to widen the ideas as much as possible. An assistant who has been only in a small retail business has often little grasp of the extent of the trade done in the palatial store businesses of the present day.

Business Premises. In regard to the best position for an optician's shop this may be considered as following the rule of businesses depending on public support. By that is meant that the best positions for other businesses are also the most suitable for the optician. When the business is solely devoted to that of a sight-testing optician, the shop need be only of modest dimensions, but a good space is required for the testing-room and a smaller room will be needed as a workshop. The space available will largely influence the apportionment of these various departments. For instance, it is not difficult, by screening a side of the shop partially, to carry on sight-testing in the same room as serves for retailing, and in many cases the workshop portion is advantageously carried on in a part of the shop.

Capital. The amount of capital required may be stated at £250, but the beginner should bear in mind that an optician's business is slow in growth, and that it will probably be three years before he can judge of the progress he has made. For this reason it is well on taking premises to stipulate for a three years' agreement, and not to enter upon a long lease. The agreement should contain a clause giving the tenant the option of taking out a lease at an agreed rental. The following is how the capital can be roughly apportioned:

Window fitting and outside signs ..	£20
Shop fitting	40
Stock	100
Testing-room fittings	10
Testing appliances	15
Work-room appliances	5
Advertising	10
Working capital	50
	£250

The outside of the shop of an optician is usually painted in black and gold, or at least, some dark colour. There is a tendency to create new titles for the optician's shop which, in the infancy of the business, is not altogether to be regretted. Some opticians give their premises such titles as "Ophthalmic Institute," "Sight-testing Parlour," "Refraction Rooms," but as long as the public can be made to understand what is meant it is quite open to the optician to invent any title he may choose.

Outside signs in the form of large gilt spectacle frames are good for appealing to the public. Such a sign costs from 20s. to 40s. Enamelled copper spectacles (costing from 3s. 6d. to 10s.) may also be affixed to the window in addition to a small amount of copper lettering. A popular ornament for an optician's shop is the coat-of-arms of the Spectacle Makers' Company, or the crest of the British Optical Association. These are obtainable in cast iron, painted in colours, or as glass tablets illuminated in colour. The last-named are frequently placed inside the window along with, or in place of, the optician's diplomas, which the beginner should possess.

Window Display. The diplomas issued by the examining body are handsome productions, and, if exposed in the window, are calculated to impress the public. The interior of the window is arranged with either ebonised fittings or draped with purple velvet. Formerly there was a dearth of suitable articles for window display, but of late years the problem has been amply solved by the wholesale houses. Among the window attractions may be noted models of the human eye (costing from 5s. to 40s.), charts of the eye, wax busts and faces upon which spectacles and eyeglasses are fitted, and cards showing spectacles in various stages of manufacture. The last-named applies particularly to pebble spectacles, lumps of Brazilian crystal also forming a great attraction. Prismoidal glass blocks of various colours have become a recognised ornamentation of the optician's window. These are obtained in sets costing about 30s. per dozen pieces. Folders and spectacles are displayed on velvet stands which cost from 1s. each, and sets of lenses showing the various kinds are instructive, or, at least, impress the public with the fact that the construction of spectacles is not so simple as it looks. A Crooke's radiometer never fails to attract passers-by, and it is difficult to convince some people that light is the only agency that spins the vane. An astigmatic clock always attracts. Window tickets and a handful of artificial eyes complete the severest fitted window, but the practical man will not omit to show such things as reading lenses, eyeshades, lorgnettes, motor goggles, and spectacle cases.

Fittings. In regard to the shop fittings, the walls may be utilised for the display of charts and diagrams of the eyes, or, better, for showcases, in which goods should be arranged. The counter should be covered by a glass case, in which are shown spectacles. These cases may be used for the stock of spectacle cases and chains, but at all times representative samples should be exhibited so that the public can see that these goods are made in a great variety of kinds. A stereoscope may be placed on the counter; this and some form of zoetrope is often found, particularly in the shops of opticians who sell scientific instruments.

Stock. As regards the stock carried by the optician, a practical man will have no difficulty in apportioning the suggested £110 amongst the following items: Spectacles in gold-filled, and steel frames, folders, astigmatic clips, eye preservers, coloured glasses, motor and cycling goggles, single eyeglasses (rimless, framed, and with gallery), lorgnettes (in celluloid and tortoiseshell), shooting spectacles, pocket magnifiers, reading glasses, tripod magnifiers, linen provers, eyeglass cords and chains, spectacle and eyeglass cases (including chatelaine cases), artificial eyes, eyeshades, eyebaths, and lens cleaners.

Sight-testing Room. This room requires to be from 10 ft. to 15 ft. long, but by using reflected test types, this distance can be halved. The walls should be painted in a dull-lead coloured paint, and there should be no pictures to distract the customer who is having the sight tested. The test charts are hung at one end of the room, and the patient sits at a distance of 10 ft. away, the chair being advantageously placed on a platform. The test-charts need to be well illuminated, and if natural light be not available in sufficient quantity shaded gas jets or electric light must be arranged so that uniform illumination is given. The most important item in the test-room is the trial case of lenses. The beginner is recommended to spend at least £10 on this item, as upon the accuracy of trial lenses depends subsequent success in spectacle adaptation. Some opticians would include an ophthalmometer as a necessity in the sight-tester's armamentarium. There is, however, a difference of opinion as to the usefulness of this expensive item, so that it has been thought well not to include it in the estimate. The trial case should be placed on a small table by the side of the testing chair. Reading type will also be needed as well as a trial frame, optician's rules, face measures, and prescription book in which to record results. An ophthalmoscope may also be included, and in this case allowance must be made for the ophthalmological lamp, which should be of the wall bracket variety. A hand mirror must be provided for lady customers, who should be given the opportunity of rearranging the hair, which may have become dishevelled during the testing process.

Practical Sight-testing. This will be a convenient place to give an outline of routine adopted in testing sight. The optician should stand beside the customer, who is seated, and should adjust the trial frame on the face, being careful to see that it is comfortable. As each eye is separately tested, an opaque disc is put in front of the left eye. The customer is then asked to look with the right eye at the test chart hanging on the wall, and to indicate which letters he can read. If he cannot read as much of the type as he should be able to, a + 0·5 D lens is put in the trial frame before the eye that is being examined. The customer then indicates whether he can see better or not. If the lens improve the vision, the case is one of hyperopia, and the operator continues to substitute stronger lenses until the one is reached which gives perfect sight. If, however, the customer could not see so well when the weak lens was used, it is changed for a — 0·5 D lens, and if this improves matters, it will indicate myopia, and the operator will proceed to increase the strength of the minus lenses until the proper one is reached. It will be understood that the left eye is afterwards separately tested in the same manner.

Cases occur, however, in which the patient does not see clearly all the radiating lines of an astigmatic chart, and the ordinary spherical lenses must be replaced or reinforced by the cylindrical lenses. The method is similar to that given above, except that the cylinder lenses are used and rotated until all meridians of the chart are clear to the eye. Presbyopia, or old sight, is tested for by the hand-reading type, but astigmatism, hyperopia, or myopia, may also be present, and hence the distance type should also be employed as indicated above. It is not within the scope of this article to include muscle testing, or the objective method of sight-testing. Information on these points is to be found in some of the books in the list at the end of this article.

Workshop. Here the loose lenses are kept either unedged, or of the interchangeable variety. The latter are very convenient, but not universal, hence it is necessary to stock both kinds. Lens testers, opticians' pliers, screwdrivers, soldering apparatus, tweezers, screw extractors, lens drills, a grindstone, and spare parts of spectacles and eyeglasses, are some of the articles which are allowed for in the estimate given. A bench will be needed, and if much mechanical work is done, a lathe, lens surface grinder, and similar larger tools must be added. It is not advisable for a beginner to overstock himself with tools, as the wholesale opticians undertake to do repairs and lens fitting promptly in cases where these are beyond the mechanical skill of the optician.

Advertising. The item included under this head is intended to be spent in developing the business and in letting the outside public know that there is an optician in the town. Electros of suitable blocks for newspaper illustration or bills cost 1s. each. The distribution of booklets on eye-defects or test cards is an effectual way of advertising. Spectacle lens cleaners (made of chamois leather and lettered with the optician's name), and placing the name of the optician on spectacle cases, are proper methods of advertising. The Spectacle Makers' Company do not allow their Fellows to advertise in a way which may seem to infringe the province of an oculist.

Profits. The profits of the optical business are good, but far from abnormal when one considers the limits which sight-testing imposes upon one individual. Some opticians charge up to three guineas for a pair of spectacles, but such a fee includes the most scrupulous attention to detail in sight-testing, and the finest English workmanship in the frame and lenses. A sum of 15s. to 21s. is, however, usual for a pair of gold-filled folders or spectacles, but steel-framed glasses are supplied to workmen and to the poor at fees as low as 2s. 6d. Prescription work—that is, the filling of the prescriptions of oculists—is a part of the business that is worth cultivating, as not only does such work bring the optician under the notice of an oculist, but it makes the customer return when repairs are needed. On fancy goods such as the optician sells a profit of at least 25 per cent. is obtained, these goods including spectacle cases, lorgnettes, and magnifiers. The business is, or should be, a cash one. It is this feature that makes an optician content with what is otherwise a slow-moving and somewhat tedious business.

Trade and Technical Literature. The following are the chief books and trade journals of interest to opticians:

"The Optician," weekly; "The Dioptric Review," monthly; "The British Optical Journal," twice monthly; Hartridges' "Refraction of the Eye," 6s. (Churchill, London); Taylor & Baxter's "Key to Sight-Testing," 7s. 6d. (Taylor, Birmingham); "Opticians' Handbook," 3s. 6d., ("The Optician" Office;) Druiff's "Refraction," 10s. 6d. (Anglo-American Optical Co.); Thorington's "How to Refract," 7s. 6d. (Rebman, London); Blair's "Errors of Refraction," 2s. 6d. (Bailliere, London); Maddox's "Golden Rules of Refraction," 1s. (Wright, Bristol).

For the academic part of the Spectacle Makers' Examination special books are recommended, a list being given in the syllabus of the examinations.

PAINTERS AND DECORATORS

Painting and decorating is a business in which both artistic and commercial ability should combine to produce a good income and a satisfactory position. Artistic ability is essential to the higher grades of the business, though a secondary consideration in more ordinary grades where sufficient guidance is furnished by clients, who may show passably good taste in their selections from ready-made materials. Commercial ability is essential to success in all grade of this business, for special reasons. First there is an extremely busy season during fou or five months of the spring and summer, moderate season of one or two months in th autumn, and a universally slack season for fou or five months in the winter.

Organising the Work. In these circumstances a good organiser will constantly aim at modifying the extremes, often securing, by judicious argument, the indulgence of his client as to time for the commencement of work, enabling him to maintain with fair regularity an efficient staff of men upon whose services he can depend to carry out the operative part of the business with credit and profit. Bad management in this detail would involve the necessary employment of unknown workmen at critical times. In estimating the cost of work, also, there is a point which the indifferent manager may overlook, and that is the wear and tear of brushes, tools, and plant, which should be charged on an average at from 7½ per cent. to 10 per cent. of the separate net value. Another point of commercial value is the economical management of material. So important is this point that in some large successful firms a special clerk is engaged to watch and record the use of materials only.

The Composite Business. The business pays well in the season if well managed, but the winter slackness has to be reckoned with and in one way or another provided for. Sometimes another business is run in conjunction with painting and decorating, such as plumbing, which is usually busy when painting is quiet. Some of the most successful concerns, however, have been built up without the aid of any other trade, except such as may be described as auxiliary to that of the decorator.

The employment of competent workmen to effect the operative part of the business will give some concern to the beginner. Personal supervision of work in progress is always advisable, either by the master or by a competent foreman.

Capital. On the subject of capital, an important point is that it is usual to extend a term of credit to a very considerable section of the trade's supporters—namely, house agents, whose custom is to have current accounts, and to pay quarterly, or at other periodical intervals.

Contrary to the usual run of shopkeeping, capital in this trade is not wanted *chiefly* for goods in stock for sale, nor for materials to be used on the work, but will be required to pay the wages of operatives while work is in progress. Wages in the painting trade average from 65 per cent. to 75 per cent. off the net cost of the work, which may not be returned for some months.

It has been said that a small business could be started on a capital of £60. From the foregoing particulars it will be clear that the sum named would suffice only for the smallest possible business with barely such equipment as would serve the requirements of two or three workmen at most, without margin for extension of credit and ordinary risk on occasion, and without stocking any materials.

For a concern capable of dealing independently with the average requirements of a moderate class business in the present day, it will be readily admitted that a sum of at least four times that named above, or, say, from £250 to £300, should be available.

Credit. A partial set-off against the credit to be given is that when a business is well established the manufacturers and merchants who supply the trade offer similar credit for materials used. It follows, therefore, that with reasonable good fortune a business should adequately finance itself after, say, the first year, with reasonable progression.

A considerable part of preliminary outlay will be for painters' brushes, tools, and scaffolding, such as step-ladders, planks, long and short stave-ladders (for outside painters' work), hand-carts, etc., none of which will be directly chargeable to any client's account, and can be recovered only by the charge of a proper percentage already named for indispensable wear and tear. It must also be remembered that the master is responsible, under the Employers' Liability Act, for the safe condition of all scaffolding, and must be prepared to compensate any workman who may receive injury through defect therein. This is usually covered by insuring, and the premium paid must be charged to the account for maintenance of scaffolding.

Preliminary expenditure on materials may be limited to the needs of the workshop, as the modern custom of keeping little or no stock of paperhangings or other decorative fabrics, now mainly sold from the attractive pattern books supplied (freely as a rule) by the merchants, leaves the investor free to apply that capital in other directions.

New Work. On account of special conditions as to weekly payments, up to about 80 per cent. of the value of work accomplished being usually negotiable for painters' work on new buildings, beginners find this class of work a convenient stepping stone to more desirable engagements. But the same ready money prospect also operates in the cutting down of prices, until the older firms decline to tender for new work as there would be no profit out of it to them, while the smaller master would probably work personally with his staff, and by watching every point of vantage or chance of leakage with a zeal not to be expected from the best of foremen, may secure a profit at a price lower than would be accepted by his competitors.

Showroom. A minor business such as that quoted at £60 may possibly be conducted without the establishment of a showroom, but not so the moderately good class business, with a progressive future. It has already been mentioned that the modern custom of selecting wall-papers and other decorative fabrics from the handsome sets of pattern-books supplied by the wholesale merchants has largely displaced the old custom of keeping a varied stock of saleable (and unsaleable) goods.

The higher class goods are made up in large "stand" books that may be displayed in an upright position on the floor of the showroom. For convenience of carrying to clients' own addresses for selection to be made, some merchants supply also a smaller-sized pattern-book of the same contents, and this will rest on the showroom table among other similar-sized books containing patterns of the various grades of lower class goods. It is the general custom for the merchants to mark on the back of each pattern the full retail price, from which a substantial discount of 33⅓ per cent. is allowed to the trade, no part of which should, in justice to the responsibilities of the business, be sacrificed to the client.

Both merchants and manufacturers supply the trade in this way, but the merchants will be found the most convenient to the beginner as their selections are made annually from the various manufacturers' productions and arranged in harmonious "sets," thereby presenting great variety. Their pattern-books are distinguished generally by vague titles, such as "Royal Court" wall-papers, or other fancy name, the identity of merchants being known only to the trade. Every pattern inserted in the books is kept in stock during the season—extending generally from September of one year to September of the following year—and sometimes a successful pattern may be carried forward from one season to another.

Showroom Fittings. The walls and ceilings of the showroom should be decorated with different materials in a variety of styles to show, say, three methods of treating a drawing-room, the same number of dining-room schemes, and a fewer number of schemes for other apartments as space may allow, separating these into sections by the use of mouldings that may be shown as samples of panel, picture, dado, or other mouldings used in similar positions occasionally by the decorator in the conduct of his business. These sectional examples should each be a display of good taste and careful workmanship, to inspire confidence in the customer as well as suggesting suitable modifications and colour harmonies, blending or contrasting, brilliant, medium or subdued in tones, light and airy or deep and rich, as occasion may require. Examples of painted woodwork should also be found in some variety in every showroom. These may take the form of doors, panelled on both sides, and hung upon posts between the sections of wall decoration so as to swing either way and display suitable varieties of painting in harmony with the wall schemes. One side of a door may be finished in a variety of grained woods, such as oak, mahogany, walnut, pitch-pine, maple, etc., as the painted imitation of these woods will be occasionally called for.

Fitments, such as a "cosy corner," where clients may sit while selecting their wall-papers, etc., and an arched screen between showroom and office, from which artistic drapery may hang, and in which ornamental stained glass or leaded lights may be effectively displayed, should find room when possible, because it frequently comes within a decorator's province to recommend and supply such fitments to complete the decorations of a house. These are usually white enamelled with good effect. The screen need not be higher than seven or eight feet, allowing ventilation and light over the top. In front of this screen there may be brass rods, fixed several inches from the wood over which sample rolls of wall-papers may be hung for display when required.

A long, low table with shelves underneath, for the display of smaller pattern-books, colour studies, etc., a few comfortable chairs, and the indispensable good carpet or linoleum on the floor practically completes the up-to-date showroom.

Special Discount off Showroom Goods. It may be noted that manufacturers and merchants to whom the decorator will give his orders for wall-hangings will usually supply all necessary wall-papers, relief materials, etc., for the decorative display above recommended, or to be fixed upon the showroom walls and ceiling, at the exceptional discount of 75 per cent. from list prices.

Shop Window. It is generally to the advantage of a good class decorator's business to make but little display of goods in the window. A white enamelled screen dividing the window from the showroom may be made to support a simple pleated curtain of unobtrusive art shade as a background, and a linoleum of subdued contrasting colour on the stage flooring, with one stand pattern-book opened at a pleasing decorative scheme, showing perhaps a deep attractive frieze with harmonious filling, and maybe a yard or so of rich brocaded silk draped over one end of this, will as a rule impress the right people in the right direction for good class business far more than a heterogeneous assortment of many samples. A pretty and always attractive addition to the window display is an ornamentally-designed easel, upon which rests a picture or a small-scale drawing of an interior, drawing or dining-room, billiard-room, hall, or other example of decorated work in colours, which may be obtained from the trade journals or from special artists if the decorator does not produce such drawings himself.

Wall-paper Stock. Where business prospects reasonably demand the keeping of a stock of wall-papers, this stock should generally be confined to the more ordinary kinds and lower qualities, in the sale of which there is less fastidiousness to contend with than in the higher-priced goods for best rooms.

The manufacturers and merchants quote specially low prices for "stock" orders, in "bales" of stated quantities, as a minimum total. This compensates the decorator for special risks and enables him, when his stock patterns are selected from the pattern-books, to net an extra profit, while losses upon remnants costing, say, from 2½d. to 6d. per roll of a dozen yards—of which the average room requires from seven to ten pieces—will never amount to a very large sum.

A moderate outlay on these goods, say £30 or thereabouts, would be adequate for a start and might be made to embrace 70 or 80 varieties in lots of 25 or 30 of each, with a total of about 2,000 rolls in all. These will be renewable as required during the current season, and renewals should always be compared for exactness of shades before placing into stock, and any variation should be kept apart from previous stock.

Enclosed shelves or "racks" will be required for convenient storage of these goods. The carpenter's work for construction of such racks as usually made for the purpose, may be set down at about 50s. per 1,000 rolls it is intended to place in stock. Each division of square shelving should hold about 30 or 50 pieces for careful and economical manipulation.

Sale-shop. In connection with a good class business in large towns there is very little cash trade usually carried on over the counter in the form of sales of materials only, though when a stock of paperhangings is laid in it becomes a paying department in a district where there is a considerable section of the public accustomed to buy these goods, arranging elsewhere for fixing. This is especially the case in country market towns.

Ready-mixed Paints. A profitable addition to this department will be a stock of ready-mixed paints in lever-top tins of saleable sizes, such as, 1 lb., 2 lb., 4 lb., and 7 lb. These are obtainable in various qualities from most paint manufacturers. A good quality sold at a fair price will be the most profitable in the long run, as the commoner qualities have poor covering power, and are apt to become viscid by remaining in stock.

Paints ground to a stiff paste in linseed oil, such as white lead, ochres, umbers, reds, blues, greens, etc., may be likewise saleable, and could be kept underneath the sales counter in small kegs, covered with a little water (renewed daily), and a small wooden spatula kept in each would serve to supply the required quantities. A horizontal scale or spring balance for weighing these will be required.

Oddments of Stock. Painters' oils and varnishes will form other items of probable sales in this department. These are sold by measure, usually by the gallon, half gallon, quart or pint. In varnishes the sales will generally be confined to three or four varieties, such as pale and hard oak varnishes, black Japan, stains, etc. Makers supply these made up in small sized sealed tins, for convenience of sale Painters' oils and spirits are not put up in this form, and must be sold from bulk.

Painters' brushes, tools, and sundries are likewise saleable stock, and may generally be of cheaper qualities than used by the trade workmen, as those who buy for a mere temporary purpose can seldom be induced to pay the price of the quality necessary to the expert.

Glass-cutting may also be a profitable branch of the sales department, but would be best conducted in the workshop.

Profits. It will not be found profitable to conduct this business on a margin of less than 33⅓ per cent. gross—that is, one-third of the selling price—to represent profit, which is the trade discount officially arranged by the merchants and manufacturers in pricing their pattern-books.

Workshop and Stores. The store and paint-shop may be together or separate; the workshop is better separate where space permits. They are usually situated in back premises, and should be convenient for delivery and despatch of heavy loads by horse vans, with, if possible, a good yard for storage of long ladders, planks, scaffolding, hand-carts, empty paint casks, etc., and a "lime-pit" for slaked "putty lime" (used in repairing plaster work prior to painting and paperhanging, and for lime washing); covered sheds are usually provided for these items. In the stores, shelving, in several tiers above a bench, fitted around the walls may contain all the dry colours—in tins or strong paper bags, as delivered, the more expensive coloured pigments ground in oil and turpentine, such as lakes, siennas, vandyke brown, drop black, and decorators' large tube-colours, also the stock of varnishes, enamels, and the like, while from hooks in the ceiling should be hung the reserve stock of empty paint-kettles.

Storing Stiff Paints. The heavy paints for ordinary use ground to a paste with linseed oil, such as white lead, ochre, umber, reds, blacks, driers, etc., may be stored under the benches, where they are easily obtained as required by opening the kegs, keeping a little water on the top of the paste to prevent it drying, and with a trowel or strong wooden spatula in each A good spring balance should find a place on the bench, so that every article taken out may be weighed and booked, together with the name of the client or job for which it is taken, the same care being taken to book all returns, with similar particulars, adding the dates in each case. Near the scale on the bench should be a small desk, on which is always to be found the "workshop day book." specially reserved for the entries just named, from which the general bookkeeping of the business may from time to time be accurately made up. In the centre of the store a square table covered with baize should be reserved for glass-cutting, and in a safe corner racks provided for glass.

The workshop should be fitted with benches with one or two shelves above, and drawers beneath, occupying two sides of the room, preferably with north and west aspects, as it is desirable to avoid direct strong sunlight for paint mixing. Some pigments are of a more or less gritty powder, and occasional grinding of these call for the provision of a paint-mill (small hand-power cone mill), usually screwed down on the bench of the workshop, and also of a paint-slab, with a stone "muller" or hand-grinding stone upon it. A good slab is one of thick plate glass, ground to a very level surface, and set in a bedding of cement or white lead putty, with its frame bevelled off, and screwed down to the bench. A granite cobble stone cut into halves will make two good mullers or grinding stones.

Oil Storage. In a corner of the workshop or stores a place must be found for three oil-tanks, or a stillage on which the export barrels may be placed when received. The former is the best plan, as there is sometimes leakage and loss from keeping the oils and turpentines in the wooden barrels as supplied by the merchants, due to shrinkage of the wood. Each of these tanks may contain from 50 to 150 gallons of liquid, and is fitted with a tap near the bottom for drawing off the oils as required. One will contain raw linseed oil, another boiled oil, and another turpentine, all of which are indispensable to the mixing of various paints.

In another corner bins are required for the storage of whiting and plaster. These should be in the driest corner and kept dry by being slightly raised from the ground.

A *pickle cask*, large enough to hold from 10 to 20 paint-pots and kettles, should find a place under one of the benches. In this a solution of strong soda or caustic soda should be kept, and dirty paint-pots be placed in it as returned from operative work. They may be removed the following day, and will easily be made fresh and clean by washing in clean water to be ready for further work.

Smudge Pots. Any old paint mixed and returned as surplus from work done should be carefully saved, and emptied into receptacles kept under another bench for the purpose. These receptacles are called *smudge pots*—one is reserved for white, another for pale colours, another for dark colours—and within a reasonable space of time the contents of these smudge pots may be used for ordinary work, or at later periods form good addition to red lead paint for priming new work.

On the shelves above the paint-benches will be kept small jars of all usual paint ingredients, to be handy for frequent use, also palette knives and cleaning rags, of which there should be ample quantity, to prevent wasteful and objectionable untidiness.

On one of the benches small articles such as notice boards, door-plates, etc., may be painted and lettered, also any embossing or gilding on glass may be carried out, while the centre of the workshop may be reserved for pieces of furniture under process of painting, large signboards upon easels, for lettering, etc., and the two blank walls not yet dealt with may be boarded and reserved for sketching out plans of wall or ceiling decorations from time to time, as occasion may require, to facilitate the actual work when operations are commenced.

In the drawers under the paint-benches may be kept the decorator's pencils, tube-colours, palettes, etc., also stencil patterns, gilders' materials, and other small items of value, or for occasional use.

In beginning business, so many articles are required that it is a matter of some difficulty to keep within small expenditure. But by first making sure of indispensable articles in minimum quantities, and by adding small quantities of the remaining requirements, any shortage or omissions can be made up as occasion may require.

Stock for Workshop and Stores. On these lines, the following list may be taken as a minimum stock to start a business where work for at least half a dozen men and one apprentice may be anticipated. The prices are set down at fair averages, though some of the leading items are subject to considerable fluctuations according to rise and fall of markets.

	£	s.	d.
PLANT			
8 long ladders, assorted sizes, from 10 ft. to 40 ft. length	7	0	0
12 pair assorted step ladders, 5 ft., 7 ft., and 9 ft.	5	0	0
2 pair 9 ft., and 2 pair 11 ft., painters' trestles	4	10	0
3 doz. scaffold planks (2 in.), assorted, 6 ft., to 15 ft. long	8	10	0
2 paperhangers' folding tables and trestles	2	5	0
2 hand barrows, with steel springs	14	10	0
WORKSHOP AND STORES FITTINGS (described above)			
Carpenters' work, say	15	0	0
Paint mill, say	3	0	0
Muller and slab, say	1	0	0
2 strong easels, say	1	0	0
Gas, or electric fittings, say	3	0	0
3 oil-tanks, say	6	0	0
Spring balance, and sundries, say	1	0	0
STOCK OF PAINTS, OILS, VARNISHES, BRUSHES, etc.			
Turpentine, 1 barrel (3 cwt.), say	6	10	0
Raw linseed oil, 1 barrel (3 cwt.), say	4	16	0
Boiled linseed oil, 1 barrel, (3 cwt.), say	5	0	0
White lead ground in oil, 5 cwt.	6	5	0
Zinc white, ground in oil, 3 cwt.	3	18	0
Patent driers, ground in oil, 1 cwt., say	1	0	0
Oxford ochre, ground in oil, 1 cwt, say	1	14	0
Raw Umber, Burnt Umber, Venetian Red, Indian Red, Brunswick Greens (light, middle, and deep), and vegetable Black, all ground in oil, of each, ¼ cwt. (at average prices), total	3	10	0
Prussian Blue, Raw Sienna, Burnt Sienna, Vandyke Brown, Orange Chrome, Lemon Chrome, ground in oil, of each, 7 lb. (at average prices), total	2	15	0
Drop Black, ground in turpentine, 14 lb.	0	14	0
DRY COLOURS.			
French ochres, Venetian Red, Raw Umber, Burnt Umber, Lime Blue, of each ½ cwt. (at average prices), total	2	10	0
Indian Red, Lime Greens, Vermilionette, and Ultramarine Blue, of each 7 lb., total	1	10	0
Vermilion (Genuine) 7 lb.	1	5	0
Lemon Chrome, Orange Chrome, Middle Chrome, of each 7 lb.	1	5	0
Dry white lead, dry red lead, of each 14 lb. total	0	10	0
10 cwt. best Paris whiting	1	0	0
VARNISHES AND ENAMELS			
5 gal. (in 1 gal. tins) best copal oak varnish (for outside)	2	10	0
5 gal. (in 1 gal. tins) best copal oak varnish (for inside)	2	10	0
5 gal. (in 1 gal. tins) common oak varnish (hard)	2	0	0
1 gal. (in ½ gal. tins) decorators' carriage varnish	0	16	0
1 gal. (in ½ gal. tins) extra pale Maple varnish	0	14	0
1 gal. (in ¼ gal. tins) ivory white enamel (slow setting)	1	1	0
1 gal. (in ¼ gal. tins) snow white enamel (slow setting)	1	1	0
1 gal. (in ¼ gal. tins) black Japan	0	16	0
1 gal. (in ¼ gal. tins) Brunswick black	0	8	0
1 gal. (in ¼ gal. tins) japanners' goldsize	0	10	0
1 gal. (in ¼ gal. tins) Terebine	0	10	0
1 gal. (in ¼ gal. tins) patent knotting	0	10	0
WINDOW GLASS			
One crate, say	2	10	0
SUNDRIES			
Putty (best), picked lump pumice stone, of each, ½ cwt.	1	0	0
Pumice stone powder, 14 lb.	0	7	0
Glass paper, 1 ream, assorted sizes, (Nos. 00, ½, and 1)	0	15	0
Powder size, ½ cwt. (best quality)	1	15	0
Old oil goldsize, 1 lb.	0	3	6
Gilders' cushions, knife and 3 tips	0	3	6
Gold leaf, 5 books; transferred gold leaf, 5 books	0	13	0
Filling up composition, 14 lb.	0	7	0
Paint remover (solvent), 14 lb.	0	7	0
Spirit lamp for burning off old paint	0	12	6
Paint strainers, 1 doz. (patent detachable gauze)	1	0	0
Brush holders, 1 doz. (patent suspenders)	1	5	0
Paint pots and kettles, 12 doz. assorted sizes, say	5	0	0
Stencil pins, 2 doz.	0	1	0
Steel graining combs, one set in case	0	2	6
12 covering sheets (rough sheeting, 2½ yd. wide, cut into 5 yd. lengths)	3	0	0
6 palette knives, 3 putty knives, 3 stripping knives, say	0	10	0
PAINTERS' BRUSHES			
Ground brushes, size 4/0, 2 doz. (oval shape)	7	0	0
English sash tools, sizes, 2, 5, and 8, 1 doz. each (best)	1	16	0
Bevelled varnish brushes, size 3/0, best lily bristles, 1 doz.	3	16	0
Bevelled varnish sash tools, size 5, best lily bristle, 1 doz.	0	12	0
Distempering brushes, ½ doz. 2 knot, 8 ounce, best quality	2	15	0
Stipplers, 2 only, size 8 in. by 6 in.	1	8	0
Hog-hair fitches (flat and round), assorted sizes, 2 doz.	0	6	6
Lining fitches, 1 doz. assorted, ¼ in., ½ in., and 1 in.	0	6	6
Stencil tools, 1 doz. assorted ½ in., and 1 in.	0	10	0
Graining mottlers, ½ doz. assorted	0	6	0
Graining overgrainer, assorted	0	3	6
Badger softener, size 3 in., best quality	0	10	0
Dusting brushes, 1 doz.	1	0	0
GRAND TOTAL about	170	0	0

Totalling up the above figures, and adding the cost of fitting out the showroom and offices, apart from stocking the (optional) sale-shop, it will be seen that the preliminary outlay necessary to the independent conduct of this business in a moderately good way amounts to a round sum of £200, or thereabouts, including £30 for the showroom and office decorating and furnishing, leaving a moderate balance of £100 in the bank out of the £300 recommended as starting capital with which to meet wages and other current working expenses, pending the receipt of cash returns, which should, with good management, steadily add to the capital available for reasonable expansion of the business as the due result of technical and commercial ability on the part of the organiser, upon whom all depends.

TOOLS

Varieties and Functions of Tools for Cutting, Scraping, Shearing, Detrusion, Abrasion, Percussion, and Moulding

Group 12
MECHANICAL ENGINEERING
29

Continued from page 3908

By JOSEPH G. HORNER

A VERY precise classification of tools is neither practicable nor necessary, since much overlapping occurs, specially in regard to large groups of which it is open to question whether they should be considered to operate by cutting or by scraping. A natural generalisation, however, is the following: tools which operate by (1) cutting, (2) scraping, (3) shearing, (4) detrusion, (5) abrasion, (6) percussion, (7) moulding, and (8) measurement.

With regard to the classification just given, though it is a convenient one, yet there is no advantage in adhering strictly to it in a study of tools, which is nothing unless practical. For convenience it is better to regard the processes of cutting, scraping, shearing, detrusion, abrasion, as varieties or grades of cutting operations. For they all have this in common, that they either sever, or remove, or shape material. The fact does not concern the machine-hand that the milling cutter is often a scraping tool, and the emery wheel an abrading tool. The question is, how much metal is removed, and how rapidly, by these tools. And so of others.

Before proceeding with detailed accounts of these tools, however, a brief explanation of their underlying principles will be desirable.

Definitions. The term *cutting tools* is restricted in this classification to those which operate as simple wedges, being incisive in action, or with capacity for getting sensibly under or into the material, and severing and removing a shaving or chip cleanly therefrom. Hence penetrative power is a characteristic of all these tools. *Scraping tools* cannot be classed as wedges, because the front, or leading face, is either perpendicular to the surface being operated on, or it leans over from the perpendicular. Yet there are numbers of tools which operate by scraping that are conventionally and properly considered as cutting tools. *Shearing* is an action which is strictly that of severance in a direction perpendicular to the object being severed. It is in some degree a cutting operation, but is also largely detrusive. But a *shearing cut* is also one in which the movement of a chisel, or chisel-like tool takes place diagonally in relation to the material. *Detrusive* action signifies that of a punch in the formation of a hole, or of a shear blade. *Abrasion* covers the work of grinding. Yet it is a truly cutting action, because the particles which form the grinding wheels are sharp, and penetrate, though to a minute amount, the material which they remove. But, as their action is not wedge-like, they should in strictness be regarded as scraping tools. The foregoing constitute the great group which, for convenience, are regarded as cutting tools. *Percussive tools* embrace the hammer and mallet group. Many cutting tools are, however, invariably operated by percussion, as the axe and adze, the socket and mortise chisels, and others. *Moulding tools* are those which neither cut, nor act by driving, but simply produce outlines that are the counterparts of their sections, or which are approximately so. The moulders' tools and those used by modellers belong to this group. *Tools for measurement* are second only in magnitude and importance to the cutting group. These have received immense developments in recent years, and will form an interesting study.

Cutting Tools of the Chisel Group. The condition which produces a truly cutting edge is that the faces of the tool must include an angle of a wedge shape, which angle must be less than 90°. Also, the tool in which the faces meet at the lowest angle will have the keenest edge. We know instinctively which of the two wedges A or B [1] would be the more efficient in the actual division of material, leaving out the question of strength for the present. Regarded as a wedge simply, the rule is that the power gained by a wedge bears the same proportion to the resistance to be overcome that half its back does to its height. Or, in simple language, the thinner the back of the wedge, in proportion to its length, the greater is its penetrative power.

Besides the sharp or keen edge, something more is wanted, some other qualities, without which that of mere acuteness of angle is of no value. Those other qualities are solidity, substance, and strength to back up and support the keen edge, out of which arise differences in tool angles; and again, methods of presentation to the material, since it is important that what is termed the *cutting face* of every tool shall stand in a definite relation to the face of the material being cut.

Another fact in connection with the wedge-like tool is that it sometimes acts by splitting, sometimes by cutting; and which process will predominate in any particular instance depends on circumstances. If an axe be driven into a thick piece of timber [1, C], it will not cut at all after its immediate entry, but will make its way by splitting the material to a little distance in front of the edge, so clearing a way for itself by splitting. But if it or a chisel be applied to the removal of a thin shaving, as at D, the action will be altogether that of cutting, the chisel edge penetrating and dividing the material with which it is in actual contact. The difference in the two actions is apparent from the figures, and it is a very important one. Broadly, it corresponds with the different modes of actuating the chisel, that, namely, by percussion, with hammer or mallet, and that by simple thrust alone.

Chisels. We shall now trace the elementary chisel form through numerous tools in which it is embodied, taking first the common chisels used by woodworkers [2]. In the firmer, paring, mortise, socket, or other varieties, the cutting angles vary but slightly, the difference in the tools consisting chiefly in length, substance, and method of handling. Also, in all these alike the whole of the bevel is imparted to the top or back face; never in the least degree to the front, or cutting face. Directly, whether by design or by inadvertence, that face begins to be *dubbed up*, as the term is—that is, immediately it loses its character of a perfectly flat plane—its value as a chisel is impaired, because it loses the property by virtue of which it is capable of producing a surface perfectly true, and for the production of which the chisel face must be a counterpart of that surface. Hence, in grinding a chisel the bevel is always given to one side only, and in sharpening, the bevel is renewed, or perpetuated on the one side only. For, though the carpenter rubs his chisel upon the flat face alternately with the back, he only does it for an instant, and for the purpose of throwing back and detaching the fine burr, or *wire edge*, that is produced in the act of sharpening, and which, being thus removed, leaves a keen continuous cutting edge.

Other Wood-cutting Tools. The same remark applies to the adze [3, A], which is ground-chisel-like, the whole of the bevel being on the inner or upper face. The face which lies against the face of the work is not bevelled. But it is not flat or straight like the face of the chisel, because the adze is not thrust along, o vertically downwards like the chisel. It is swung in a radius, and being used in this fashion, the face is convex, the radius of the face very roughly corresponding with the radius of the circle in which the tool is swung. Hence an adzed surface is never straight, but is formed of a succession of depressions like minute wavelets, differing in this respect from the surface left by a plane or a chisel.

Taking the axes [3, B], we find that there is no flat face which corresponds with the face of the chisel or of the adze, but there are doubly bevelled and equal edges. Hence it is not possible with the axes to produce a true surface in the sense in which it is possible to do so with the chisel, because the guide principle is lacking. And neither of these tools could be used by simply push or thrust alone; the actuating force must be purely percussive.

These elementary ideas respecting the mode of action of cutting tools will be recognised again presently in tools the relations of which to the chisel are not at once apparent. We have two elements—the *cutting face* and the *cutting angle*, the first practically coincident with the face of the material being operated on; the second ranging from 20 deg. to 35 deg. or thereabouts in thinly ground and thickly sharpened chisels respectively.

Forms of Chisels. Looking at the group of chisels in 2, observe the high degree of specialisation to which they have attained since the days of the old bronze users. The firmer, A, paring, B, mortise, C, socket, D, coachmakers', E, or millwrights', carvers, F, and the turners' [4, A], are each different in substance, mode of handling, and of use.

The only difference in the *firmer*, A, and the *paring* chisel, B, lies in the length. They are both thin and light, but the paring tool is about twice the length of the firmer, and is used for shaping over large surfaces, across which the firmer would not reach. The mallet is frequently employed to actuate the firmer chisel, but is seldom used for the paring tools. The *millwrights'* chisels are as long as paring tools, but about twice as stout, and they are employed for the heavy toothed-gearing and other work about mills, for which the lighter chisels would be unsuitable. The *coachmakers'* chisels, E, are a compromise between the millwrights' and the firmer tools, being used indifferently by hand thrust and by malleting.

The *mortise* chisel, C, is, as its name implies, designed for cutting out the mortises in timber, and is always driven to its work with the mallet. The *socket* chisel, D, derives its name from its peculiar mode of handling. The tool, instead of being tanged, as is the case with all other chisels, is provided with a socket into which the handle is driven, in this respect being a survival from the ancient days of the bronze users, for they socketed nearly all their chisels. F is a bent mortise chisel, the *lock* mortise or *dog leg* chisel.

The *turning* chisel [4, A] is a peculiar example, and forms almost a group by itself, the only tools approaching to it in form being the timber scribe, and carvers' corner chisels. It is doubly bevelled like the axe, and its edge is bevelled transversely, so that the tool cuts in a diagonal direction. It is placed at a tangent to the work, and the action when in this position is purely cutting, never scraping. In skilful hands it is a most clean-cutting and efficient tool. A very wide chisel with a single bevel is the *drawknife*, B, used for roughing down edges and narrow faces.

There are a considerable number of chisels made for special trades, the most curious of which are *carvers'* chisels [5], in which, in consequence of the irregular character of the work, various outlines are given to them. The chisels are straight, and *bent* [5], A, and right and left hand *corner*, B, and C. The *vee* tools, D, E, F, or *parting* tools, are like double chisels, and are used for working out vee-shaped grooves and angular corners. These are also straight and curved, and of more or less acute angles.

Chisels for Metals. The engineers' chisels for metal are all formed on the same type as the *cold* chisel [6, A]. This is a doubly bevelled tool, always driven by the percussive action of a hammer, as at F. It does not split at all, but cuts by the edge only, so severing just so much of the material as it is in actual contact with, differing in this respect from the axe and hatchet, which, operating on soft and fibrous timber, split and

Round nose slotting tool

divide the grain in advance of the cutting edge. Cast and wrought iron, steel and brass are attacked easily with the cold chisel. Its edge may be straight, or slightly convex crosswise, but never hollow, since that would cause the tool to *draw in*. There are other chisels made on the same principle, but named according to their specific purposes or forms, as the *cross cut* or *cape* chisel [6, B], the *diamond point* or *nicker*, C, the *cow-mouth*, D, the *round nose*, E ; and the smiths' *hot* and *cold setts* [7, A to D], *anvil chisels* [7, E], etc., all of which are operated percussively.

There is a group of turning chisels for wood which do not cut at all, but simply scrape, their faces being presented normally to the tangent of the surface of the work. These embrace the firmers, the round nose and side chisels, the hollow chisels, and other tools of special outline, the edges of which are the counterparts of the profiles of ornamental turned work in hard woods, ivory, and metals.

Gouges. *Gouges*, which are a large family, are strictly chisels, differing therefrom only in the plan view of the edge, which forms a curve or sweep, more or less *flat*, or *quick*. Hence the term "hollow chisels" formerly applied to them. Necessarily, gouges are made in an extensive range of curvatures. A gouge of very large radius is flat, one of very small radius is quick ; *middle flat* designates some intermediate curves. But there are six series of curves made, so that a gouge of any width can be had in six different curvatures. The widths made range from ⅛ in. to 2 in. Almost every type of chisel has its counterpart in a corresponding gouge, so that there are firmer [8, A], paring [8, B], carving [9], millwrights', turning, etc., all having the same characteristics as the chisels. There is one other distinction, however, of importance, and that is the division into *inside* and *outside* gouges, according as the bevel of the tool is ground off on the inside or outside sweep. Paring and millwrights' gouges are ground on the inside ; firmer, carvers', and turners' gouges upon the outside. The former are therefore used only for straightforward cutting ; the firmers and carvers are employed for shaping concavities. The turning gouge operates along a line simply, the work revolving.

Handles. The handling of these tools is that which is best adapted for their special work. The mortise and socket chisels [2, C, D] are provided with the stoutest handles of all, to withstand the shocks due to continued and hard percussion ; the firmer [2, A] and carvers' and parting tools [5] are lightly handled, their outlines varying with taste and convenience. The turning tools [4, A] have long handles to enable the workman to maintain firm grip and leverage against the shocks and forces tending to throw them away from, and to damage, the work.

Planes. The tools hitherto considered have no control save that afforded by the steady coercion of the workman's hands, maintaining due pressure between the tool faces and the faces of the material. In the planes a great advance is made. Set and coerce a chisel in a *stock* of wood or metal, and we have the plane which produces accurate surfaces, the stock exercising the necessary control. But in the planes we meet with an apparent departure from the principle previously stated that the cutting face of the chisel should be as nearly as possible coincident with the face of the material. The cutting irons of most planes are set at an angle of 45 deg. in their stocks [10], the exceptions being unimportant and few, chiefly affecting planes of a special character, and some of those used for hard woods. In the spokeshave [11], which is a kind of bastard plane, exact coincidence exists between the cutting face and the face of the material, yet the spokeshave does not approach the planes in value. The reason is apparent. The want of coincidence of the faces of tool and work receives compensation in the planes by the *stock*, the long face of which coerces and controls the iron, rendering its cutting action practically identical with that of a chisel, while the spokeshave embodies the guide principle only in a very minute degree—so little, in fact, that though it cuts sweetly, it is unable to produce accurate surfaces.

The efficiency of the plane, therefore, is due to its stock, in the absence of which the iron, being set at an angle, would be drawn in, and follow the course of the timber grain, curly or otherwise, much as an unassisted chisel tends to do when working lengthwise of similar grain. But it would be impossible to remove shavings and produce a true face on curly stuff if the plane-iron were set like that of a spokeshave ; the timber would be torn up whenever the iron met with cross grain. Its action would be too wedge-like, too much like that of a knife. Actually, on very hard and curly material, the ordinary plane has to be set very finely, and used with care, and then to be followed by the scrape, in order to obliterate the marks of the torn up grain ; and for this reason planes used exclusively for hard woods are sometimes made of a more upright pitch than those for ordinary woods. For these reasons a plane whose iron should be set at a lower angle than that ordinarily employed would be useless for all except the softest and straightest grained woods. In veneers, which have very curly grain, the surface is prepared for the glue by a toothing plane, with the face of its iron perpendicular to the surface of the work, scraping it absolutely.

Actually, however, the angle of the *cutting face* of a plane-iron is not so high as it might appear to be at first sight. The angle of presentment of the iron is not that at which it is set in the stock, but that at which the bevel is ground and sharpened. The first is about 45 deg., the latter seldom more than 10 deg. or 12 deg., oftener perhaps, 5 deg. or thereabouts, as sharpening is repeated. This, however, would be quite enough to lead or draw the chisel edge inwards without the coercion afforded by the stock.

The Top Iron. Necessarily, the setting of the iron at an angle in the stock deprives its cutting edge of some measure of that support which the true chisel has when its face is coincident with the face of the work, and so makes the action of the plane approach remotely to that of scraping. But here two agencies come into play; first, the rigidity of the stock itself, secondly, the influence of the *top iron* [**10**]. The latter is screwed tightly down on the face of the cutting iron, almost close down to the cutting edge, and imparts such rigidity thereto that no chatter of moment takes place when cutting. This is one function of the top iron; another is the breaking of the shaving, the shaving curling up the convex end of the top iron with the minimum of friction [**10**]. But when an iron stock is employed, it is usual to employ a single cutting iron only, which also illustrates the influence of the rigid top iron in lessening chatter; for the iron stock is more rigid, more free from elasticity and vibration than the stock made of wood, and there is thus less need to use a top iron, which is often then discarded. We shall meet with this question of rigidity and of curling off of the shaving again in the metal-cutting tools.

The analogy between the plane and the chisel and gouge is seen further in the straight and the profiled forms imparted to the edges of the irons. Planes producing straight faces are the jack, trying and smoothing, the jointer, and panel, the rebates, ploughs, and filisters. The *rounds* and *hollows* [**12**, A and B] produce concave and convex edges; the various *moulding* planes, edges of numerous profiles, C. Difficulties in cutting arise in the last-named, because the proper cutting angle cannot be maintained ta all sections of the profile, and the planes in consequence *drag* and work hard, as do hollows and rounds in a slight degree. But these have been largely displaced by rotary machine cutters, which always act by simple scraping, the faces of the cutters standing perpendicularly to the faces of the mouldings being *stuck*.

We learn from the plane that, provided the action of the cutting chisel is rigidly coerced, it is not necessary for guidance that the flat face of the tool should coincide with the face of the material being cut, as it is in the chisel when hand operated. The control is transferred to the stock. Also, that beyond the wedge form of the tool there is really little in common between the two classes of tools. We have the curling up and free exit of the shaving on one side, and the clearance between the lower edge of the iron and the material, both of which are essential to sweet operation, and there is the essential of rigid fixing. Again, it is of no importance whether the bevelled edge of the iron is lowermost in the stock, as in the wooden planes [**10**], or the plane face lowermost, as in many of the iron ones. The plane will now help us to understand the action of the metal-cutting tools.

Turning and Planing Tools. Although there is no essential difference in the chisels and cognate tools used by the woodworker and the chisel-like tools of the turner and metal planer, yet the work of the latter is more or less a mystery to the former. Acquainted only with the keen chisel, easily operated by the hand, the shaving of hard metal seems to be due to some occult virtue in the material of which the tool is formed; the analogies in form being somewhat disguised, are overlooked. Even so, the constant use of tools for metal working tends to blind the engineers' machinist to the real kinship between those tools and the ones employed by the carpenter; each, however, is akin to the other.

A Typical Tool. Examining now the formation of the tools used for turning and shaping metal generally, the wedge form is still obvious, but it is modified by other essentials. Taking the typical roughing out tool in profile, as used for iron and steel [**13**, A], the *tool angle*, *a*, is a true wedge, though much more obtuse—from 50 deg. to 70 or 80 deg.—than the corresponding angle of a chisel, or a plane-iron. It is, however, no more obtuse than is necessary for its permanence of service. The carpenter's chisel would not endure for a moment; the engineer's tool retains its edge for several hours. The angle *b* is the *clearance* angle, or *bottom clearance*, and should be only just sufficient to prevent such friction between the tool and the work as would involve wasted energy and undue heating. If the clearance angle is made excessive, then, in order to leave a sufficiently thick *tool angle*, *a*, to the cutting edge, the angle *c* of *top rake*, or *front rake*, has to be diminished, and this is an evil. It is a principle that the nearer the line *d e* approximates to the tangent *f g*, or to a plane face being cut, the more nearly perfect is the action of the cutting tool. Actually the angle *b* should not exceed from 3 deg. to 6 deg. for iron and steel, any alteration after this for harder or softer metal being made in the inclination of the line *d e*. For hard steel, and steely cast iron, the angle *c* must be small—in other words the tool angle *a* will be large; for wrought iron and mild steel, the angle *c* will be larger and *a* smaller. In the latter the purely cutting action will be more pronounced than in the former.

The Graver. The facts just stated have so vital a bearing on the efficiency of cutting tools for metals that it is well to put them in another way. A suitable cutting angle or tool angle, *a*, is only one of the essential conditions. Take as an illustration the elementary form of the graver, the old hand turning tool for metal [**13**, B to E]. Its relation to the tool held in a slide rest or tool holder is shown below by the dotted section at F. Now, even though the angle *a* is not varied, very different results will follow with different angles of *presentation*, which will alter the angle of top rake *c*, and that of bottom rake or clearance *b*. Compare with the preceding figure at A. If the tool is raised, as in D or E, it will not cut, but scrape only, and its edge will be rapidly abraded. Or if lowered as in C, though the top face would give more freedom of escape to the shaving than at B, the lower face would have less clearance.

Hence results depend very much upon the manner in which the tool is presented to the work. Though the broad rule is that the top face of the tool should approximate as much as possible to the plane of the face or surface which is being cut, or to the tangent to the same, this rule is not invariable, since it is modified by the nature of the material. The harder and tougher the quality of the latter, the more essential is the observance of the rule. The more brittle the material, as at F, the less necessary. The reason is to be found in the fact that material which is hard, tough, and fibrous yields shavings which are strong and difficult to break. They come off in long spirals or ribbons, G, often many yards in length. If they can slide off unbroken from the sloping face of the tool the latter is not charged with the extra severe and unnecessary task of breaking up and comminuting the shaving into small chips, but is able to fulfil its legitimate function of dividing or cutting economically. A tool which has to break its chips is subjected to extra strain, and, what is of far more consequence, becomes unduly heated. Rise of temperature limits the cutting capacities of a tool enormously, and, therefore, whatever tends to diminish friction and lessen heat favours its cutting power. The bending over of a shaving without causing its fracture is thus a very important element in a cutting tool. It is seen not only in the metal-working tools, but in the carpenter's planes. The "irons," as we have seen, are set at such an angle that the shavings creep out in continuous lengths.

Solid Tools. The tools used in metal cutting are not usually set in such a way that their axes are in the same plane as the faces of the work. This would be far too inconvenient. The necessary form is imparted by forging and grinding in the case of solid tools. Exceptions to this rule of imparting tool angles by forging and grinding occur in the case of tool points, held in tool-holders, or cutter-bars, and in the case of hand-operated tools [13, B to E], notwithstanding that the essential angles of presentation to the work are alike in each.

Forms of Tools. Again, though copper and lead can be cut and turned with the tools for operating on wood, the case is very different when iron and steel are concerned. The power required to cut hard metal is immensely greater than that absorbed in cutting wood and soft metal. Thus a Whitworth lathe removing cuttings from mild steel at a rate of 50 feet per minute, the cuttings having a section of ¾ in. by ¼ in., absorbs the enormous amount of power supplied by a 60-horse power electric motor. For this reason the broad chisel edges of the woodworker, represented, say, by a 1½-in. chisel, or by a 4-in. axe or adze, are scarcely used by the metal-worker, except for the finest finishing; the stress and the force required for operating would be too great. Therefore, narrow edges are the rule, not exactly points, but edges of a sensible width, seldom, however, exceeding ¼ in. or ⅜ in. in width when metal has to be removed in considerable quantities, and generally less than ¼ in. in width. A group of these tools is shown in **14** and **15**, being straight forward and right and left handed, etc. Many are used on lathes and reciprocating machines alike. Some are special to a particular machine, but however their shapes in plan vary, their sectional forms are based on the principles just explained.

Cranking. What is termed the "cranking" of the tool is quite independent of its cutting action. Its purpose is to prevent the tendency to hitch which is present when the tool is thrown backwards during heavy cutting, which hitching cannot happen when the tool point is in a line with the back of the shank because it then strikes off, in the case indicated, by the dotted line *h* [13, A]. This peculiar function is not so necessary to lathe work where the circular outline of the work receding from the tool prevents risk of a hitch. But in planing and shaping machine tools operating on flat surfaces the tendency to catch is always present, and then the cranking of the tool is a necessity, unless, as is often now done, the tool is made of a very stout section. Another reason is that the labour of grinding is lessened, and the necessity for reforging does not occur so frequently. If the tool were not hollowed out on the top, the repeated grinding of the top face would soon cut out a deep angle into the bar, which would be weak and give trouble. Being hollowed, the top face can be ground many times before the hollow is lost, and reforging required.

By means of narrow-pointed, chisel-like tools formed on those principles the largest majority of engineers' work is cut. By a succession of cuts of narrow width and of greater or less depth, the largest surfaces are operated on. In the width of an inch the number of successive cuts, or *feeds*, will range from about four in heavy tooling to 40 or 50 in very light work. When increased cutting is done it is generally depthwise, *depth of cut*, rather than in width, such being found more economical.

Slowness of Operation. All conditions being equal, the harder the material the slower the speed, and the smaller the quantity of material removed in a given time. It is the principle of work in one of its many applications. Deep cutting at high speed is practicable in woodwork, but not when metal is concerned. The heat generated would be so excessive that the tool would lose its cutting edge almost immediately and become very hot. And the work, too, if of small dimensions would become hot and distorted, so that when it resumed its normal temperature it would not be of correct shape or dimensions. Actually, it would be correct to say broadly that the generation of heat sets the limit to the speeds used for cutting metal with tools of temper carbon. This is very much affected by the forms of the tools themselves, and the efficiency or otherwise of the lubrication adopted; but when all is done that is possible in these conditions the limitations of speed are soon passed. There are certain speeds suitable for cutting each kind of metal or alloy, and though these vary with the conditions just named, they cannot under similar conditions be exceeded to any considerable extent.

PURE AND IMPURE WATER

Properties of Water. Sources of Supply. Rivers, Springs and Wells. Varieties of Drinking Water. Town Supplies. Impurities. Distribution

Continued from page 4020

By Dr. A. T. SCHOFIELD

WHAT is water? A fluid or chemical compound composed of two parts of hydrogen to one of oxygen, the three volumes being reduced to two in the compound and represented by the formula H_2O, is the theoretical answer. Such a fluid is hardly ever met with in a natural state in all the waters that are found on the earth's surface. Distilled water is sometimes of this composition, but not always. The compound is also pure when artificially formed by electrolysis from the two gases.

Properties of Water. The properties of water are peculiar—it freezes (ice) at 32° F. and boils (steam) at 212° F. It attains its maximum density, or greatest weight, shortly before freezing, at 39° F. It therefore sinks to the bottom, and getting colder rises to the surface again to form ice as it becomes lighter.

The weight of water is 770 times greater than that of air. As we have said, water boils at 212° F. (when the barometer is at 30°) and becomes steam and increases to 1,600 times its own volume. In vacuo (or without atmospheric pressure) water boils at 32° F. An increase of 20 atmospheres raises the boiling point to 418° F.

Water has a "skin," due to surface tension, on which many aquatic insects are light enough to move about without getting wet, breaking through it with difficulty. This "skin" is elastic, and tends to contract in all directions. It gives a spherical form to tears and raindrops, so that we get the greatest bulk with least surface. Water has the toughest skin of all natural fluids except mercury; it has also many other qualities, such as incompressibility, of use in hydraulics.

Sources of Water. We now proceed to consider the sources of the various kinds of fresh water, which ultimately come from rain. Rain-water either flows on the surface of the earth or sinks in, and this forms upland surface waters, rivers, springs and wells. It originates in clouds, which are mists formed of water distilled from the sea by evaporation. As the atmosphere is cooled, what is called "saturation point" is reached, and the air can no longer contain the moisture, which collects in drops and descends as rain. If the point of saturation is not reached above 32° F., the water falls as snow [see GEOGRAPHY, pages 294 and 456].

Rain-water is, of course, theoretically pure—that is, nothing but H_2O. It may be so sometimes in the clouds, but is not so as we know it; for, as a matter of fact, it receives many impurities from the lower air before it reaches the ground at all, and thus contains nitrates, ammonia, spores, germs, and various solid bodies, besides salt and sulphuretted hydrogen. As England is an island, the amount of salt in rain-water here is large, amounting to as much as two grains in a gallon, while the nitrates are only ·007 per cent.

Quantity of Rain-water. The amount of rain-water that now falls is deficient in quantity, but is supplemented by the vast bodies of fresh water existing in lakes, etc., and underground. Even if more were lost the rainfall is not sufficient to supply 50 people per annum. The annual average of rainfall in Great Britain for 20 years is 36½ in.; locally it varies between 20 and 70 in. annually, eastern coasts being the driest, and western hill districts, like the English Lakes, the wettest. To find the quantity of the rainfall, multiply the area of the surface in square feet by half the rainfall in inches; this gives the amount of gallons. One inch of rainfall equals 101 tons per acre. The number of inches multiplied by 14½ gives the number of million gallons per square mile. One inch of rainfall is 4½ gallons per square yard. The rainfall in the wettest vear is double that of the driest, and one-third above the average. To find the rainfall on a roof, take the *horizontal* area of the roof, with a slight allowance for evaporation, and apply the rule as above. A roof of 60 sq ft. horizontal measurement with a rainfall of 30 in. per annum will collect 2¼ gallons a day. These formulæ are simple and easily remembered. Rain-water to be drunk must be filtered and stored in a tank, preferably of neither metal nor wood. As rain-water falls it becomes aerated to some extent, which is an advantage. Out of 30 in. of rainfall, nearly two-thirds (19 in.) sink into the ground.

Of course, all the impurities gathered by rain-water as it falls through the lower air are multiplied a hundredfold, until the roof is washed clean. The first water off a roof should therefore always run to waste, and the rest be stored. Automatic separators are ingeniously contrived to effect this. Rain-water is not palatable, and is never a favourite beverage, though some countries have to depend almost wholly upon it. It is best stored in slate, but when kept a long time, as at Gibraltar, Jerusalem, and elsewhere, it is preserved in covered underground cisterns. The capacity of the tank should be two gallons for every square foot of the roof.

Upland Surface Water. Upland surface water we find in lakes and ponds in higher lands. The water is generally pure and soft, but contains a considerable amount (3 grains or more per gallon) of vegetable matter. It is often artificially stored by dams on the moors, and is therefore sometimes peaty in colour and taste. It is being increasingly used, and is supplied from lakes to Liverpool, Manchester, Glasgow, etc. Though excellent for washing, its chief danger is that common to all soft water—dissolution of some of the lead of the pipes through which it flows. It is probable that, ere long, with the increasing impurity of the Thames, some upland surface water will have to be supplied to London.

River Water. Rivers are naturally pure, and their water is harder than the surface water, but less hard than spring water. There is great danger of contamination from the banks and towns. No river in England is long enough naturally to purify and completely deposit the sewage that falls into it. The natural process of purification is performed by vegetation, which oxidises it by dilution and by precipitation. The deadly micro-organisms (typhoid) which may abound at a sewage outfall, instead of multiplying as they would do in pure water, soon decrease and die out as they are preyed on by the numerous large bacilli that abound in river water. Here we reach a great truth to which we may allude again—*viz.*, that the pollution of a large river by infective germs is of little danger compared with the contamination of wells and streams; in the former the germs tend to disappear, in the latter, to multiply rapidly.

Springs and Wells. Shallow wells catch the ground and subsoil water; deep wells tap the water stored beneath impervious strata. Shallow wells are generally under 50 ft. deep, but one only 30 ft. deep may pass through rock and tap "deep well" water. The depth of a well is supposed to equal the radius of the circle which it drains, but this varies more or less according to the character of the soil. Shallow well water is very hard, nearly always impure, and often foul from sewage. Deep spring well water is pure, and may be hard or soft.

Artesian Wells. Of very ancient origin in the East, these may be called artificial springs, for where the pressure on the subsoil basin is very great, the water rises at once to the surface, and may even do so in the form of a jet.

A good illustration of the way water lies underground is found in what is called the London Basin [1]

The extent of this basin may be judged when we know that the southern outcrop of the town greensand is at Sevenoaks and the northern at Dunstable, a distance of 40 miles. It is believed that the water of a well in Trafalgar Square, 390 ft. deep, flows into the ground in Hertfordshire. In the chalk there is a "fault" west of Hendon which allows a great deal of water from the chalk outside this area to enter the Thames near Reading; some 300,000 gallons also enter the river daily near Windsor.

1. DIAGRAMMATIC SECTION THROUGH LONDON BASIN, SHOWING STRATA AND UNDERGROUND WATER
Reproduced by permission from Diagrammettes by W. H. Knight

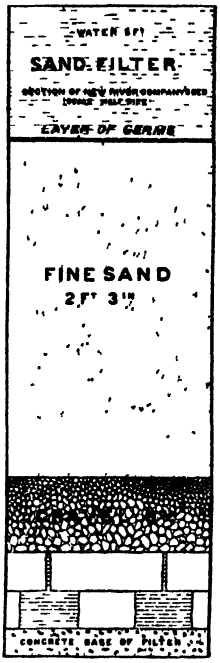
All the water in this basin below the London clay is generally good though mostly hard; above the clay it is fouler, at any rate suspicious.

Shallow Wells. All shallow wells in London are now foul and dangerous, and in villages they are often the same.

The best rocks in England for yielding good water are chalk and new red sandstone. The site of a city is generally determined in the first instance by the water supply. Subsoil water varies in height according to the time of year. When it is high, as in March, it is unhealthy; when low, as in October, it is healthier.

Coming now to the country, shallow wells are very common in cottage gardens, which frequently contain two holes only a short distance apart, one in which sewage is stored, and the other from which water is drawn. As the ground is porous, the result is that the water is really dilute sewage, though it appears light and sparkling, and may not even smell till it has stood a little while. It may be drunk for years if no contagious germ has fallen in, for it is not necessarily infectious.

Wells in which the water-level is easily depressed by pumping are the most dangerous, as they will suck water from 20 to 100 times the distance of the depth of the depression. The alteration of the level of the subsoil water is often a danger. When low, the sewage and the well water may remain distinct; when the water rises it may connect the two.



2. A SAND FILTER

Foul Wells. Pollution of a well depends on:

(1) Its position as to cesspools.

(2) The amount of depression of water-level by pumping.

(3) The porosity of the soil around.

Foul wells show their impurity best after rain, also if the water be kept a short time, or is a little warm. Village wells should be sunk on a level above the source of possible pollution, and at 200 times the distance of their depth from any possible source of impurity. The mouth should be covered, and the well should be level with the neck for the first 30 ft. and fitted with an iron pump. The pump is called a "suction pump" if the water has not to be raised 25 ft, which is about as high as it will rise by atmospheric pressure. It is called a "force pump" when the water is over this depth, and water has then to be "forced" up by pressure. In this case buckets, being cheaper, are generally used.

Deep Wells. Deep wells, to ensure purity, should always be bricked down to the impervious stratum through which the well is lined and through which the surface water cannot pass. This precaution was omitted in a well near Liverpool, bored through new red sandstone, with the result that it drained all the shallow wells around. These were then practically cesspools, and naturally fouled the deep well. An elaborate system of drainage had to be devised, and it was four years before the deep well could be used again.

In deep wells nitrates are found, but the water is otherwise pure and quite sterile—*i.e.*, free from all germs. As already pointed out, this is not such a safeguard as it at first appears; for if typhoid or other germs should get access to it, they thrive incredibly, as there are no other germs to destroy them, nor any light or air as in rain-water. The air in water is generally in the proportion of 1·8 parts of nitrogen to 1 of oxygen, a different proportion to that in the atmosphere. This dissolved air gives water a pleasant taste, which is absent in boiled water containing no air; the latter can be made palatable by pouring it through toast.

Drinking Water. Good drinking water should be selected from the purest sources, and should have no taste, smell, or colour. If the quality of water appears doubtful, set a glass aside in a warm, dark cupboard for two days; if it becomes cloudy and smells, it is bad. Water varies according to its source: from alluvial soil it is generally impure; from chalk soil it is generally good, with temporary hardness; from limestone it is good, with permanent hardness; from millstone grit it is pure and not hard; from granite and the primitive rocks it is pure, but may have salt dissolved in it.

Water from springs, deep wells, and upland surfaces is wholesome; that from stored rain and lowland surfaces is suspicious. Shallow well water and sewage rain-water are dangerous.

Water Supply of Towns. We now turn from the varieties and qualities of water to the water supply of towns, which is as follows in round figures:

London	30	gallons	daily	per	head
Edinburgh	40	"	"	"	"
Dublin	35	"	"	"	"
Glasgow	50	"	"	"	"
Berlin	15	"	"	"	"
Vienna	22	"	"	"	"
Sheffield	20	"	"	"	"

Hospitals have 60 to 90 gallons daily per head.

Four gallons daily per head is the absolute minimum possible, and fifteen gallons daily per head is the practical minimum all round. The amount consumed daily per head is 100 ounces, one-third being in food.

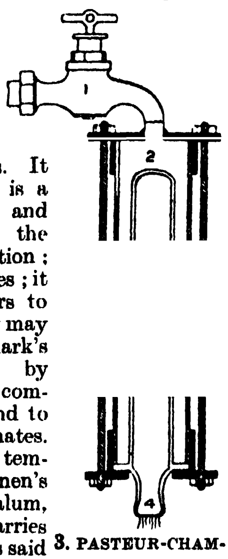
London is supplied with 120,000,000 gallons daily, but 15 gallons per head are lost daily in transit. A waste-detector placed in Lambeth has saved 14 gallons per head per day. The best supply is 25 gallons daily per head for private, and 10 gallons for public use.

Impurities in Water. The impurities found in water are obvious—a matter of great importance.

Various minerals are held in water termed pure, rendering it thereby *hard* or *soft*. The hardness in water is called *temporary* if it is due to carbonate of lime, and *permanent* if due to sulphate of lime and salts of magnesia. Of course, carbonate of lime in common chalk is insoluble, but with the addition of some carbonic acid it becomes bi-carbonate, which is soluble. $CaCO_3$ (chalk) + CO_2 = Ca_2CO_3 = bicarbonate. This change is effected by rain-water, which contains CO_2, by washing the surface of chalk; hence, to precipitate the lime, all that is needed is to draw off the CO_2 by boiling. This precipitated chalk produces temporary hardness and forms the principal part of the fur on boilers and kettles.

Hard Water. One degree of hardness is due to 1 grain of salt per gallon, as shown by "soap test"; it requires 1 extra volume of soap solution to make a lather; hence 5 volumes of soap solution are required to make a lather in water with 24° of hardness. Each degree of hardness requires 2¾ ounces extra of soap, to make a lather, to each 100 gallons of water. Water up to 20° of hardness is not injurious to healthy people if it be temporary or due to bicarbonate of lime only, though it may be harmful to gouty persons. Water should not, however, for health have above 50° of permanent hardness or sulphates (not deposited by boiling). Water with hardness up to 6° is all called *soft*.

Hard water soon blocks up boilers and pipes, and is a cause of waste in many ways. Nearly one-third of all the tea used in London is wasted by hard water; and Glasgow, when it substituted the soft water of Loch Katrine for hard for washing purposes, etc. saved £36,000 in soap alone per annum. In cooking (especially boiling), the salts get deposited in meat and vegetables, making these hard and indigestible.



3. PASTEUR-CHAMBERLAND FILTER
1. Inlet of tap water 2 Water chamber under pressure 3 Porcelain chamber through which water percolates 4 Outlet for filtered water

The fur in boilers is a source of many troubles. It corrodes the metal; it is a non-conductor of heat and wastes fuel; it coats the food; it prevents solution; it lessens the size of pipes; it allows the sides of boilers to become red-hot, and they may crack and explode. Clark's process softens water by adding enough lime to combine with the CO_2 and to precipitate all the carbonates. But it only removes temporary hardness. Maignen's Anti-Calcaire adds lime, alum, and carbonate of soda, carries down all organic refuse, is said to remove most of the permanent hardness as well, and prevents the crusting of boilers. Professor Nesfield's process purifies drinking water of all organic and dangerous deposits by adding iodine, and then converting this into a soluble salt by a salt of soda. It claims to kill all bacteria in water in one minute, and the water afterwards is clean, harmless, and palatable.

Source of Impurities. Pure rain-water only contains half a degree of hardness. Most rivers are hard; the Thames contains 15°. Hardness in water is bad for gouty people, and maps of the British Isles are prepared showing where the water is hard and where soft, so that people may select their place of residence accordingly.

Impurities in water may be produced (1) at the source; (2) in transit; (3) in distribution; (4) in storage.

Lead and Iron. The first, and perhaps the most dangerous impurity is lead. Permanent hard water soon forms a deposit of sulphate of lead inside the pipe, and thus protects it from being dissolved; but chalky water attacks lead, while soft water soon forms an oxide of lead, which is soluble in water. This is detected at once by adding sulphuretted hydrogen, which produces a brown coloration. The action of water on lead is not yet wholly understood. The soft water of Loch Katrine transferred to Glasgow acts on the lead, and yet there is no poisoning. Heat, pressure, and stagnation favour the action of lead in the water. Proper filtration removes it.

Block tin pipes are needed for *very* soft waters (especially with nitrates), and for all aerated waters. There is a system of adding carbonate of lime to soft water which prevents contamination in lead pipes. This has been done at Sheffield.

Iron in the water sometimes dissolves the lead. If there be more than one-twentieth of a grain of lead per gallon, the water is deemed unfit to drink; one-tenth of a grain may produce symptoms of poisoning. At Claremont, seven-tenths of a grain was found in the water. Cast-iron pipes are, of course, safe.

The purest and softest water and aerated water get most contaminated, also water with excess of organic matter (nitrates) and chlorides.

Organic Matter. Organic matter is either suspended or dissolved in water. It should not exceed 2 or 3 grains per gallon, and may be in one of three forms:

1. Unchanged—dangerous.
2. Consisting of ammonia—less dangerous.
3. Consisting of nitrites and nitrates—harmless.

The nitrogen alone may be also in a fourth form—4·00 gas—which is harmless. There should not be in ordinary water above 1 grain per gallon of nitrites or nitrates. In pure water there is none. Of ammonia (free—*i.e.*, combined with an easily decomposed substance) there must be less than ·05 per million. Rain-water often contains much more. Nitrates are due to animal pollution. When there is much albuminous ammonia—*i.e.*, ammonia in organic substances not easily decomposed, with nitrates, etc.—the cause is vegetable pollution.

Deep wells may contain free ammonia and chlorides without being polluted, but in shallow wells these cause pollution. General solids in water should not exceed 8 grains per gallon, though in chalk they may rise to 14. Sewage water may be clean and drunk with impunity, and is even fattening, if free from pathogenic germs, which cannot be detected. The two diseases most easily conveyed by water are typhoid and cholera. Any oxygen dissolved in water is mixed with it mechanically, as in air, and is not chemically combined.

Distribution of Water. Aqueducts have been used from the earliest ages. They existed in Pompeii 312 B.C. The Romans used inverted syphons to cross valleys; now water is conveyed uphill and downhill in iron pipes in a gentle flow. In towns water and sewage pipes should never be laid together. The former should be plunged into pitch or varnish, and either glazed to avoid corrosion, or heated to a white heat (1,200 F.); steam should then be passed over it, forming a protecting oxide. The pipes should have spigot joints, rimmed with lead and not with gaskin and tar. Water waste preventers should be fixed to each main to detect leakage. All house pipes are of lead for convenience in levelling, etc., and it is here the danger occurs with soft water.

The largest city in the world (London) still depends on rain-water, and uses one-third of the Thames. It is calculated that of ten glasses of water one at least has been used before; in fact, is dilute sewage. The principal supply is taken at Hampton and stored to settle and clarify in reservoirs capable of holding a week's supply. Five hundred and sixteen million gallons daily are taken by five companies.

Filtration. The water is then filtered through 3 ft. or more of fine sand and gravel [2]. The finer the sand, the fewer microbes pass through it. Ordinary sand lets half through; fine sand, 14 per cent.; very fine silver sand only 5 per cent. The fine sand used to be removed and well washed as needed. The flow of water through must not exceed 30 gallons per square yard per hour. By filtration mere surface water is changed into pure ground water. The newest method of using the sand filter is to allow a jelly-like scum to accumulate over the sand consisting of innumerable bacteria, and constituting a living filter. The crowding microbes on this surface penetrate into the sand, nitrify the organic matter and destroy other and poisonous germs. This surface should not be disturbed as long as the water will pass. In such a filter the sand should be 1 ft. thick, and the water should sink through at the rate of 4 in. per hour.

When such a living filter is in good order 99½ per cent. of the germs are removed. No filtered water should have more than 100 germs per cubic centimetre of water. The water at Altona receives all the sewage of Hamburg, and yet, by filtration, is purer than the unfiltered river Elbe above Hamburg.

In some cases a layer of magnetic carbide of iron is placed under the sand to oxidise organic matter into nitrites and nitrates.

Slate cisterns are good, but they leak; they must not be jointed with red lead, and are often made with grooved sides and set with white lead. This soon leaks; the plumber repairs the leak with red lead, and poisoning ensues. Zinc or galvanised iron cisterns are sometimes used; in this case the iron cistern is dipped into wetted zinc when made. The best supply is a constant service so that no cistern is needed; then no fouling occurs. Screw-down taps are wanted.

The drinking supply should, of course, be separate from that used for closets. Lead cisterns are bad and are most dangerous when new or scraped; wood cisterns are also bad, but stoneware is a good material. The cistern should be dark and well covered.

Analysis of Water. Points of importance to be noticed in analysing water are: Suspended solids, dissolved solids, hardness (temporary or permanent), chlorates and nitrates, ammonia (free or albuminous), absorbed oxygen. Points of minor importance are the fixity or volatility of solids; *loss in solids or ignition*, and the presence of nitrates, sulphates, and metals in solution.

The hardness is decided by the soap test—thus, 70 cubic cent. = 70,000 milligrammes, and as there are 70,000 grains in a gallon, therefore the milligramme is 70 cubic cent. = grains in gall. The soap solution contains 17 grains of Castile soap to 1 litre of water. One cubic centum of this neutralises 1 grain of salts of magnesium or lime.

Chlorine is shown by adding nitric acid and nitrate of silver. One grain of chloride per gallon gives a haze, 4 grains turbidity, and 10 grains a precipitate. The presence of organic matter is shown by the disappearance of the pink colour caused by adding primary acid potash. Free ammonia is revealed by Nessler's test. Lead or copper are shown by adding hydrochloric acid and sulphuretted hydrogen, which gives a brown coloration. There is *no test* for poisonous germs.

Microbes do not necessarily unfit the water for use, but they show the presence of nitrates, which they reduce to nitrites. Low vegetable organisms purify the water and are found in all running streams. Higher animal organisms are also common in pure streams, and, like the ascaris or fluke, may be dangerous.

The following table gives the average analysis of water

CONTENTS.	Rainwater in tanks.		Upland lake water.		Deep wells		River with sewage		River at source

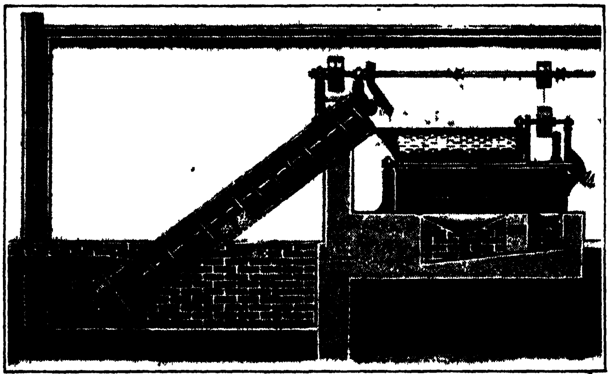
BEET SUGAR MANUFACTURE

Processes in Making Beet Sugar. Extracting Sugar from Molasses. The Beet Sugar Factory. Candy and Caramel. Invert Sugar

From Beet to Beet Sugar. The outline for the process of manufacturing sugar from beet is as follows: The beets are washed from adhering earth and stones, and then, by means of an elevator, sent up to a machine which slices the beets into pieces resembling vermicelli. The slices are then put into large iron cylinders and "diffused" with hot water, by which means the sugar is obtained in solution. This sugar solution is then mixed with about 2 per cent. of lime and carbonic acid gas passed into it. A chemical reaction takes place, and carbonate of lime is thrown to the bottom of the vessel, taking with it most of the impurities. The liming is repeated, and sulphurous acid gas passed in; another precipitate then forms, and leaves a clear liquid, which is evaporated until sugar is thrown out in a similar way to that followed in the case of cane sugar manufacture. The divisions into which the subject can conveniently be divided are: (1) washing and slicing, (2) diffusion, (3) saturation, (4) evaporation and (5) crystallisation.

Raising the Beets to the Washers. The beets are conveyed to the washing tanks by bucket elevators, scoop-wheel elevators, or screw conveyers [10]. The *bucket* elevator is not much used, at least in modern factories, as the grit and earth from the beetroot cause a disastrous amount of wear on the buckets and chains. The *scoop-wheel* consists of a long enclosed wheel, with a series of scoops on the circumference. The beets are conveyed down a channel to the bottom of the wheel, and are caught by the bottom scoop. The wheel of scoops revolves, and as each scoop takes up its quantity it passes higher up, and is replaced by the one behind it. When the scoops reach the top of the wheel their contents are automatically thrown into a channel which conveys them to the washing machine. To lift the beets to, say, 18 ft., the wheel requires to be very large and cumbrous, hence, if the distance be more than a few feet, the screw elevator is used. The *screw conveyer* is, perhaps, the most convenient means of transporting beets, and is also useful for lifting water at the same time. As will be seen from the illustration, the screw conveyer consists of a heavy hollow spindle with a spiral blade, the whole being placed in an inclined position. A screw conveyer about 40 in. diameter and 25 ft. long raises about 600 tons of beets in 24 hours.



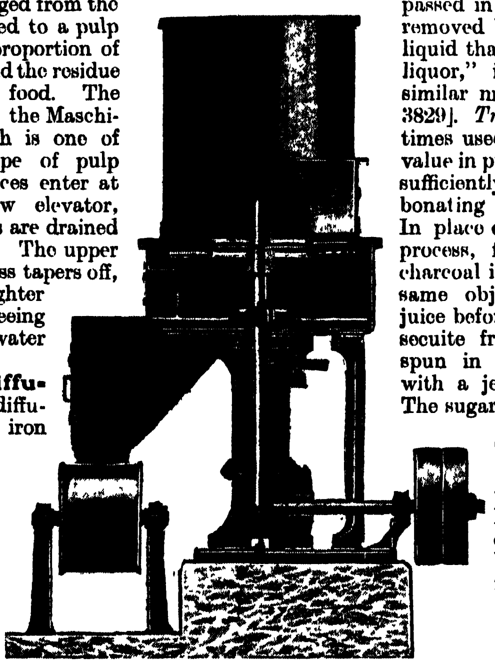
10. SCREW CONVEYER FOR ELEVATING BEET

The Washing and Slicing Machines. Washing removes soil and pebbles, which would not only injure the slicers, but introduce much mineral impurity into the subsequent diffusing vessels. The simplest form of beet washer is known as the *whisk* washer. It is fitted with a stirring gear consisting of a central shaft to which vertical arms are attached. The vessel in which the stirring gear is attached is of wrought iron, open at the top, and fitted with a perforated bottom, through which earth and stones fall. Underneath the washing machine there is a discharge arrangement for the water, and the stone trap is fitted with a manhole for cleaning out the stones. Another form of washer consists of a perforated drum, into which the beets are put, and which revolves in a water trough fitted with discharge arrangements like the whisk machine.

After washing, the beets are conveyed by an elevator to the slicing machine on an upper floor. This elevator may be of the bucket variety, in which an endless chain of buckets is employed.

The slicing machines cut up the roots into "cossettes," or slices. A useful pattern is shown in 11. Extra sets of cutter-boxes and knives should be ordered with the machine.

Diffusion. Formerly the beets were rasped to a pulp, the juice pressed out in hydraulic presses, and the solid mass dried by centrifugal machines. Schützenbach then suggested macerating the dried roots in warm water, but this comparatively slow process was replaced by the diffusion process, on the suggestion of Dubrunfaut. The sliced beet is conveyed to the diffusion battery by a band conveyer. Fig. 12 shows a battery in a series of twelve diffusers arranged in a circular manner, the one shown being fitted up by the Compagnie Fives-Lille. The hopper at the top revolves, and feeds the diffusers in turn with cossettes. Diffusion batteries are also arranged in straight lines of twelve or fourteen diffusers. The method of discharging the diffuser varies, but the bottom discharge for exhausted beets is preferable, as shown in 13. Dr. Pfeiffer's patent discharge is effected by means of compressed air. As soon as one cell of the diffuser is charged with cossettes, it is shut down, and warm water run in. This water takes up some of the sugar, and is then passed into each of the other diffusers in turn. The smaller cylinders shown outside the circle of diffusers are called calorisers, and reheat the water, which, as it passes from the diffusers, loses much of its heat. The exhausted beet is discharged from the diffusers, and is conveyed to a pulp press, where a large proportion of the water is removed, and the residue left ready for cattle food. The spiral elevator press of the Maschinenfabrik Grevenbroich is one of the most modern type of pulp presses. The spent slices enter at the bottom of a screw elevator, and in passing upwards are drained of much of the water. The upper part of the elevator press tapers off, and presses the slices tighter and tighter, thus freeing them of most of the water they contain.



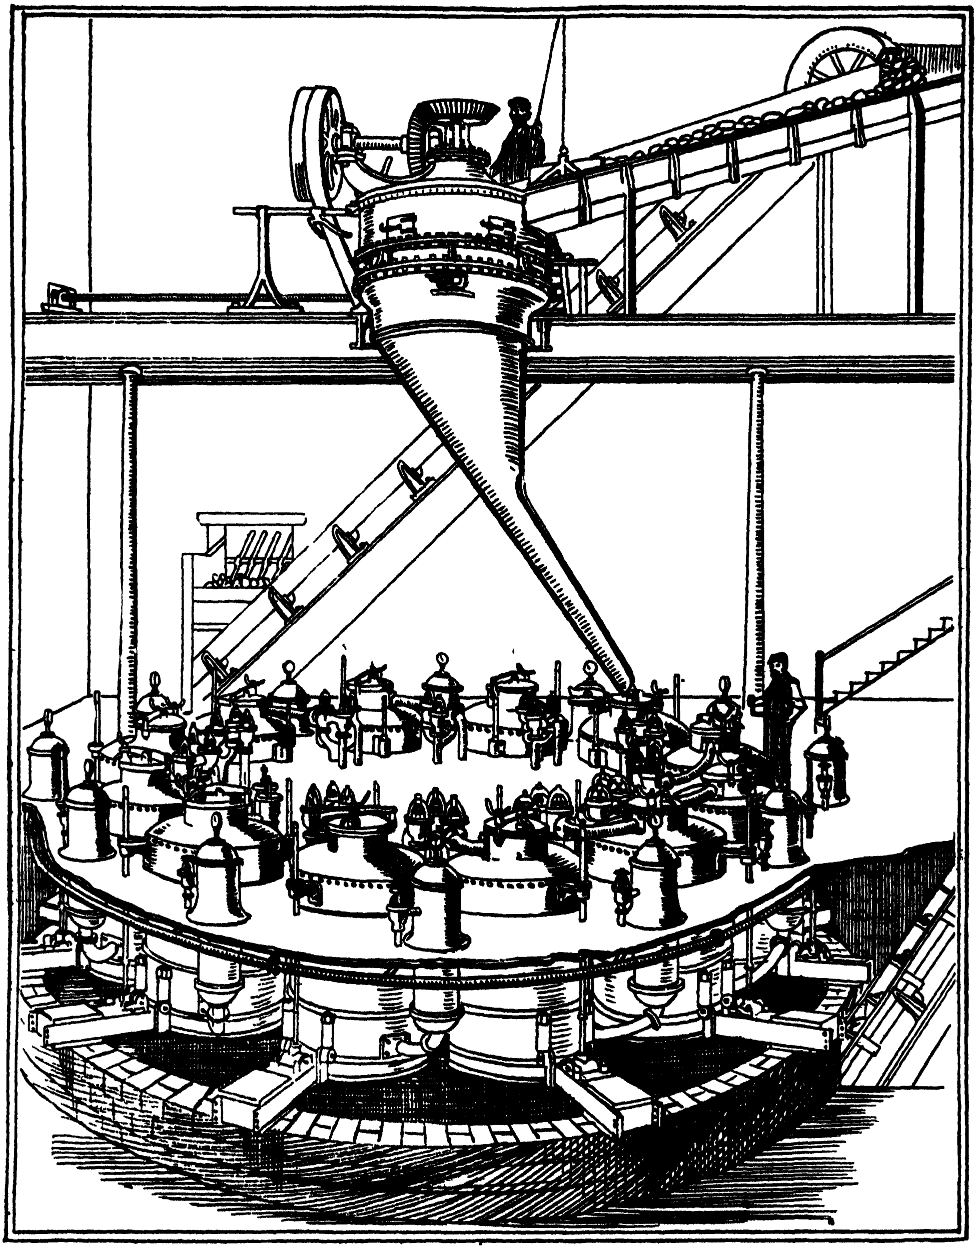
11. BEET SLICER

Continuous Diffusion. In continuous diffusion the diffuser is an iron cylinder, and contains a perforated iron cylinder 4 ft. in diameter and 36 ft. long. The axis is formed by a smaller cylinder, and between the two is a helix. The inner cylinder is revolved at such a rate that beet slices travelling along the helix take about one hour to go the whole length. The cossettes are continually immersed in water, which enters at one end, at 86° F. The conditions for good diffusion are fulfilled when the cossettes and water move in opposite directions. This type of diffuser is stated to require but little attention, and less labour than the battery type, but it has not yet come into general use. The temperature in the diffusers is maintained at 70° C. to 75° C., but this is not enough to kill the germs of fermentation, which often cause much trouble. To prevent incipient fermentation, antiseptics are added to the beet chips. Hydrofluoric acid in the proportion of two to six grains per hectolitre has been recommended by Verbiese, Van Voss improving on this by using ammonium fluoride. Sulphurous acid, and aluminium bisulphite have also been advocated as suitable antiseptics. It is the presence of enzymes in the juice that causes its darkening, these enzymes acting as carriers of oxygen.

Saturation. The juice is conveyed to the saturation tanks where two to three per cent. of lime is added in the form of milk of lime. The juice is then submitted to carbonic acid gas, this process being called *carbonatation.*

Double and Triple Carbonatation. The precipitate that falls takes down with it many of the impurities in the juice, and the heat that is applied sends up a scum. The clear liquid is decanted, the scums and sediment being filtered in a filter press. The clear juice is again treated with a smaller quantity of lime, carbonic acid gas passed in, and the resulting precipitate again removed. Finally, sulphurous acid gas is passed in and the sulphide of lime removed by filtration. The clear liquid that results, known as "thin liquor," is next evaporated in a similar manner to cane juice [page 3829]. *Triple carbonatation* is sometimes used, but while it is of great value in practice, it is not considered sufficiently superior to double carbonating to warrant general use. In place of the sulphurous acid gas process, filtration through animal charcoal is sometimes done with the same object of obtaining a clear juice before evaporation. The massecuite from the vacuum pans is spun in centrifugals and washed with a jet of steam to whiten it. The sugar resulting from this treatment is termed *first jet.* The liquid that flows from the centrifugal contains the molasses and is reheated, filtered through charcoal, and evaporated. When spun in the centrifugals the sugar yielded is known as *second jet.* The molasses is treated a third or fourth time and smaller quantities of *third* and *fourth jet* sugar obtained. The final molasses is treated for the recovery of the sugar by special processes described later.

Carbonic Acid Gas. The carbonic acid gas used in carbonatating is obtained by roasting limestone. The kilns [15] in which this is done are either separately fired with coke or constructed to deal with coke and lime in alternate layers. The interiors of the kilns are built of firebrick and cased with iron plate. The carbonic acid gas is drawn off through two pipes near the top of the kiln and the gas is then passed into a cooler and washer. The kilns are charged from the top with lime or lime and coke. The gas washer is a cylindrical vessel; the gas enters near the bottom and meets a shower of water which falls from near the top of the washer. The gas finally leaves by an outlet at the top of the vessel to be pumped into the beet juice. The Sangerhäuser Actien-Maschinenfabrik have a form of washer in which the gas is led through narrow streams of water which drip from projections inside the washer. The points to bear in mind in regulating the limekiln are to use lime as free from alumina and silica as possible; to use a coke giving

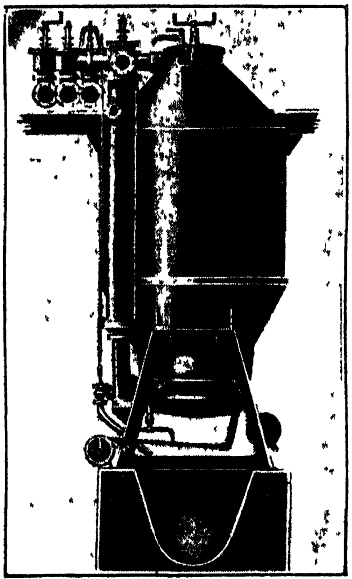


12. CIRCULAR DIFFUSER

as little ash as possible, say a maximum of 7 per cent. of ash ; and to see that the charging be done regularly. Sometimes, from indifferent charging, the charge lodges on the sides of the kiln, this being known as *scaffolding*, and if the air be not properly regulated free air will be mixed with the gas, or if too little be admitted carbon monoxide will be formed. Air in the gas may also be due to leaks in the kiln.

Sulphurous Acid Gas. Sulphurous acid gas is given off when sulphur is burnt in the air. It exerts a powerful bleaching effect on the beet juice. Special iron furnaces are made for generating the gas, the upper part in those made by the Maschinenfabrik Grevenbroich being fitted with a water-jacket to prevent overheating. Sulphur is fed in at the top, and combustion is started by inserting a red-hot iron and kept up by passing in compressed air. The fumes, known as sulphurous acid gas, are pumped direct into the beet juice at the stage indicated above.

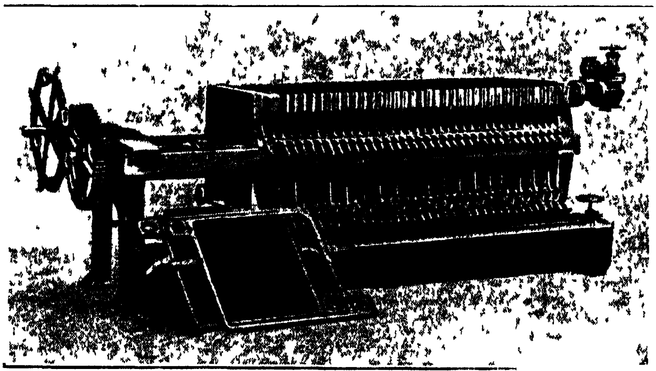
Lime. The quicklime removed from the limekiln is used in the sugar factory for making milk of lime. This is usually done in brick tanks, but special lime-slaking machines are sold for the purpose. Sufficient water is used so that when all action has ceased the lime is still covered with water. Before being used the lime is diluted with water to make milk of lime. It has been found that slaked lime formed in the presence of large excess of water is inferior to lime which is dry slaked, and that solution of sugar is an improvement on water alone as it tends to preserve the lime. Some workers recommend dry-slaked lime to be added to the beet juice instead of milk of lime, but others allege that darkening of the juice results from using the solid.



13. DIFFUSER WITH BOTTOM DISCHARGE

Saturation Plant. Carbonatation and sulphuration are carried on in square saturators, either sunk in the floor with working valves controlled from the top or so arranged that the valves are in the front of the apparatus. The carbonic acid gas is admitted by valves, and there are also provided steam coil, inlet and outlet valves, and juice valves. Saturation with sulphurous acid gas is conducted in similar saturators which are connected with the gas supply from the sulphur furnace.

Filter Presses. The horizontal type of filter press [14] now so largely used consists of a heavy cast-iron frame, supporting a number of square plates by means of projections on the sides of the plates. The square plates are corrugated on the surface, and upon each plate is placed a filter cloth. A series of these plates is screwed tight together by means of levers, and then the sugar-juice is pumped or forced through the press by means of a central conduit. The pressure sends the clear juice through the cloths, leaving the sediment on the cloth in a cake. In another form of filter press now generally preferred, the juice enters at the corner of the filter plates. Other types of filters are the Taylor filter, the Danek filter, which works at pressure, and the Claritas filter, which is designed for filtration without pressure. Sand filters should also be mentioned, as they are a cheap method of obtaining clear sugar juices.



14. FRAME FILTER PRESS WITH SIEVES

Special machines are made for washing the filter cloths. These consist of a cylinder in which is a revolving shaft carrying paddles.

Dupon devised a purification process for beet juice in which baryta replaces some of the lime, but Kruger regards baryta as a dangerous addition.

Purification by Electricity. Several electrical processes have been proposed, some in conjunction with the use of ozone. The combination of ozone and electrolysis is more powerful than either separately; but there seems but little chance of the electrolytic treatment becoming profitable. In one electrolytic process hydrosulphite is decomposed in the juice, and in another method albuminate of barium is used before passing the syrup through electrolysing troughs.

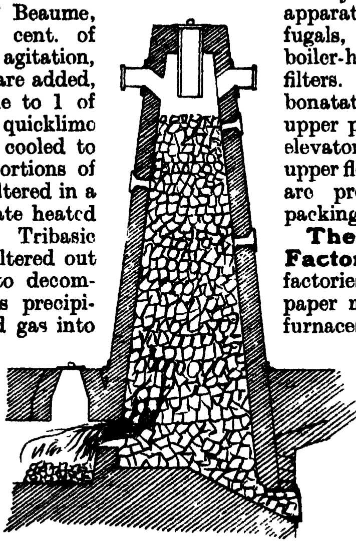
An aluminium process has been devised from which good effects are obtained. It consists in adding aluminium powder to the juice and then ammonium sulphate.

Crossfield and Stein's process for the purification of beet juice, in which peroxide of hydrogen is used, is referred to in the lesson dealing with sugar refining.

Extraction of Sugar from Molasses. One of the most important problems in the sugar industry is how best to recover the sugar which remains in the molasses obtained in the manufacture of crystalline sugar from cane or beet.

The earliest process was that of Dubrunfaut, who submitted a diluted molasses to the process of osmosis, with the idea of separating the salts that prevented the sugar from crystallising. This method was not profitable to work. The fact that sugar forms a compound with baryta, strontia, and lime has been taken advantage of in separating sugar from molasses. In Schribler and Segferth's processes molasses was mixed with lime, and the saccharate of lime thus formed was separated by alcohol. Bodenbender and Manoury introduced modifications of this process, but in all alcohol was required, and this is an objection, owing to the price or fiscal difficulties.

The Steffen Process. Steffen eliminated the use of alcohol. He discovered that lime forms with sugar three different saccharates—the *monobasic* saccharate, the *bibasic* saccharate, and the *tribasic* salt. The tribasic saccharate is with difficulty soluble in 200 parts of water, but is quite insoluble in water saturated with the tribasic salt itself. When precipitated under certain well-defined conditions it is granular, and can be readily washed in the filter. The operations in the process are: Forming the bibasic saccharate in the cold; boiling to form sugar and tribasic saccharate; and filtering the tribasic salt. The process is worked as follows: Molasses is diluted with water until it has a density of 6·6° Beaume, equal to from 7 to 8 per cent. of sugar. Then, with constant agitation, small quantities of quicklime are added, in the proportion of 1 of lime to 1 of sugar. After each addition of quicklime the temperature rises and is cooled to 15° C. before adding further portions of lime. The mixture is then filtered in a filter press and the clear filtrate heated for ten minutes at 100° C. Tribasic saccharate is formed and is filtered out and washed with hot water to decompose it. The residual lime is precipitated by passing carbonic acid gas into the solution, and the sugar obtained by filtering and evaporating. It is usual, however, to employ the tribasic saccharate instead of lime for treating raw juice. The other liquors are used for diluting further quantities of molasses and are eventually used as a fertiliser when they become laden with the mineral impurities of the molasses. The Steffen process is equally applicable to the recovery of molasses in refineries, the slight variation involved being in the treatment of the saccharate. The saccharate from the presses passes into the dissolving pans, where it is dissolved by means of sugar syrup which has been saturated with carbonic acid gas and heated to about 70° C.; the sugar solution is then diluted with sweet waters so that it contains approximately 5 per cent. of sugar. After filtration the liquor is fully saturated with carbonic acid gas and treated as above.



15. LIMEKILN

The Use of Strontia. Scheibler has since worked out on these lines a process in which strontia is used. Strontium saccharate is formed, separated by filtration, and washed with a 10 per cent. solution of strontia. The warm solution is then cooled, strontia monobasic saccharate and sugar being yielded by the decomposition of the bibasic salt formed when hot. The strontia solution is decomposed by carbonating, filtration, and evaporation. The strontium carbonate is calcined to form the oxide, and this with water gives the hydrated salt, which is used over again.

Beet Sugar Factory. The cost of a factory for manufacturing beet sugar may be estimated at from £30,000 to £40,000, this sum providing the machinery for working 300 tons of beetroot a day. The factory building would take about a year to construct and fit, and would cost about £8,000. A working capital of about £40,000 is also required for paying for roots and current expenses. Mr. Stein has recently shown a balance-sheet of beet sugar works in which a gross profit of £17,500 is produced on a capital of £80,000 after allowing for depreciation. Such a factory would purchase beetroots from the growers in the neighbourhood. In regard to the general arrangement of the factory the ground floor is usually taken up with the beet-washing apparatus, the diffusion battery, centrifugals, vacuum pumps, beet elevators, boiler-house, limekiln and bone-black filters. On the next floor are the carbonatation apparatus, the triple effet, upper part of diffusion apparatus, beet elevator, and laboratory, while on the upper floor are the vacuum pans. Rooms are provided for storing sugar and packing purposes.

The Waste Products of Sugar Factories. The *bagasse* of cane sugar factories can be utilised as a fuel, for paper making, and as manure. Special furnaces are required for burning bagasse. With a Grundel semi-gas furnace it has been found that when dry bagasse is used more steam is obtained for a similar grate surface, and if the draught be properly controlled an economy of fuel is effected. Damp or a mixture of damp and dry bagasse can be burnt on emergency although there is of necessity a diminished production of steam. Dry cane leaves (trash) are only slightly inferior to bagasse as fuel. Bagasse wet from the mill is commonly regarded as being equivalent in fuel value to from one-fifth to one-sixth of its weight in coal. Bagasse has also been proposed as a food for cattle.

Molasses is used as a fuel, for the manufacture of alcohol, and for feeding cattle. One method of using it as fuel is to sprinkle the molasses on the bagasse on its way to the furnace, or it can be sprayed on the burning bagasse. Animals take molasses fodder willingly and no bad effect has been observed, no purgative action has been noted, and the quantity of milk in the cow fed on molasses fodder is increased, though it does not keep so well. Organic acids specially suited for mordanting wool have been made from vinasse.

Dried *diffusion pulp* from beet-sugar making should be dried before being used as a cattle food, otherwise it tends to bring on certain diseases. *Beet tops* are used for feeding cattle or left to rot in the field as manure. The *waste liquors* from beet sugar factories have also been used as a source of ammonia.

Sugar Candy. Sugar candy is used largely for priming beer and wine in addition to its well-known use as a sweetmeat. The syrup after being filtered bright is boiled in a vacuum pan until the requisite concentration is reached, the point being technically known as boiling to "thread" or "feather." The candy pans or pots have holes drilled in the sides, and threads are stretched across the hole, being filled up on the outside by a mixture of beeswax and resin to keep the syrup from running through. The syrup is filled into the pots, which are then transferred to a store to cool gradually in from 9 to 12 days. The rate of cooling influences the character and quantity of candy formed. The lower shelf or store cools the syrup the more rapidly, but the yield is inferior in quality. This is sometimes corrected by adding more water to the pots on the lowest tier.

Caramel or Burnt Sugar. Caramel is the brown substance produced by the action of heat on sugar or glucose. It is used in very large quantities as a colouring for beverages, gravies, and sweetmeats. The processes of manufacture are based on those of Asrymusry, who gave two recipes—one for the production of rum colouring, and the other for beer or vinegar. For *rum colouring*, take 3 kilos of caustic potash or soda and 6 kilos of water, or 4 kilos of carbonate of potash and soda and 8 kilos of water. Dissolve with heat in a large iron pan, and add 120 kilos of glucose or 130 kilos of syrupy glucose. Boil over the fire till irritating vapours begin to appear, then decrease the heat and stir continuously till the required shade is produced, and stop the process by adding 30 to 40 kilos of water in a fine jet. For *beer* or *vinegar colouring*, 6 kilos of carbonate of ammonia, 6 kilos of water, and 120 kilos of glucose are required, the method of making being the same as for rum colouring. The addition of alkali has for its object the production of a darker and brownish shade, and renders soluble the small quantity of ulmic acid which is always formed towards the end of the cooking, thus enabling a solution to be made from the caramel which is not cloudy.

Salmon and Goldie, who made a research on this subject in 1900, gave the following as a good recipe. The glucose used must be a well-prepared maize glucose. About 5 cwt. of good white glucose is melted in an iron vessel. At a temperature of 95° C., this takes about one hour, and when all the glucose is melted the temperature is raised to 110° C., another 20 minutes being required. Then add 45 oz. of carbonate of ammonia and 15 oz. of chloride of ammonia, and stir occasionally till the caramel is formed, some two hours' boiling being needed. This change is very noticeable, not only on account of the increase in volume of the caramel to about double, but because of the evolution of greyish-yellow vapour, which is very pungent, staining the hands yellow. The temperature of *coming on* is about 154° C. The heating is continued till the caramel is so thick that it can only just be stirred. This takes about another hour, but the time varies. The heat is now turned off, and if solid caramel be required, it is thrown out on to iron plates, allowed to cool, and broken up with hammers. If fluid caramel is being made, sufficient water is added to produce the required density. Heat is applied and the caramel is then passed through sieves to remove any carbonaceous or extraneous matter, and subsequently stored in iron tanks.

Some Modern Improvements. Since this method was published, the only other improvement of importance is that introduced in a patent taken out by Gonville and Jarvis in 1904. These inventors melt glucose or other carbohydrate to a syrup, and run the syrup into another vessel, where it is mixed at the atmospheric pressure with ammonia in solution, or otherwise, without the application of heat. The mixture is then transferred to a third vessel, in which it is heated with agitation to a temperature of about 220° F., at about which temperature and atmospheric pressure it is maintained until caramelisation is sufficient.

Another branch of the investigation of Salmon and Goldie had reference to the addition of alkalies to the caramel at the latest stage of its manufacture. They found that the employment of a small quantity—say, half a pound—of sodium or potassium hydrate to 100 lb. of caramel distinctly improves the flavour, and that it plays an important part in keeping the colour dissolved in the beer in which it is employed.

Analytical Data. Good caramel should conform to the following requirements:

1. The intensity or colouring power of a caramel solution, measured in a Lovibond's tintometer, using a 0·10 per cent. aqueous solution and a 52-series yellow-tinted glass, should show 18 degrees on Lovibond's scale.
2. The average specific gravity of caramel fluid is 1·377.
3. The average copper oxide reducing power, calculated as dextrose, is about 33·87 per cent. of the weight of the fluid caramel.
4. The mineral matter should not exceed 0·80 per cent. of the weight of the fluid caramel.
5. The caramel should not be affected by proof spirit or weak acetic, tartaric, or citric acid solutions, and it should not cloud pale ale.

Test for Caramel. A rough test given by Thorpe for ascertaining the presence of caramel in beer is to add tannic acid. If malt only be present, the colour is precipitated, but caramel colour is not altered. In wines, paraldehyde is used as a test, the caramel being thrown out by that liquid as a brown precipitate sticking to the bottom of the vessel.

Sweetmeat Caramel. Sweet caramel has no connection with true caramel, or burnt sugar, but is prepared by boiling down a solution of cane sugar and glucose syrup to the solidifying point, a hard, glassy mass being produced. About 10 per cent. of glucose is needed to prevent the cane sugar becoming opalescent and granular; but in time, by absorbing moisture, the caramel becomes opaque. To prevent this as far as possible the squares are wrapped in paraffin paper. Vacuum pans yield a lighter-coloured product than that made in open pans, but in either process the rule of boiling is, "the quicker the better." The mass is coloured and flavoured appropriately

Invert Sugar, or Saccharum. Invert sugar is an important product in the brewing industry. It is used in beer to improve its quality and stability and as a substitute for part of the malt. Beers in which this malt adjunct is used are preferred by the public, on account of the lighter character and full flavour thus given to them. Invert sugar is prepared by heating a solution of cane sugar with dilute acid or yeast, which causes the constitution of the sugar to be altered or inverted, a mixture of dextrose or levulose being produced. Invert sugar for brewing purposes should possess a full molasses-like flavour, and on this account jaggery is preferred by saccharum makers. A good product can, however, be made from refined beet sugar.

Garton and Parsons, in 1856 and 1859, took out patents for the inversion of cane sugar with small quantities of acid; and Herepath, in 1862, prepared invert sugar by adding 3 oz. to 4 oz. of pure hydrochloric acid to each cwt. of dissolved sugar, maintaining the temperature at between 180° F. and 212° F. for one to three hours. The acid was then neutralised by alkalies, and the product was ready for use in the brewery.

Wohl and Kollrepp's Process. The technical defect in previous processes consisted in the fact that comparatively weak solutions of sugar had to be employed, which necessitated subsequent concentration, with danger of deterioration. There was also a large quantity of acid to be neutralised. Wohl and Kollrepp found that 30 per cent. solutions of cane sugar could be easily inverted, their process being based on the following facts:

1. The rapidity of the inversion of cane sugar in concentrated solution by dilute acids in 40 to 80 per cent. solution at 45° C. to 105° C. is far less dependent on the proportion of the quantity of acid to the quantity of sugar present than it is on the quantity of water. As 80 per cent. sugar solution contains only one-sixteenth as much water for an equal quantity of sugar as a 20 per cent. solution, the complete inversion of an 80 per cent. solution, if this action were independent of the excess of sugar, would only require one-sixteenth as much acid in proportion to the sugar as a 20 per cent. solution, other conditions being equal. Owing to the retarding influence of the excess of sugar about one-twelfth of the quantity of acid required for a 20 per cent. solution is actually necessary.

2. In the inversion of cane sugar with acids there takes place, along with the decomposition of the saccharose and at a speed increasing with the concentration of the sugar solution, a re-formation of products of condensation of the dextrose and levulose, and of both one with the other, which precedes and accompanies the decomposition and colouring, and the speed of which increases more rapidly with the concentration of the acid than does the power of inversion of the latter. Each acid has a very low degree of concentration, at which, when heated for from about a half to one hour at 80° C. to 95° C., it completely inverts a quantity of cane sugar that may amount to as much as about four times the quantity of dilute acid employed without decomposing or colouring the invert sugar formed.

A Working Example of the Process. These investigators calculated out the quantity of acid and the time required for various concentrated solutions of sugar, the following being a working process founded on the facts:

One ton of finely ground white sugar is melted at about 95° C. with 2·4 hectolitres of water in a heated and closed pan provided with agitating mechanism. After cutting off the steam 0·222 litres of pure 38 per cent. hydrochloric acid, previously diluted with ·10 litres of water, is stirred in, and the temperature maintained at from 80° C. to 90° C. for about half an hour. The colourless invert sugar syrup is drawn off, and is ready for immediate use.

The vessel in which the inversion is to be carried out should preferably be of copper or iron lined with enamel, and have steam jacket, stirring gear, and means for introducing live steam. About 560 gallons of boiling water is introduced into the inverter, and the temperature maintained at 190° F. to 200° F. by means of the steam jacket. One cwt. of sugar crystals is run in by means of a hopper, and the mixer started. As soon as the sugar is partially dissolved a second cwt. of sugar is added, and the process repeated until a ton of sugar has been dissolved. Next, 13½ lb. of a 10 per cent. solution of hydrochloric acid is run in and mixed, stirring being continued over one hour at a temperature of 190° F. to 200° F. No neutralisation of the product is necessary, owing to the trifling amount of acid in the finished invert. The invert produced is white or only faintly yellow, and is intensely sweet with a flavour like honey. When cold it is a viscous mass, and on standing for some weeks a magma of crystalline glucose separates. One ton of sugar crystals yields 2,357 lb. of invert sugar.

Tompson's Yeast Process. Any commercial saccharose is dissolved in water heated to 95° F. to 160° F. one part of yeast per 100 of sugar being added and allowed to stand five hours. At the end of this time all the cane sugar is inverted. The most favourite strength of sugar solution is 20 per cent., and 130° F. is the best temperature to employ. The yeast is separated by adding sulphate of lime and filtering. This process can be worked to great advantage with low grade raw sugars, but the product is not so well adapted for priming purposes.

The invert sugar solution can be purified by charcoal filtration, as in refining sugar, and concentrated in vacuum pans.

Saccharum is found commercially in the fluid and solid forms; the liquid form is crystallised by seeding it with small lumps of solid saccharum. With sugar at £15 a ton, saccharum can be made at about 12s. 8d. per cwt.

BANKING

2

Continued from page 3973

By R. LAING

THE important place attained in this country by the second function of banking (the receiving of money on deposit), although fostered indirectly by the legislation intended to restrict note issues [see below], is in the main due to the preference exhibited for it by the general trading and saving community. A reference has been made previously to the transference of capital from one locality to another, and in practice this is done through the branch receiving the deposits of an agricultural district remitting the surplus money held by it to an office in some manufacturing centre, there to be lent out to traders requiring additional capital. If, however, after all such demands have been satisfied, an unexhausted surplus remains, an additional source of lending is brought into operation. All capital which cannot be profitably employed in the country flows naturally, through the instrumentality of the banks, to London, and is there made the means of financing investors in the loans of our needier neighbours and of maintaining London as an exchange centre.

The Employment of Money. As a natural consequence of issue or of deposit, the lending of money at interest follows, as otherwise no profit would be made by the institutions concerned.

The agency of banking in acting as a middleman between borrower and lender has, in some measure, been encroached upon by the rise of joint-stock companies and the facilities given through them for direct investment. One most important section, however, remains unaffected—the employment of money deposited for a short time, pending a favourable opportunity for investment. This is lent through the agency of the banks to the industries which, at the time, are most in need of *temporary* capital.

Every banker in this country is, to a certain extent, a dealer in arbitrage, in receiving for collection documents on other towns and granting drafts on these places, charging, of course, a commission for doing so. In the constant preparedness to do such business, he resembles the Paris dealers to whom reference has been made, and removes what would be, in the absence of such preparedness on his part and on the part of others, an irritating check to commerce—*i.e.*, he saves the B's the necessity of seeking for and bargaining with the A's. The functions of loan and remittance are combined in the discount of a bill payable in another locality.

The function of the safe custody of valuables, which requires no explanation, was in reality the precursor of that of deposit, the care of the client's money following naturally the keeping of his securities.

The Business of Banking. The business of banking is carried on by private partnerships, by ordinary joint-stock companies, and by companies having a certain amount of Governmental privilege and supervision (usually connected with the right of issue). The supervision exercised may reach the point of actual control of the bank's business by Government officials, the directors appointed by the shareholders occupying but a secondary place. In addition, numerous instances will be found of firms or companies who are not considered bankers in the ordinary sense, but who are largely engaged in certain banking business—say, bill discounting, foreign exchange, etc. The operations of any bank depend to a great extent on its clientele and on the locality in which it transacts business—a country banker, for instance, will not deal with shipping business. These operations are further referred to in the succeeding sections.

Space does not admit of a detailed historical resumé showing how the Bank of England (referred to hereafter as the Bank) came to be regarded as the focus and centre of the financial world of this country, but only permits of those incidents and enactments being touched upon which exercise a direct influence on the present-day position.

The Establishment of the Bank. The Bank is the offspring of a political organisation. At the time of its establishment, the reigning monarch, William III, was none too securely seated on his throne. Notwithstanding his undoubted abilities, he had not overcome the prejudices of the Tory party, but had, unfortunately, seriously alienated the sympathies of the districts in which they predominated. He was dependent, to a very large extent, on the support of those trading centres whose merchants dreaded the possibility of the return to power of the Stuart Dynasty, and made it the first article of their political faith to support that which stood to prevent the occurrence of such a contingency. The merchants and citizens of London, the largest of all such centres, having still in mind a scandalous breach of trust perpetrated upon them by a Stuart king, were at once the most important and the most vehement section of the Whig party, and were the means of enabling it, in the divided state of the country, to maintain a front against the power of France.

The Government, in consequence of the ceaseless war expenditure, were never free from financial embarrassment, and, therefore, when at a time of particular gloom a proposal was made for the establishment of a corporation to subscribe in the first place a new loan, they readily agreed to concede to it certain privileges and monopolies in banking.

These privileges were limited to a certain number of years, but this clause was rendered completely inoperative by the never-ending financial predicament of each succeeding Government, the Bank authorities, at each renewal of their charter, being able by some judicious assistance (coupled with that rendered during the period then elapsed) to retain each and all, and even at times to add to their stringency. At no time, as a result of the continual struggle with France, was any Government able to bargain with the Bank authorities on even equal terms, the matter only being brought to a conclusion by the Act of 1844—the arrangement that is at present in force.

The Bank's Monopoly. The practice of banking at the close of the seventeenth century was looked at very differently from the way in which it is now regarded. Deposit banking in its present form was non-existent, and it was deemed impossible to make banking profits without the right of issue, this dogma being so firmly held that, to all intents and purposes, banking and note issue were interchangeable terms. In consequence of this, when it was desired to give the Bank the sole right of corporate or joint-stock banking in England (afterwards restricted to the district within 65 miles of London) it was deemed sufficient to enact, to quote the words of the Act of 1708:

"That during the continuance of the said corporation of the Governor and Company of the Bank of England it shall not be lawful for any body politic or corporate whatsoever, created or to be created (other than the said Governor and Company of the Bank of England) or for any other persons whatsoever, united or to be united in covenants or partnership, *exceeding the number of six persons*, in that part of Great Britain called England, to borrow, owe, or take up any sum or sums of money on their bills or notes payable on demand, or at a less time than six months from the borrowing thereof."

Banker to the Government. In consequence of this privilege and the interpretation accorded to it by current opinion, the only rivals which the Bank encountered in its trading were the private banks of the metropolis, and these, restricted in their number of partners to six, tacitly admitted their inferiority to a large corporate body possessing the support and friendship of the Government, gave up in time, although under no obligation to do so, their own issues, and used the notes of the privileged institution. Although not a State bank in the strict sense of the word, but only an ordinary trading company, it held the privilege already touched upon, acted as banker to the Government, and was regarded by the private bankers as possessing a prestige greater than their own. With the rise of deposit banking, an additional weight was given by the circumstance that when it was discovered that joint-stock banks could transact a profitable business (without the issue of notes) within the restricted area, the banks which then entered the field of operations did not dispute the place they found accorded to the Bank of England, but, on the contrary (the preliminary acrimonious disputes originating in the jealous anger of the Bank authorities having been closed), gradually established with it the present friendly relations, *and concluded by making it the depository of their reserves.*

The Country's Final Reserve. The Bank, originally established solely with a view to transact corporate banking and to lend some very acceptable assistance to Government, had already the care of the greater portion of the paper currency of the country committed to its charge; but this action on the part of the other joint-stock banks saddled it with the more onerous duty of controlling and safeguarding the final reserve of this country, a duty which, although never formally admitted by the Bank authorities, claims the closest attention of the Court of Directors.

The Bank's note issue can, however, have but little claim upon their time, the duties of the Bank in this connection having been laid down with great rigidness and exactness by the Act of 1844, which, in effect, converts the Bank (for this purpose) into what is nothing more nor less than a machine. It will be quite sufficient, in consequence, to briefly recount the objects of this Act and the means taken in it to attain them.

The domain of finance is a particularly fascinating one for Parliamentary theorists, and, in consequence of the crises of 1797 and 1825, there existed, at the beginning of last century, a very considerable body of politicians deeply interested in this question. They were possessed by the firm conviction that the crises and their attendant evils were solely due to excessive issues by the country banks, who were held to have encouraged the most reckless speculation. Their £1 issues, circulating largely in the hands of a class at that time uneducated, and in consequence extremely liable to unreasoning panic (in the event of any suspicion arising as to the circulating medium), were singled out for special attack.

Country Banks and Panic. The disease was considered too desperate for cure. The small notes were got rid of, and the Act of 1844 was passed to cripple, and in time destroy, the country circulation—a process that seems to be approaching completion.

The following constitute the chief provisions of the Act of 1844:

1. The Bank of England was divided for the purposes of the Act into two departments, those of Issue and of Banking. The Banking Department (carrying on business in the ordinary manner), is not dealt with by the Act.

2. The debt due by the Government to the Bank, and sufficient securities to make up a total of £14,000,000, were to be taken over by the Issue Department, and that department was authorised to hand to the Banking Department notes equalling this sum. In addition, it was authorised to hand to the Banking Department notes in exchange for all bullion transferred, with the provision that the silver bullion held at any time by it was not to exceed one-fourth of the amount of gold bullion concurrently held by them

3. Notes at the rate of £3 17s. 9d. per standard ounce were to be given by the Issue Department in exchange for gold bullion tendered to it.

4. If for any reason some country issue lapsed, the Crown in Council was authorised to increase the issue of the Bank against securities to the extent of two-thirds of the lapsed issue. The reasoning on which this provision was founded was the supposition that against such issues an amount in bullion equalling a third of their sum would be held by the issuing banks as a reserve, and would, on the issues lapsing, be thrown into circulation, the net loss in currency being only two-thirds. The authorised issue against securities is now £18,450,000.

5. The weekly return, dealt with later, was ordered.

Country Issues. We now give a list of the regulations with respect to country issues.

1. Issuers restricted to those issuing on May 6th, 1844.

2. Those then issuing allowed to continue, subject to certain conditions.

3. All claiming right to issue to return a statement of their *average* issue for the 12 weeks ending April 27th, 1844, and this to form the *maximum* of their future issues.

4. Penalties imposed in the event of this maximum being exceeded, or of failure to render weekly returns.

5. The Bank of England authorised to compound with those wishing to cease issuing, at the rate of 1 per cent. per annum, all payments to terminate in 1866.

6. Issues lost if issuer became bankrupt, or ceased to issue, or if bank with six or less partners increased the number to more than six. A country joint-stock bank, issuing notes, establishing an office within 65 miles of London (the National Provincial Bank is an example) does so at the cost of the loss of its issue, while if two joint-stock banks of issue unite, the resulting corporation can only retain the issue of one whose name it takes.

7. A yearly licence of £30, payable for each place of issue —four licences to cover all branches open prior to 1844.

8. Any company or corporate body allowed to carry on banking business within 65 miles of London, provided no bills were drawn, accepted, or endorsed by it payable to bearer on demand.

Position of the Bank in a Crisis. No note may be issued under £5. The Bank of England notes, which are legal tender in England (save when tendered by the Bank) are only payable at the office of issue or in London—repayment of a note issued in Birmingham cannot be legally demanded at Liverpool, but it is payable in gold on demand at Birmingham or London.

Subsequent events speedily showed that, whatever merit the Act could lay claim to, its automatic action could not prevent in the slightest degree those recurrent crises (ascribed formerly to excessive country issues) to regulate which was the primary intention of its framers. On three separate occasions (in 1847, 1857, and 1866) the operation of the Act was suspended as the only means of combating the existing panic, and on each of these occasions a continuance of the Act's restrictions would have entailed the stoppage of the Bank.

The approach of anything like a financial crisis at once makes an impression on the Bank's reserve. Bankers all over the country are called upon to grant loans or to repay deposits (with a consequent withdrawal of their balances at the Bank). As the tightness increases, so do the demands on the Bank—the increased demand for settlement of debts in cash requring an enlarged circulation of currency. The notes of the Bank of England possess so great a prestige that even in the severest panics this country has known they have been accepted by all as the equivalent of gold. An increase in this universally accepted credit money will, as in the past, speedily combat the effects of a panic, by enabling all solvent individuals to obtain the assistance they require ; but until the suspension of the Act makes it permissible for the Bank to issue without regard to bullion in its vaults, every note issued brings the automatic stoppage of the Bank nearer, and increases rather than diminishes the panic and failures.

The Bank's Weekly Return. Before the operation of the Bank's discount rate can be dealt with, some explanation of the weekly return required by the Act of 1844 is desirable. The following is a copy of that for the week ending February 7th, 1906 :

BANK OF ENGLAND

An account pursuant to the Act 7 and 8 Vict., cap. 32 for the week ended on Wednesday, February 7th, 1906.

ISSUE DEPARTMENT

Notes Issued ..	.. £50,405,050	Government Debt ..	.. £11,015,100
		Other Securities ..	.. 7,434,900
		Gold, Coin and Bullion	.. 31,955,050
	£50,405,050		£50,405,050

BANKING DEPARTMENT

Proprietors' Capital	.. £14,553,000	Government Securities	.. £12,584,867
Rest	.. 3,581,456	Other Securities ..	.. 33,311,131
(c) Public Deposits*..	.. 9,638,276	(a) Notes	.. 22,171,330
(d) Other Deposits ..	.. 41,794,989	(b) Gold and Silver Coin	.. 1,620,306
(e) Seven Day and other Bills	119,913		
	£69,687,634		£69,687,634

* Including Exchequer, Savings Banks, Commissioners of National Debt, and Dividend Account

February 8th.

J. G. NAIRNE, *Chief Cashier.*

The practice of the Banking Department is to deliver to the Issue Department all bullion held by it, with the exception of about a million sterling (retained as till money), and to receive in return notes of an equal value. The *real* issue (*i.e.*, the circulation in the hands of the public, in the above example) is therefore £28,233,720 (£50,405,050 less £22,171,330). As it is in the power of the Banking Department to demand from the Issue Department coin or bullion for the notes held by it, the available metal reserve of the Bank was accordingly £23,791,636 (£22,171,330 plus £1,620,306). So long as the

Act remains in operation, the Bank cannot allow the total bullion in its hands to fall below the amount of the real circulation less the issue authorised against securities—the amount of bullion in the case given being represented by the figure £9,783,720 (the real circulation being £28,233,720, and the authorised issue £18,450,000). Once the bullion in the vault reaches this point the Bank ceases to do business, no matter how greatly its assets exceed its liabilities, or how readily its notes are accepted, unless the operation of the Act is suspended.

The item of £14,553,000 is the capital of the shareholders, while that for £3,581,456 is the rest or reserve fund of undivided profits (which latter is in practice not allowed to drop below £3,000,000). The liabilities of the Bank to the Government and public are composed of the remaining three items, in this instance amounting to £51,553,178.

The Bank's Reserve. The last item of these three is a small one, consisting entirely of outstanding drafts, and is easily provided for, while, except in time of war, the public deposits occasion, or should occasion, no trouble to the Bank authorities. The periods of collection and expenditure are regular, and the reserve to be kept against them is easily ascertained, while it is safe to assume that the Government will not be forced to withdraw its deposits in time of peace to satisfy its creditors. The variations of the remaining item are not so regular, and one section in particular, the bankers' balances, is very liable to sudden withdrawals.

The Bank's directors have weekly to decide if, in their opinion, and in view of every circumstance, the reserve comprised of items *a* and *b* is a sufficient one to be kept against *c*, *d*, and *e*. The proportion deemed to be safe is not a constant one, and, indeed, it may happen, through an unexpected financial movement, that the reserve formerly considered inadequate may be looked upon as too large, although it has remained stationary, and the Bank's liabilities have at the same time largely increased.

The factors which may qualify so largely the relative amounts are the state of internal trade and of international exchange, while the lever with which the Bank endeavours to keep its reserve at the desired proportion is its Minimum Discount Rate.

Influence of the Markets. But the Bank finds its task to-day by no means so easy of accomplishment as in the past. Then it dominated the discount market of London (at that time without a serious rival or competitor), any change in its rate having an immediate effect. To-day the position is greatly altered. The markets and exchanges of the Continent and America must now be reckoned with; the conditions of exchange, in consequence of the changed circumstances of commerce, are much more complex; it is surrounded by discount institutions with which it does not in ordinary times compete, whose business in some cases exceeds its own, and whose interests may run contrary to its proposed action; the demand for gold has enormously increased; and, while some other markets absorb greedily all metal that flows in their direction, they are by no means so willing to part with it in turn. In consequence the Bank may sometimes be compelled to supplement an alteration in its rate by entering the open market and taking measures to see that the rates obtaining there approximate to its own.

Long and Short Exchange. It is evident that a bill payable 90 days after sight is not so valuable as one which is payable on demand, the difference equalling the discount which the holder of the former bill would require to pay if he desired to realise the draft. The French merchant in Paris in buying a bill on London takes this, of course, into consideration, and, as he is only entitled to take credit when remitting to London a bill at 90 days (instead of one at sight) for the amount his London correspondent will receive on discounting the document, he will require an allowance from his fellow Parisian which will balance matters. The cash value of a bill for £1 payable in London in 73 days, if discount is at 5 per cent., is £$\frac{99}{100}$, and, if the French sight exchange is at 25.25, its cash value in francs in Paris is $\frac{99}{100}$ths of 25.25 = 24.99¾. In the same manner a London merchant purchasing a bill on Paris payable in 73 days will require, assuming sight rate at 25.25 and discount in Paris at 5 per cent., to receive, expressed in the face value of the bill. $\frac{100}{99}$ths of 25.25 francs (or 25.50½ francs) for each £1 in cash.

A change in the London discount rate entails a corresponding variation in the long foreign exchanges, which does not extend to the sight exchanges. An increase to 6 per cent. would, if the sight rate continued to be quoted at 25.25, alter the cash value of the bill for £1 at 73 days on London to 24.94 $\frac{7}{10}$ francs, while a fall to 4 per cent. would result in a quotation of 25.04⅘ francs. A *rise* in interest in London allows bills drawn on it at a usance to be purchased for a less amount in foreign currency, and renders unprofitable the resale of bills already held. The rates given are quite arbitrary, and in actual practice stamps and other factors enter into account.

The Effect of Bank Rate on Market Rate. The interest allowed by bankers and bill brokers in this country on deposits lodged with them varies with the Bank's discount rate. Any rise or fall in the Bank's rate is reflected in the deposit rate and consequently in the discount rate of the open market, competition tending to keep the margin of profit between these two rates uniform. A rise in the Bank's discount rate (implying a rise in interest rates all over the country) is, however, regarded by the trading community as a most disagreeable check on industry and production, only justified by the existence of some dangerous tendency, which cannot be defeated save by means of such an agency.

One striking difference between the practice of banking on the Continent and in this country is the prevalence of foreign exchange business there compared with the absence of it here. This statement seems, at first sight, to be ridiculous, but what is meant is that, while a Manchester banker will not hold a bill on Paris in his bill case, but will forward it at once to London for collection or sale, a Paris banker will retain a Manchester bill until maturity should it be worth his while to do so. Again, the British manufacturer or merchant has no wish, as a rule, to indulge in the speculation of exchange. All his calculations are based in sterling money; he knows exactly what he requires to receive or pay in this currency to make his usual profit, and, if the foreigner will remit to or draw upon him a bill in English sterling money, he will cheerfully leave to him any pickings or pleasurable excitement he may obtain from the fluctuations in exchange. As a result an enormous number of bills are drawn on the Continent upon this country, and these form a favourite source of investment among Continental bankers.

Effect of the Bank's Discount Rate. The rate at which they are discounted is the London one, and, should the foreign rate of discount rise above this, it will be to the advantage of the Continental banker to sell or discount his London paper and invest his money at home. If this is done to any great extent the exchange will be forced down, and may in time approach the gold point unfavourable to this country. On the other hand, by raising the rate in this country this danger is averted, and if the excess over the Continental rate is sufficiently great it will in time induce a flow of gold to this country through the lock-up of paper drawn at a currency.

The Bank's directors, therefore, when the reserve is low, the foreign exchanges unfavourable, or the outlook unpromising, prevent by their influence over the money market of this country the export of gold, or even induce its import; while, if the reserve be high, the exchanges favourable and the outlook settled, they will, by the reduction of their rate, assist industry and commerce throughout the country.

Private and Joint-stock Banks. The other banks divide themselves naturally into two distinct classes—the private and the joint-stock banks. The former were at one time a very numerous body, no locality being without its bank, the partners of which were recruited from local families, but of the vast majority no trace is left save a string of names (as an alternative title) on the stationery of the branch of the absorbing joint-stock bank. In not a few instances one family established themselves as bankers in various localities, the style under which the business was carried on varying according to the nomenclature of the local partners.

The London bankers enjoyed a higher standing than their provincial compeers, but even of them only a few now remain. The present day tendency is in the direction of large joint-stock companies possessing numerous branches, some in the agricultural districts, and others in the manufacturing or trading centres, each institution being in this way independent of any outside agencies for deposit or loan business, the total number of bank offices in this country at the close of 1905 being 7,393. No supervision or control is exercised by the Bank of England over its business competitors, although its notes are used by them, and it is made the depository of their reserves. This, however, does not free the Bank from being called upon to assist all and sundry in time of panic.

Branch Banks. A number of branches spread over a large tract of country gives to any bank an increased security—a crisis in any particular part, which would, perhaps, bring about the suspension of a purely local bank, being met by means of the assistance of branches situated in districts unaffected by the movement. The agency of London bill brokers in the employment of the surplus deposits of a bank in an agricultural district in the re-discount of bills held by a bank doing business in a manufacturing county is dispensed with by the amalgamation of the two institutions. The balance between any particular branch and all the other branches (if the amount is due *by* it) shows the excess of its loans and cash balance over deposits—*i.e.*, the excess of assets possessed by the bank at that office. A deposit branch will, on the other hand, be a creditor of the other offices. The nature of the local business transactions have a great effect on the items composing the running account between any branch and the other offices.

The banks in the manufacturing town referred to in the last article will, if the foreign merchants pay in bills on London, receive and remit these for their credit in London. In this way they provide funds to enable the London office or correspondent to meet the cheques on the manufacturing town, issued by the manufacturers in payment of raw material, which cheques will be presented through the Clearing-House by the agents of the bankers of the raw material suppliers. Again, if in the receipts of any office there is contained a greater or lesser amount of cash than it can pay away in the ordinary course of business, the cash balance will be adjusted by periodical remittances to or from another office.

NORTH & CENTRAL AMERICA

North America—continued. The United States. The Federal Republic of Mexico. The States of Central America. The Panama Canal. The West Indies

By Dr. A. J. HERBERTSON, M.A., and F. D. HERBERTSON, B.A.

THE UNITED STATES

New England. New England consists of the states of Maine, New Hampshire, Vermont, Massachusetts, Rhode Island, and Connecticut. All belong to the highland region, and rise from a narrow coastal plain to rugged forested highlands, which make lumbering and the allied industries important, especially in Maine. The rivers form falls where they leave the highlands. Along this fall line, at no great distance from the sea, are many manufacturing towns, using cheap water and electric power. Boots, shoes, and textiles are manufactured in the Massachusetts towns; cheap clocks and other Birmingham wares in Connecticut; jewellery in Rhode Island; and boots and shoes in New Hampshire. Fisheries in the coastal waters and on the Newfoundland Banks are important, and much fish is canned or dried for export. Boston (Massachusetts) and Portland (Maine) are the busiest ports and commercial centres. Important universities have been founded, Harvard (Cambridge, near Boston) and Yale (New Haven, Connecticut).

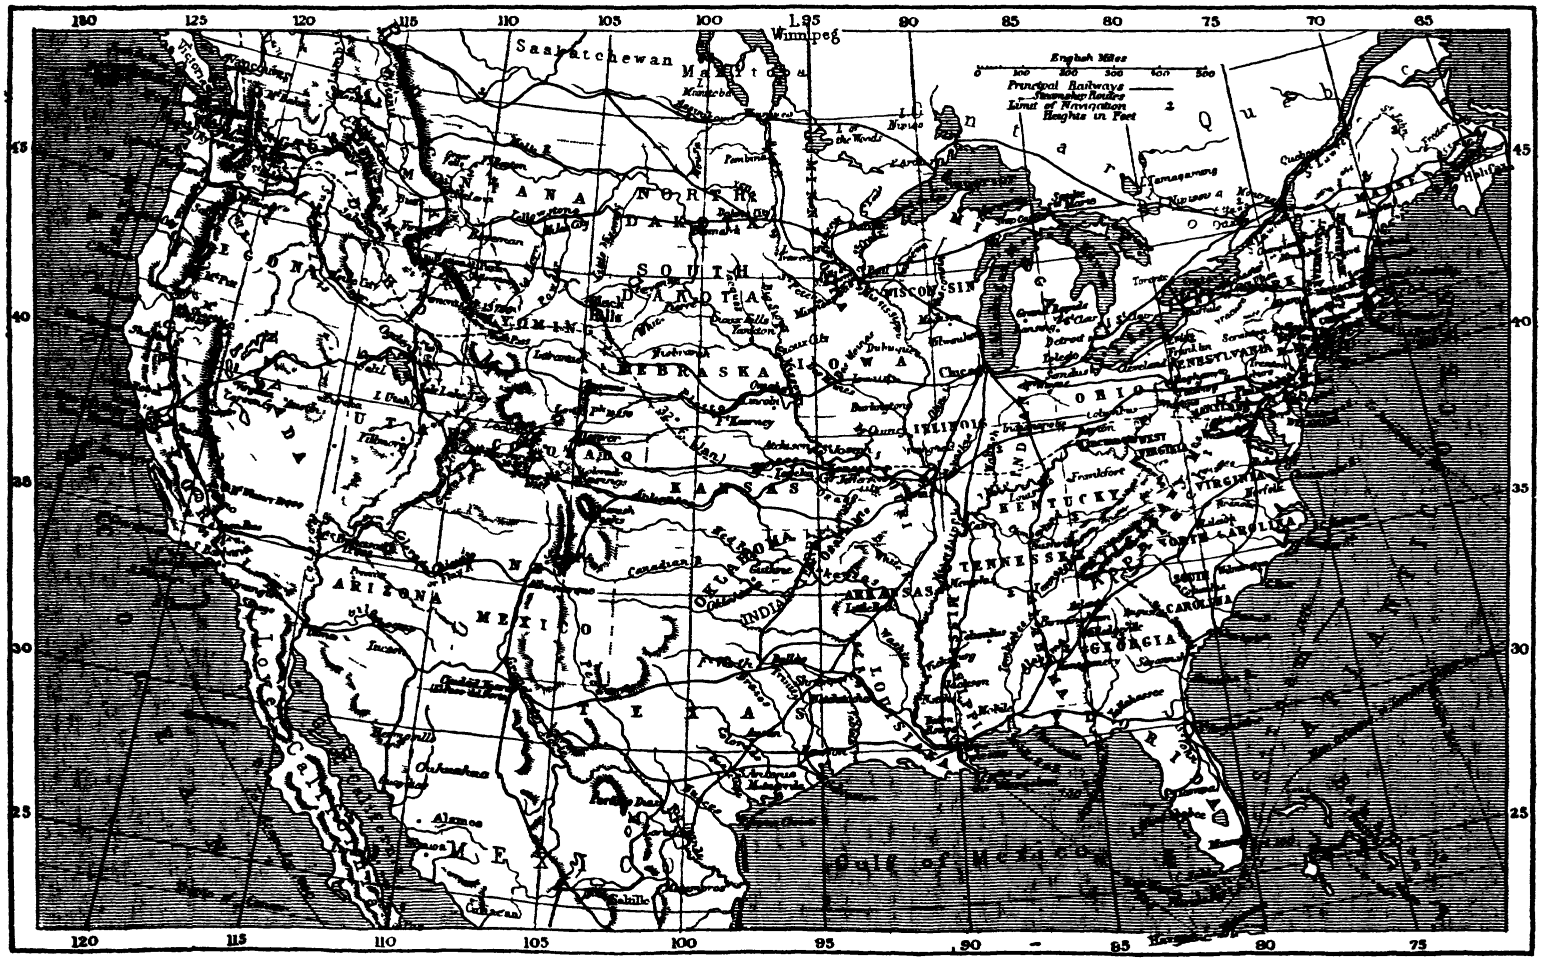
Resources of the Mid-Atlantic States. New York, Pennsylvania, and Maryland lie partly on the Appalachian plateau and partly on the coastal plain, the breadth of which rapidly increases to the south. New Jersey, Delaware, and the district of Columbia, the territory containing the Federal capital of Washington, are on the plain. The Appalachian heights are lowest in the north, where the Hudson and Mohawk valleys, the latter followed by the Erie Canal, make communication across them easy. The Delaware and Potomac make important routes further south, where the height and ruggedness increase.

The forests of the Appalachians supply valuable timber. The Pennsylvania highlands contain immense deposits of coal, iron, and petroleum, making this a wealthy industrial region, with many flourishing towns, of which the greatest is Pittsburg, on the Ohio. Many manufacturing towns—such as Trenton, in New Jersey—have grown up at points where the rivers form falls on leaving the highlands. Lumbering, farming, and dairying are all important, and the fisheries off the coast are of considerable value. Chesapeake Bay has large oyster fisheries, and Baltimore exports both fresh and canned oysters. The whole region is very prosperous, and only a few of the innumerable flourishing towns can be named.

New York, the largest port and commercial and manufacturing centre, has more than half the population of London. It is built on the shores of the Hudson and on islands at its mouth. Among its natural advantages are a magnificent harbour on the Atlantic, and easy communication with the St. Lawrence, the Great Lakes, and the west, by the Hudson and Mohawk valleys. It is the outlet for the whole country east of the Rockies. Built on a relatively limited space, and with an enormous population crowded into a small business quarter, it expands upwards by erecting enormous buildings, or skyscrapers, twenty or thirty storeys high, one building containing the population of a small town. It is a fine city, with broad streets and beautiful parks.

Some Flourishing Cities. The beautiful scenery of the Hudson valley has earned it the name of the American Rhine. Albany, the capital of New York State, is built at the head of tidal navigation. The Mohawk valley and Erie Canal lead to Buffalo, on Lake Erie, which utilises the power supplied by Niagara for its flour mills, distilleries, breweries and machine shops. Troy, near Albany, manufactures shirts. Pittsburg, already mentioned, has oil wells and refineries, as well as the largest steel works in the United States. It was the old Fort Duquesne, and commands many routes to the west, and the important route east across the Appalachians by the Potomac. The outlet of Pennsylvania is the port of Philadelphia, which manufactures locomotives, vessels, and machinery generally. In New Jersey is Trenton, famous for pottery, and Jersey City, in reality a suburb of New York. In Maryland, Baltimore competes with New York and Boston in shipping prairie wheat, which is brought across the Appalachians by the Potomac Gap. Its commerce also includes many products of the southern states and its own manufactures. Washington, the Federal capital, the City of Magnificent Distances, is finely planned on modern lines, with many parks, broad avenues, and national monuments. The Capitol is the meeting-place of Congress, and the White House, the residence of the President, who holds office for four years.

The Southern Atlantic and Gulf States. Virginia, North Carolina, Tennessee, Alabama, and Georgia, belong partly to the Appalachian region, which is here very high, rugged and difficult to penetrate. The forests of the mountains and of a strip of land near the coast are extremely valuable, and timber and turpentine are valuable exports. All the coastal states—Virginia, North and South Carolina, Georgia, Alabama, Mississippi, Louisiana—have hot, moist coastal swamps, in which many valuable crops are grown, chiefly by negro labour. The summers are extremely hot, and the winters warm. Texas, Mississippi, the Carolinas and Georgia lead in cotton, Louisiana in sugar—also cultivated in Florida and Georgia—and in rice,



142. THE UNITED STATES OF AMERICA

also raised in the Carolinas and Georgia. Much of Texas is too dry for agriculture but forms good grazing country. The stock from Texas and from the adjacent Oklahoma and Indian Territory is slaughtered or sent east. Coal is widely distributed in Alabama, Tennessee, Indian Territory, Arkansas and Texas, iron in the first two states, and petroleum in Texas. Steel is manufactured at Birmingham, in Alabama. The cotton manufacture is developing rapidly, especially where water power is available, as at Atlanta and Augusta, in Georgia.

Richmond, in Virginia, at the head of tidal water on the James River, manufactures cotton and tobacco. The Atlantic ports, Norfolk, Wilmington, Charleston, Savannah, and the Gulf ports, Pensacola, Mobile, New Orleans, Galveston, and Houston export cotton. The Atlantic ports also ship lumber and turpentine.

The Prairie States. West of the Appalachians are the prairie states of Michigan, Wisconsin, Minnesota, North and South Dakota, Ohio, West Virginia, Kentucky, Indiana, Illinois, Missouri, Iowa, Kansas, and Nebraska. The north-eastern portion of this area is within the forest belt. Parts of West Virginia and Kentucky are in the forested Appalachian region, but west of these the Black Hills of South Dakota are the only considerable elevations.

These prairie states are the great food-producing regions of the United States. In the eastern prairies wheat is grown in the north, and maize, locally used to fatten hogs, in the south. Stock is kept on the drier ranches of the west. Flour-milling, brewing and distilling, are important in the large towns of the farming regions, and the slaughtering of cattle, the canning and preserving of meat, and the preparation of hides and leather, are important industries in the large towns nearer the ranching districts. The states round the Great Lakes are densely forested, and the lumber industry in all its forms is important. The mineral wealth is great. Much iron is mined round the western end of Lake Superior, and copper is abundant near the south shore in Michigan. Coal is widely distributed, and petroleum and natural gas abound in Ohio and Indiana. Gold is obtained in considerable quantities in the Black Hills of Dakota. Many industries are growing rapidly, the principal, in addition to those connected with food-stuffs, being the manufacture of railway plant, for which both iron and timber are easily obtained. Shipbuilding is important at many of the lake ports. Add to this the very great facilities for movement in all directions across the level prairies, and the admirable water communication by lakes and rivers, and the actual and potential riches of these states become evident.

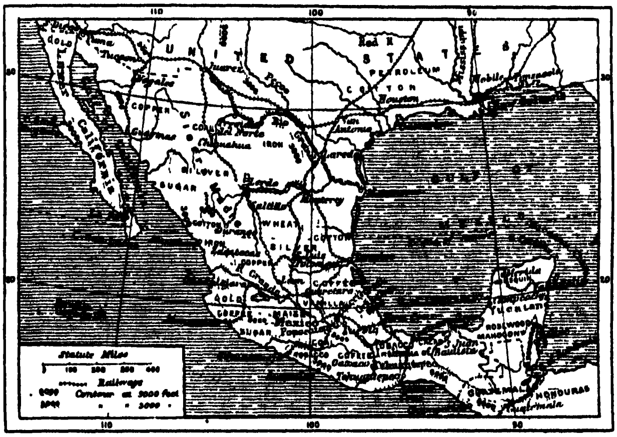
Cities of the Prairie States. The capital of the prairies is Chicago, on Lake Michigan, built on the site of an old fort from which there was an easy portage to the Illinois tributary of the Mississippi. This is now followed by a canal, which permits through water communication between the Gulf of St. Lawrence and the Gulf of Mexico. Chicago is one of the greatest railway centres in the world, and the half-way house at which the products of east and west are exchanged. It has important manufactures of iron and finished lumber, but its characteristic industry is the slaughtering and preserving of the cattle and hogs fattened further west. Other important meat centres are Kansas City, Omaha, and Indianapolis. Cincinnati, once nicknamed Porkopolis, no longer deserves the name. Population has moved west, and Cincinnati, formerly on the western margin of the settled area, is now too far east to be a meat market of the first rank. Its situation makes it an important commercial and transport centre. The leading state in lumber is Wisconsin. Minnesota takes the lead in flour-milling. The greatest flour-milling town is Minneapolis, at the Falls of St. Anthony, which supply the necessary power. It is practically continuous with St. Paul, the head of unbroken navigation on the Mississippi. Duluth and the lake ports ship much wheat. Brewing and distilling are important at Milwaukee, on Lake Michigan, at Louisville (Kentucky)—famous also for its tobacco market—built where rapids interrupt the navigation of the Ohio, and at many other advantageously situated towns. Cleveland (Ohio) has large ironworks, and is the port from which much Lake Superior iron ore is sent to Pittsburg. Of route towns note the importance of St. Louis, at the confluence of the Missouri and Mississippi, where many routes by land and water converge. These are but a few of the conspicuously prosperous cities in a region which little more than half a century ago was almost untrodden by white men.

The Mountain States. Little need be said of the mountain states of Montana, Idaho, Wyoming, Nevada, Utah, Colorado, Arizona, and New Mexico. They are large, infertile, and thinly populated. Lying in the lee of lofty mountains, their climate is very dry. Most of the drainage is to the Pacific or the Gulf of Mexico, but in Utah and Nevada there is a great area of inland drainage, the Great Basin. The little rain that falls evaporates very quickly, and the rivers flow to lakes whose level is not high enough to allow an outlet to the sea. South-western Arizona and Eastern California form the American desert. The natural resources are much less valuable than in the prairie states. The mountains contain great mineral wealth, including gold and silver; but mining alone never leads to the permanent development of a region. Unless other sources of wealth are there, prosperity vanishes when the richer mines are worked out. These states have few such permanent resources. Ranching is successful in the eastern parts of Montana, Wyoming, and Colorado, but the risk of losing stock through want of water makes it more precarious than in the prairie states. Agriculture is possible with irrigation. In the future great engineering works for irrigation will doubtless be undertaken. Salt Lake City, in Utah, illustrates the prosperity which results from successful irrigation; and this prosperity is spreading to the irrigated regions at the eastern base of the Rockies.

Towns are not yet numerous. Denver (Colorado) has smelting works and other industries. Cheyenne (Wyoming) is the centre of the ranching country, and an important railway centre. Natural beauty and bracing air are assets which will become valuable. Colorado Springs is already a frequented health resort.

The Pacific States. The Pacific states, Washington, Oregon, and California are wooded in the west but arid in the east. Lumbering is important. Much of the timber used in the woodless districts of China comes from Puget Sound. Much wheat is grown in the fertile valleys between the coastal ranges, and the mountains further east. The valley of Southern California, with the climate of Italy, produces all fruits in perfection, and manufactures wine. The salmon fishery is important in many rivers.

The chief town is San Francisco, with a fine harbour of great natural beauty and railway communication with all parts of the continent. It is the New York of the Pacific, and the starting-point of the trans-Pacific lines. Seattle and Tacoma (both in Washington) and Portland (Oregon) are important ports further north and terminal stations of transcontinental lines. Of inland towns the most important is Sacramento, in the Californian valley.



143. MEXICO

Alaska. Alaska is on the margin of tundra and forest, and belongs to both regions. Gold is abundant in the sands of the Yukon and its tributaries and on the seashore near Nome. St. Michaels is the port of the Yukon. From Dyea the railway is carried to the upper Yukon, in Canada.

MEXICO

South of the United States lies Mexico, a federal republic of many states and territories, under an elective president.

Mexico is a continuation of the southern United States, which it resembles. It lies between the Atlantic and Pacific Oceans, and includes the southern part of the Californian peninsula in the north-west, and the low peninsula of Yucatan in the south-east.

Mountains and Rivers. The two oceans are bordered by mountain ranges, between which is enclosed the plateau of Central Mexico, a continuation of the Colorado plateau. This plateau rises in height from about 3,000 ft. in the north, to 8,000 ft. in the Anahuac plateau, on which is the capital, Mexico City, in the south. Many ranges cross the plateau, and in the extreme south is a lofty chain of volcanoes, active, dormant, and extinct. Orizaba (18,500 ft.) is one of the highest points of the continent.

South of the Rio Grande, which forms the Texan frontier, the rivers are impetuous mountain torrents, or flow in deep, rocky gorges, or *barrancas*, which may be 1,000 ft. deep. These barrancas are often dry, except after rains, but they make communication across the plateau difficult.

The Pacific coastal plain is narrow. The Atlantic coastal plain is about 60 miles broad and fringed with lagoons. Mexico has very few good natural harbours in a coast-line of 6,000 miles.

Climate. Three zones of climate are distinguished by the Mexicans. Up to 3,000 ft. is the *tierra caliente*, or hot belt, with a tropical climate; from 3,000 to 9,000 ft. the *tierra templada*, or temperate belt; and above 9,000 ft. the *tierra fria*, or cold belt. Within these belts there is naturally considerable variation, according to elevation.

Northern Mexico and the Californian peninsula resemble the adjoining arid regions of the United States, and only the mountains receive rain. There is a desert area in the lee of the western Sierra Madre. Elsewhere, there is more or less rain during the summer wet season, but the dry season is rainless.

The *tierra caliente* is covered with tropical forest, producing palms, rubber, and the valuable rosewood and mahogany. In the *tierra templada* the plateau is treeless, but the mountain slopes are forested with evergreen oaks and, higher, with the usual temperate forest trees. In the drier regions the vegetation is of the desert type. Giant cacti are common, and the agave, or American aloe, from which a highly intoxicating drink and a most useful fibre are obtained, is very abundant.

One of the most forbidding varieties of cactus grows to from 5 to 15 ft. high, the whipstock arms being without branch or joint but covered close with heavy, recurved thorns, like tigers' claws. Then there is the tree yucca, big of trunk and branched like an oak, and bearing on the end of each arm a bunch of bayonet-shaped leaves, the dead stems of which form the bark, and so dry that when lighted the whole flames up. Or, again, there is the pita haya, mightiest of cacti, which, as single stems or branches, look like green telegraph poles or giant candelabra.

Mexican Scenery. With its combination of forest and desert, plateau, mountain and barranca, the scenery of Mexico is very varied. A traveller in the north-western Sierra Madre writes: "One may traverse a group of high, dome-topped hills, beautifully studded with dwarf pines or mountain oak, and clothed with long grass, the home of the antelope and the turkey, and in another mile these may be suddenly cut off by some huge chasm, surrounded by towering crags and steep, water-worn gullies. Then may follow a glimpse of the main ridge, crowned with its pine and cypress forests, and perhaps streaked with snow. At high altitudes, throughout this range, occur the charming level plots called llanos, and known in the Rockies as parks. These are frequently seen at a parting of the waters, where an infant stream creeps through the deep, alluvial soil, and nourishes the meadow-like expanse surrounding it. Groups of stately trees are dotted over these tracts. Within an hour or two of mule riding all this may have given place to a series of precipitous heights, wild, ragged, and nearly bare, except of cactus and mosquito."

Agriculture and Minerals. With water, the soil of Mexico is fertile, and where irrigation is possible, two crops a year can be grown. The agricultural methods, as might be expected in a tropical country, where four-fifths of the people are wholly or partly of Indian blood, are very primitive. In recent years, much attention has been given to better methods on the larger farms or *haciendas*. In the coastal belt it is almost impossible for white men to do heavy work. Coffee is the most profitable of the crops of the tierra caliente, which also produces sugar, cacao, cotton, and vanilla. The dry climate of Yucatan suits fibre plants, the most valuable of which is henequen, or sisal hemp. On the plateau, wheat is grown wherever irrigation is possible; the vine does well in many districts, and maize and tobacco are cultivated in the Anahuac plateau. An immense variety of fruits, tropical and temperate, come to perfection. Mexico is enormously rich in minerals. Its 1,300 silver mines turn out many millions pounds' worth of silver annually. Gold is also worked, as well as iron, copper, and tin. There are deposits of coal and petroleum, but, owing to their situation, it is doubtful whether they can be profitably worked, and many locomotives have to use wood fuel.

Economic Conditions. There are some manufactures, including textiles, pottery, straw hats, etc., but the great resources of Mexico will probably always be agriculture and mining. Mexico has several natural disadvantages. The better watered and more thickly peopled southern plateau lies 8,000 ft. above the sea, communication with which is therefore difficult and costly. Till 1873, when the line from Mexico to Vera Cruz was opened, there was no railway from the coast to the plateau. Mexico is now connected by several routes with the lines of the United States, but even on the plateau the numerous mountains and barrancas make the construction of railways difficult and costly. There are no navigable rivers except in the Atlantic coastal plain, which is unsuitable for white settlement. These causes, and the preponderance of Indian over European blood, made Mexico develop more slowly than its great neighbour.

Towns. Mexico City, finely situated in a plain 8,000 ft. above the sea, dominated by the great volcanoes of Popocatepetl and Ixtaccihuatl, carries on various manufactures. The ports on the Atlantic are Tampico and Vera Cruz, and on the Pacific the Acapulco, one of the finest harbours in the world, and Mazatlan, all connected with the plateau by rail. A railway crosses the Isthmus at Tehuantepec.

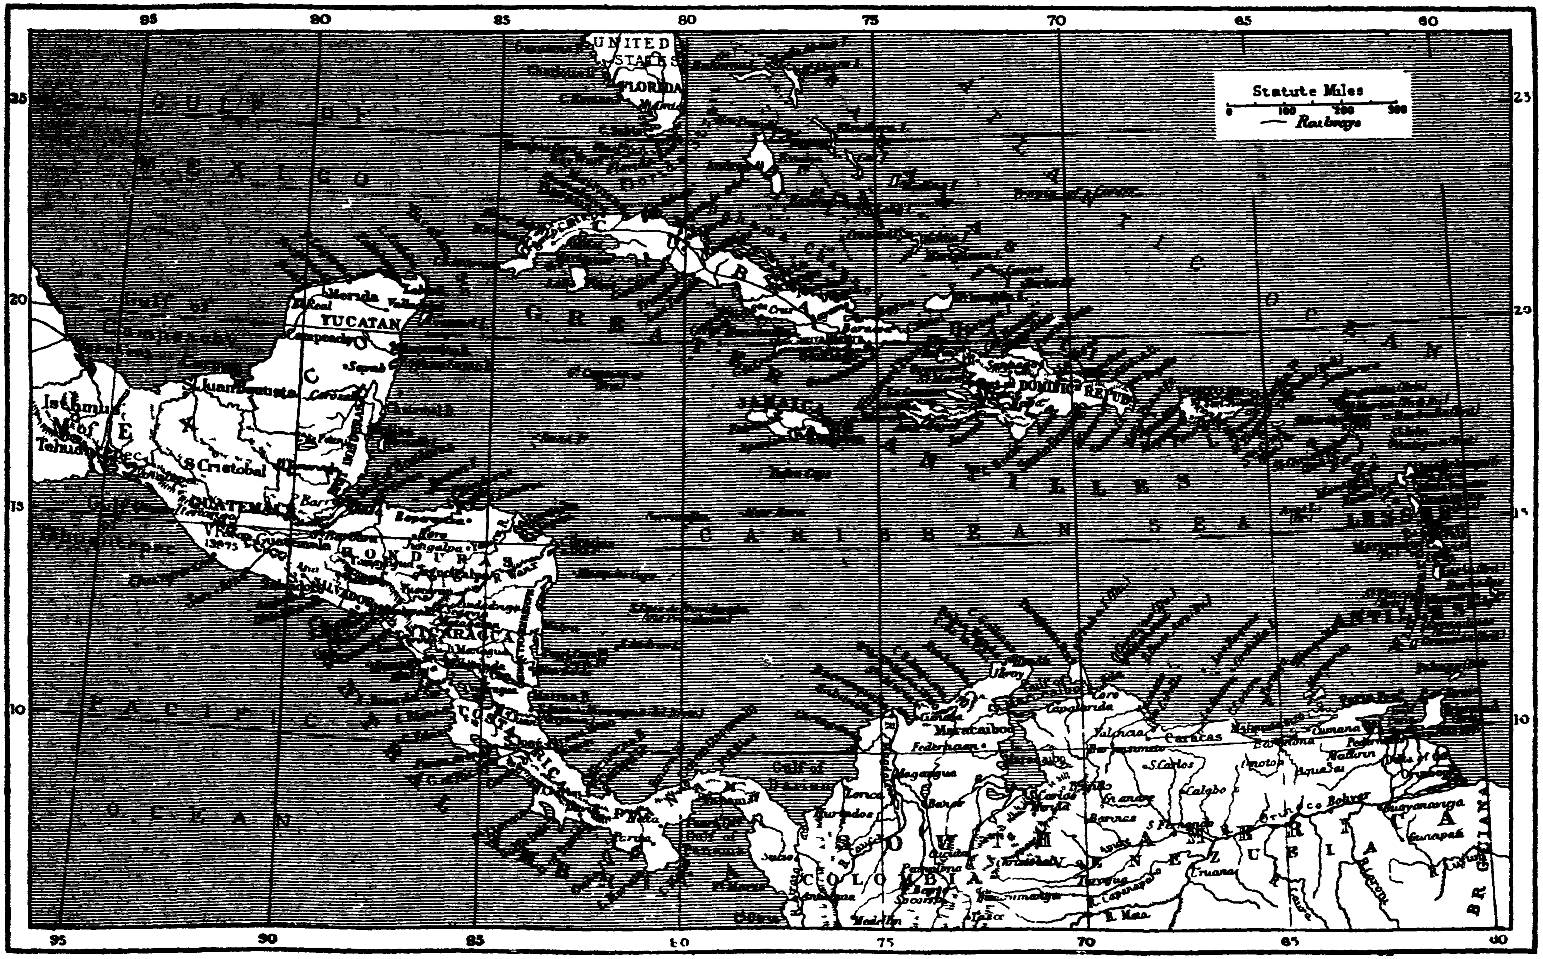
CENTRAL AMERICA

Central America is united to North America by the Isthmus of Tehuantepec (130 miles broad, 390 ft. high), and to South America by the Isthmus of Panama (31 miles broad and 285 ft. high). Its length of 1,200 miles is occupied by the southern part of Mexico, British Honduras (7,500 sq. miles), and the republics of Guatemala (42,500 sq. miles), Salvador (8,000 sq. miles), Honduras (46,000 sq. miles), Nicaragua (48,000 sq. miles), Costa Rica (21,000 sq. miles), and Panama, all with few white inhabitants.

Climate and Products. Central America is mountainous and volcanic, with one important depression, occupied by Fonseca Bay, Lakes Managua and Nicaragua, and the San Juan river. Here it has been proposed to unite the Pacific and Atlantic oceans by cutting a canal. Among the difficulties attending the enterprise is the existence of an active volcano on an island in Lake Nicaragua. The coastal plains are narrow, forested, and often swampy. The same zones of climate and vegetation—tierra caliente, tierra templada, and tierra fria—are found as in Mexico. The rainfall is everywhere heavy. The forests of the tierra caliente supply rubber, mahogany, logwood, bananas, coco-nut palms, drugs, and other produce. The cultivated crops include cacao, cotton and coffee—that of Costa Rica being specially good; and cotton, tobacco, maize, wheat, potatoes, etc., are grown at suitable elevations in the tierra templada, much of which is forested. The west is the better cultivated and more populous side.

Towns. Belize, in British Honduras, ships mahogany, logwood, rubber, coco-nuts and bananas. In Guatemala a railway runs from the Pacific port San José to the capital, Guatemala City, and thence across difficult country to the Atlantic port Puerto Barrios. The coffee, sugar, vanilla, and indigo of Salvador are shipped from La Libertad, the port of the capital of San Salvador. Honduras contains no towns of importance. In Nicaragua a railway runs by Leon, Managua, on Lake Managua, and Granada, on Lake Nicaragua, to the chief port, Corinto, on the Pacific Coast. Another line crosses Costa Rica from the Atlantic through San José, the capital, to Punta Arenas on the Pacific.

A railway 45 miles long is constructed across the narrow Isthmus of Panama from Colon or Aspinwall on the Atlantic to Panama on the Pacific. A great ship canal is in course of construction.



144 CENTRAL AMERICA AND THE WEST INDIES

THE WEST INDIES

The West Indies lie between North and South America. Off the coast of Florida are the low, infertile coral Bahamas, belonging to Britain and producing chiefly sisal hemp. The Greater Antilles are Cuba (45,000 sq. miles), Jamaica (4,200 sq. miles), Hispaniola (10,000 sq. miles), and Porto Rico (3,700 sq. miles). The numerous Lesser Antilles are all small. Off the mouth of the Orinoco are the British islands of Tobago and Trinidad (1,870 sq. miles).

Climate and Products. All the West Indies are tropical, though most are high enough to have a temperate climate and products in the highlands. Late summer and autumn is the rainy season, and the heaviest rainfall is on the east. Destructive hurricanes often cause immense loss of life and property, while disastrous earthquakes and volcanic eruptions occur from time to time. In '1902 the eruption of Mont Pelé, in Martinique. one of the Lesser Antilles, destroyed the town of St. Pierre and nearly 30,000 inhabitants.

The soil is very fertile, especially in the volcanic islands, and all kinds of tropical produce can be raised. Most of the islands are covered with dense forests, producing mahogany, and other valuable timber. The once flourishing sugar industry is declining, except in Cuba, through neglect of modern methods of cultivation and also owing to the competition of bounty-fed European beet sugar.

Beauty of the West Indian Scenery. Every traveller vainly tries to paint the beauty of a scene made up of mountains, forest, and sea. " The mountains range higher and higher," writes Kingsley of Guadeloupe, in the Lesser Antilles, " with corries and glens, which, when seen near, must be hanging gardens of stupendous size. Tiny knots on distant cliff-tops are really single trees of enormous height and breadth. Gullies, hundreds of feet in depth, represent the rush of the torrents which have helped through thousands of rainy seasons to scoop them out. In singular contrast with the rugged outline is the richness of the verdure. Each glen has buried its streamlet a hundred feet deep in vegetation, above which here and there towers the grey stem and dark crown of some palm. The islands, though intensely green, are not of one, but of every conceivable green, or, rather, of hues ranging from pale yellow through all greens into cobalt blue. As the wind stirs the leaves and sweeps the lights and shadows over hill and glen, all is iridescent, like a peacock's neck, till the whole island, from peak to shore, seems some glorious jewel—an emerald with tints of sapphire and topaz, hanging between blue sea and white surf."

Tropical Fruits. The fruits of Cuba show the profusion of Nature's gifts in the tropics. Besides the well-known banana, orange, lemon, lime, and fig, are many fruits unfamiliar to us. "The rose-apple, or rose-fruit, is as large as a good-sized peach, smooth-skinned and cream-coloured, with an odour and taste of attar of roses. The mango grows on a tree very similar to our apple-tree. It is the size of a pullet's egg, yellow in colour, grows in long bunches, and is very juicy when fully ripe. The sapotilla is a fine tree, with a bell-shaped white flower, as fragrant as apple blossoms. The delicious fruit is the size of a peach, in a rough russet skin. The custard apple grows wild, and is also cultivated. It is green in colour, tough-skinned, acid in flavour, and full of small black seeds. The star apple is so-called because when cut in half a star appears in the centre. The meat is green in colour, is eaten out of the skin with a spoon, and tastes like strawberries and cream. The guava, though not eaten in its natural state, is of universal use in making the well-known guava preserves and jelly. It has a peculiar odour, which will scent a room for hours. The tamarind grows in a pod-shape on a lofty shade tree, and when ripe is of the consistency of marmalade and quite as luscious. The alligator pear is used as a salad. Last, but not least, is the pineapple. The fruit grows out of a bunch of great leaves 18 in. or 2 ft. from the ground."

The Greater Antilles. Cuba is an independent republic, though with intimate relations with the United States. It is the largest of the islands, and is mountainous in the west, where the tobacco from which the famous Havana cigars are made is grown on the lower slopes of the Organos Mountains. Sugar is grown in the hilly centre. The eastern mountains are rich in iron. The rich forests contain many valuable trees, including the royal palm, mahogany, and the Cuban cedar, of which cigar boxes are made. Havana, the capital, is on the north coast.

Jamaica, the largest British island, rises to over 7,000 ft. in the eastern Blue Mountains. Many rivers water its fertile valleys. Bananas have replaced sugar as the chief export. Coffee, cinchona, allspice, ginger, arrowroot, tobacco and cacao are also cultivated in the clearings of the forest, which covers most of the island. The capital is Kingston.

Hispaniola consists of the black republics Haïti (capital, Port au Prince) and San Domingo (capital, Santo Domingo). It has the usual West Indian resources, but these are little developed.

Porto Rico, a possession of the United States, is very mountainous. Cattle are kept on the higher grass lands, while the plains and valleys produce the usual West Indian crops. The capital is San Juan.

The Lesser Antilles. The largest islands —Guadeloupe (580 sq. miles) and Martinique (380 sq. miles)—are French. Both are volcanic. The usual crops are raised. The islands forming the Leeward and Windward groups are British. On Santa Lucia is Castries, formerly a British naval station, the best harbour in the West Indies. Barbados has a dense negro population, engaged in cultivating sugar. The Dutch and Danish islands are of no great importance

Trinidad and Tobago. Sugar and cacao are the chief products of Trinidad and Tobago. The Pitch Lake of Trinidad supplies large quantities of asphalt, brought down to Port of Spain, the chief town.

HARMONIUM PRACTICE

Reading at Sight. The Registers. Stop Combination Effects. Choice of Secular and Church Music. Practice Hours

Group 22
MUSIC
29
HARMONIUM AN
AMERICAN ORGAN

contd. from p. 3955

By J. CUTHBERT HADDEN

In the matter of reading music, the study of harmony helps to a wonderful extent. The frequent appearance of certain chords leads to such an intimate acquaintance with these chords that the player by-and-by, recognising them at once as a whole, is saved the trouble of "spelling out" to himself their individual constituents. Before beginning to play an unfamiliar piece, it is necessary to make yourself familiar with the key and the time. If the key is a difficult one, impress on your memory its third and seventh notes, especially; play, too, once or twice the scale formed upon that key, and its relative minor. Then it is well, before starting, to look over the piece from beginning to end, as very probably the first page presents no difficulties, while the second may unexpectedly present something of a very startling nature. One of Schumann's maxims to young musicians is: "Should anyone place a composition before you to play for the first time, look it through previously." This advice should certainly be followed. In reading at sight, it is useless to stop when a mistake has been made. If you do this, and return to the passage, you are *practising*, not reading the piece.

To gain confidence in playing at sight it is well at first to take some simple piece for reading—simple not only as to technical execution, but simple as to key. The practice should be regularly kept up, and as great a variety of material as possible chosen. "Playing at sight," says Ernest Pauer, "is a kind of economic musical knowledge, and the following conditions are necessary for it: (1) a good grounding in technical execution; (2) a regular and systematic knowledge of fingering; (3) a cheerful and ready disposition; and (4) undivided attention and concentration of the mind on the work in hand." Some of these remarks are, of course, much beyond our present stage, but many of them will be of help now, and all can be recalled as the student advances.

Four-part Playing. We return now to the "Harmony Player," and begin the work of the third step with four-part music and four new keys. In previous exercises the compass of the hand has been within a fifth. But this has been only a concession to the learner; music cannot be confined within such a restricted limit. The compass must now be widened, and that involves certain extensions of the thumb and fingers in order to reach the outer notes.

Look at Ex. 37. You will see that the right-hand part ranges from B to G—a sixth. Now, were it not for the B, which occurs four times in the alto, the whole might be played with the fingers in their first positions. As it is, we must give two notes to the thumb, using it for its own proper digital (C), making it shift down to B when that note occurs, and back again to C. In the left-hand part the compass is also a sixth, and the thumb is treated in the same way as in the right hand by making it move upwards to A in the last bar and down again to G. This shifting of the thumb will be found constantly necessary in the inner parts, and the student should learn to manage it as neatly as possible so that the break in the sound may be all but imperceptible.

A short prelude is the form in which the next exercise is presented. It is very simple until we reach the third bar, where, in two chords, the right hand has three notes instead of the usual two. The upper parts of this and the following bars should be practised thoroughly by themselves before combining with the under.

The fingering from the beginning of the penultimate bar to the end will be:

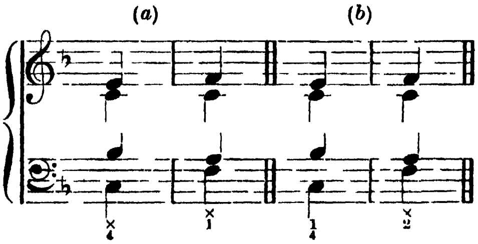
|	4	3	2	|	3	2
|	2	1	·	|	1	×
|	×	×		|		

Notice to keep the first finger on the tenor A in the last bar of the left-hand part when the fourth finger takes the bass D. The tendency will be to shift the thumb on to it, but there is no necessity for this.

Practice in the Key of A. Ex. 39 brings forward the key of A with three black digitals. It is not difficult in itself, but may require considerable practice on account of the strange key. In the left hand we are obliged to break our rule regarding the use of the thumb on a black key. There is no other way—keeping them in the left hand—of playing the C sharps which occur in the tenor but by shifting the thumb upwards from B. The C♮ intervening makes this uncomfortable at first, and the fingering in early attempts may be far from smooth. But the difficulty can readily be mastered by practising the left hand by itself slowly.

In Ex. 40 we reach the practical limit of sharp keys with the key of E, employing four black digitals. In the right hand the × will have to shift from E to D♯, and in the left (sixth bar) to move upwards to C♯. Space need not be taken up in speaking in detail of Exs. 44–50. Though introducing the stretch of an octave, they will prove of no difficulty if the preceding exercises have been mastered.

A word may, however, be said about a definite left-hand fingering for the cadential form of the dominant seventh chord as seen in the last bars of Exs. 44 and 45. Take Ex. 44 as example. Ordinary hands would usually play the B♭ and A of the tenor as at (*a*); in the case of those having longer fingers, it would be most convenient to play these notes as at (*b*):



This is such a common progression that the student should decide at once which of the fingerings he will adopt, and stick to it.

Ex. 51 brings the key of A♭, with four black digitals. It is simple until we reach the last cadence. Here the thumb cannot play both G and E♭ in the alto, but by a little stretch the G may be taken by the first finger. The thumb of the left hand has a good deal of shifting to do, having to play in all four different notes—E♭, D♭, C and B♭. A short chant in G follows, where we have the peculiarity of three parts in the right hand almost throughout. This, again, involves a good deal of thumb shifting in the inner part, the fingers being left free as much as possible to play the treble smoothly. The right hand fingering should be:

4	4	3	4	–	2	1	4	4	3	4	–
1	1	1	1	–	×	×	×	1	1	1	–
×	×	×	×					×	×	×	–

In Ex. 42 you will observe that a scale passage is completed between alto and bass. Keep the E firmly down, and do not be alarmed at the dissonance produced by the entry of the D in the left hand. The last chord in the next exercise has three of its parts in the left hand. Keep the fourth finger on the continued E, take the B with first finger, and the D with thumb, shifting the latter on to the C♯ in the last chord. Ex. 43 might have come sooner, for it introduces the key of E flat, with only three black digitals.

In the right hand the compass is a seventh. A♭ being the highest note, we play it with the fourth finger, and this, giving the tonic to the first finger, necessitates the thumb taking both B♭ and D. An exception will be found in the penultimate bar, where we are obliged to stretch the first finger down to D, the thumb being already occupied with the B♭ held on in the alto. In the left hand the thumb has to play three notes—A♭, G and F. The remaining exercises in this step are all in keys already learnt, and involve no special difficulties. The last, however, Ex. 53, gives directions for the use of certain stops, which suggests that we had better turn aside for a little now, and try to learn something of the tone character of the different registers.

Use of the Registers. This is, indeed, very essential. The full resources of a good instrument can be brought out only by a player who knows what are the special individual qualities of the "knobs" at his command—how and when to use them, singly and in combination. Nothing produces a worse effect than the indiscriminate use of the various registers, and nothing is more common with amateur players. Of course, as Mr. King Hall observes, since no two harmoniums are precisely alike in *timbre*, it is impossible to draw up a table setting forth accurately the qualities of the registers individually; but the following remarks can be taken as approximately correct. Taking, then, the stops of our original instrument of four sets of vibrators in pairs, treble and bass, we have:

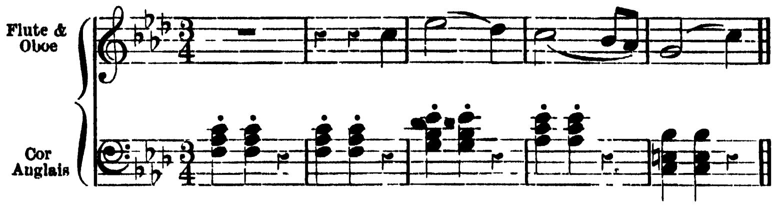
1. FLUTE; 1. COR ANGLAIS. This is one of the most useful stops in the instrument, suitable alike for slow or quick music, and may be effectively combined with any of the other stops. Its tone is of a round and fluty character, comparatively full, and with the advantage over some of the others of promptness of speech. It corresponds with the diapasons of the pipe organ, and should be used for all music of a soft nature.

2. CLARIONET; 2. BOURDON. This stop somewhat resembles 1 in being of a round and fluty quality, but the tone is much broader and heavier, and the response to the touch is slower. When you draw it, you will observe that it produces sounds an octave lower than the actual note played. Hence, if you were to use this stop alone it would be necessary to play the music an octave higher than written. But, as a matter of fact, 2 is seldom used alone except in the treble for solo work, as we shall see presently.

3. FIFE; 3. CLARION. This stop produces sounds an octave higher than written. It is of a bright and reedy character, prompt in speech, and adds brilliancy when combined with the other stops. It should rarely be employed alone, except for echo effects in secular music, and in some other cases. The tone, in spite of its brightness, is so slight that when used with either of the stops which sound the notes as written, the higher octave is scarcely heard, being absorbed in the greater volume of the standard pitch registers. The student must not confuse "Clarion" with "Clarionet."

4. OBOE; 4. BASSOON. This stop is supposed to imitate the tone of the instruments after which it is named. The tone of the *Oboe* especially is thin and reedy, of a softer quality than the *Flute*, but of the same standard pitch. It is rather slow of speech, but may be used very effectively for music of a pastoral nature, and can be drawn instead of 1 when a quieter effect is desired. The *Oboe* is also used for

solos, and, combined with the *Flute*, makes a fair imitation of the voice, as here:



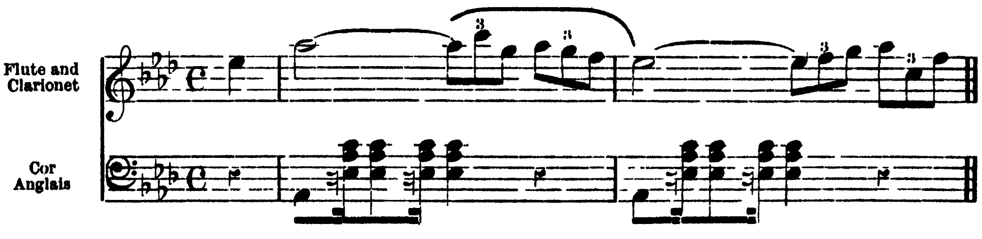
Among the stops in larger instruments will be found: 5. MUSETTE and 6. VOIX CELESTE, both on the right-hand side The first is a soft, reedy stop, more delicate than the *Oboe;* the second is generally joined to some other stop, and by tuning its reeds a little sharper than those of the latter, a clear, ringing, vibrating effect is produced. The *Voix Celeste* may be used for solo work, either alone or with the *Clarionet*, but should not be used with all the other stops.

Effects from Combinations of Stops. The possible effects which can be produced out of only eight sounding stops are almost endless in their variety. One or two suggestions may be offered. For ordinary four-part playing a very serviceable and effective combination is 1 and 4 for both hands. Also 1 and 2, which, with the music played an octave higher than written, will be found useful for most compositions of a serious cast. Stops 2 and 3 and 1 and 3 are a sort of "fancy combinations," as Mr. King Hall calls them: the first for sacred music, the second for music of a light, bright nature. In many instruments a couple of ordinary pitch registers are perfectly able to assert themselves against one lower octave stop; and when this is the case there is no need to play the music an octave higher than written. But the greatest advantage to be gained by 2, with the right hand transposed an octave higher, is that a solo may be played (with a soft left-hand accompaniment) without any risk of going below F—the dividing place of the stops—and finding the melody disappear.

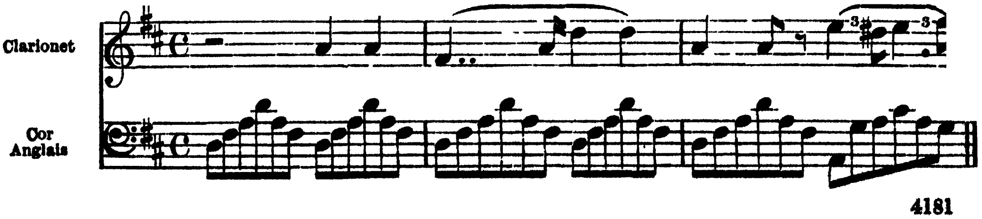
Solo Passages. In order to give prominence to a solo a louder tone must be used in the right hand than in the left, and it follows that unless 2 is used in the manner mentioned the solo will suffer should its range take the player into the bass part of the instrument. Of course, where the solo does not go below F, any loud combination may be used with as soft an accompaniment in the left hand as can be obtained from the particular instrument in use. Generally speaking, the *Sourdine* offers the softest accompaniment for a solo melody with a single stop; but sometimes it is so strong that the right hand must be played with 1, 4, or with *Celeste*, or with 1 and 2, an octave higher.

An effective manipulation of the stops is as essential to the harmoniumist as to the church organist Without it, his instrument is reduced to the level of a dead monotone, as it were; with it, the instrument becomes instinct with life, capable of giving expression to all the varying shades of emotional feeling which musical composition may inspire. Of course it is necessary that one should play fairly well before making a special study of the tone colours rendered available by the various stops. Tone colour is of very little use in merely elementary work, where the player is very much occupied with other things. But as soon as he feels that he has gained a certain facility in the use of the keyboard, he ought to devote a considerable amount of time to the special study of the stops.

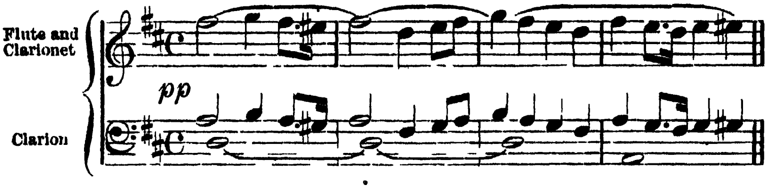
With regard to effects of what may not inaptly be called a secular character, it is difficult to make a selection. The following are offered merely as hints which the student can readily adapt and improve upon according to the resources at his command. A charming orchestral effect is produced by combining *Clarionet* and *Flute* in melodies requiring to be doubled, as in the following from *Le Prophète*:



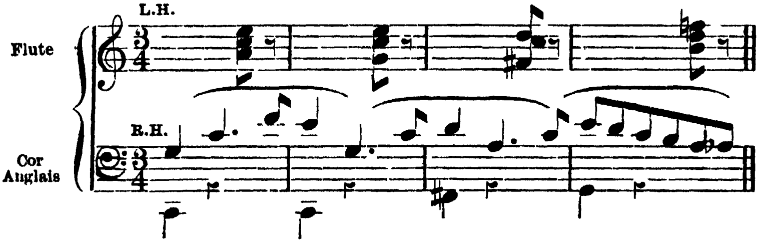
The *Clarionet* stop may also be used alone with good effect in baritone solos, as in this example:



The value of the *Clarion* stop, again, may be tested by such an example as the following:



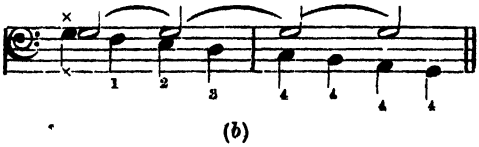
Even with only *Flute* and *Cor Anglais*, such an excellent effect as we have here may be produced:



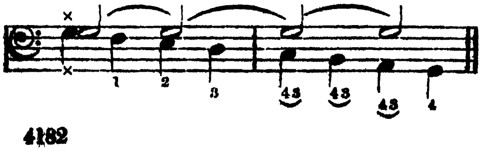
These, as we have said, are only hints. If the student will but test them carefully for himself, he will feel competent to make further successful experiments on his own account Experience, assuming his own good taste, will reveal to him many charming combinations which he will readily find a means of adopting as his repertoire increases.

Finger Releasing. With the fourth step of the "Harmony Player" we arrive for the first time at the system of fingering peculiar to the harmonium and the organ. This is the system known as *finger releasing*. Hitherto the student has been able to play the outer parts (the treble and bass) of all his exercises without any jumping of the fingers. In the inner part the thumb has been allowed (necessarily) to shift or jump from one key to another—a method which can never be allowed for the outer parts (unless when marked *staccato*, of course), because these being specially prominent, the slightest break in the continuity of the sound is immediately noticed. In short, on the harmonium we must have *legato* fingering We cannot, for example, play the following as at (*a*), which would pass on the piano; we must play it as at (*b*), releasing the fourth finger always in time to provide a finger for the next note:

(*a*)



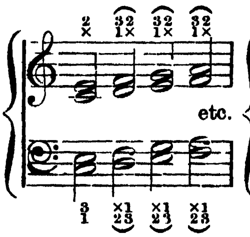
(*b*)



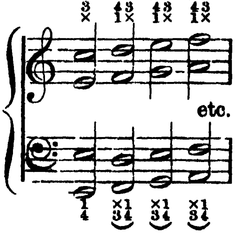
This is a method of fingering which will be found more or less, as the need for it arises, in all the exercises remaining to be studied. The learner whom we have been guiding thus far must now begin to practise it systematically; and it is at this point that the student who already plays the piano may begin What *he* has to learn first of all is emphatically the legato fingering. Many useful exercises for giving facility in this direction are included in both Mr King Hall's "Harmonium," and Stainer's American Organ Tutor. The student will probably find it best to take first the simple scale C, and play it up and down, releasing all the available fingers in turn. [See next page.]

Practise this very carefully before going further, each hand separately, and with the lines of fingering in their alphabetical order, as marked. Be sure that a perfect *legato* is obtained, that the key is held firmly down while the finger is being released. The professional student would be required to carry the exercise through all the scales in order to gain the necessary facility in relieving the fingers upon the black keys. The amateur may, for the present, content himself with the above, having mastered which, he may go on to practise double notes with finger releasing; first thirds, as at (*a*), and next sixths, as at (*b*):

(*a*)



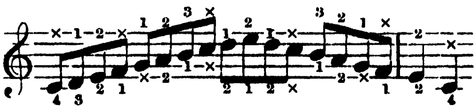
(*b*)



These exercises, and others which will be found in King Hall and Stainer, are indispensable to the cultivation of the true *legato*, the charm of the harmonium as of the organ. The student who already plays the piano should work through them all at once; our learner who has been going through the "Harmony Player" may, after having accustomed his fingers to the releasing style by the scale, and two exercises as illustrated above, proceed with the four-part and other exercises from No. 55 on to the end of the book. He will then acquire a thorough command of the style necessary for the playing of psalm and hymn tunes, chants, etc. For this special purpose the eight pages of chants and hymn tunes printed in Stainer's tutor might also be gone through with advantage, particularly as various methods are there shown of playing this class of music, with the usual two parts in each hand, with the melody in octaves, with the melody on a solo stop, and with the bass in octaves.

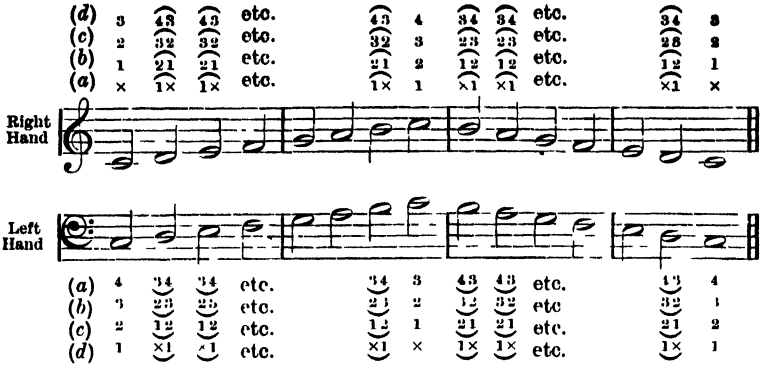
Pieces. The student who desires to play pieces chiefly will probably not wish to give so much time to church music. In that case he may start at once with the "Thirteen Original Pieces" of Mr. King Hall; or, if he feels that he is not quite advanced enough for these, let him work up the Stainer exercises in two, three, and four parts. These are fully fingered, and represent styles quite different from the psalm or hymn tune; though marked for the American organ, they are equally well adapted to the harmonium.

In playing pieces where there is a single part in either hand, especially if the music moves at all quickly, it is usual to employ what is known as scale fingering, the turning of the thumb under the fingers, or the fingers over the thumb. Thus, if the following scale passage occurred, it would be fingered, for the right hand as above the stave, for the left hand as below:



In a case of this kind there is no need for finger-releasing, of which, indeed, the time does not permit. The learner whose ambition is to play pieces chiefly would thus do well to go through a complete course of scale exercises in all the major and minor keys in common use. Such a course will not only add to his facility in fingering; it will add to his reading power, and give suppleness and dexterity to the hands besides.

The rules for fingering the scale are simple in principle, though they require at first great attention. In the ascending right hand, the thumb is placed on the first white key which occurs, and afterwards follows the second and third fingers alternately. In descending, each note is played with the same finger as in ascending, and the same rule is followed, but in reversed



(d) 3 43 43 etc. 43 4 34 34 etc. 34 3
(c) 2 32 32 etc. 32 3 23 23 etc. 23 2
(b) 1 21 21 etc. 21 2 12 12 etc. 12 1
(a) × 1× 1× etc. 1× 1 ×1 ×1 etc. ×1 ×
Right Hand
Left Hand
(a) 4 34 34 etc. 34 3 43 43 etc. 43 4
(b) 3 23 23 etc. 23 2 32 32 etc. 32 3
(c) 2 12 12 etc. 12 1 21 21 etc. 21 2
(d) 1 ×1 ×1 etc. ×1 × 1× 1× etc. 1× 1

order, the third and second fingers passing alternately over the thumb. In the left hand the fingering of the ascending scale follows the rule of the descending scale in the right, and *vice versâ*. A printed set of scales with the fingering marked can be obtained from any music-seller. If the student has a piano, they may be practised chiefly—not solely—on that instrument.

General Hints on Fingering. In regard to the whole subject of fingering, it may be remarked that facility cannot be forced; it must be allowed to come in its own time. With experienced players fingering is a sort of second nature; they "never think about it"; the fingers seem to work like automatons, adapting themselves in some mysterious way, almost mechanically, to the music being played. Let it be said, too, that whatever method of fingering secures to the individual player the smoothest result, and affords the greatest convenience, *that* is the fingering for him. The finest players occasionally differ as to their fingering, and allowance must always be made for the construction and size of the hand. One of the greatest secrets of good fingering is the habit of looking forward to the coming phrase, seeing, if even vaguely at first, what has to be done, and so preparing the fingers as to secure the best rendering of the passage. In any case, there must be no slovenly, "anyhow" fingering. The person who fingers badly or carelessly can never be a really good and satisfactory player.

Selection of Pieces. After you have finished with your tutors and are able to play fairly well, you will naturally desire to work up a repertoire of pieces. If you are contemplating church playing, then, of course, sacred music—collections of voluntaries, etc.—is what you will direct your first attention to. There is plenty of music of this kind, and we can mention here only such collections as we think to be educationally as well as practically most useful to the student. For those who have mastered the exercises in the "Harmony Player," the best selections of pieces to follow that work are Volumes VIII. and XII. of the "Harmonium Album" (Curwen). These are fingered throughout, and are very suitable for beginners. The "Harmonium Album" extends altogether to 15 volumes. The first 14 comprise some 500 voluntaries, while the fifteenth is chiefly made up of movements from popular operas. The same publishers have also a collection of interesting "Harmonium Studies," by J. Frank Proudman, and a couple of volumes of musicianly "Sketches for Harmonium," by John Kinross. The best work to succeed Mr. King Hall's primer is the same author's "Original Studies and Arrangements for the Harmonium or American Organ." The studies are peculiarly valuable, and the editor's directions as to their rendering are sufficiently clear.

Voluntaries. Collections of "voluntaries," expressly so-called, are numerous. One of the best is that of Mr. J. W. Elliott (Novello), in two volumes, containing altogether about 350 pieces. Collections of original harmonium voluntaries by Oliver King and Max Oesten, issued by the same publishers, may also be recommended. It is better that the young church player should draw upon such works as these until he has gained experience enough to make arrangements for himself. For general use there is nothing better than the two volumes of "The Harmonium Treasury" (Novello), in which we have a series of select pieces, secular as well as sacred, admirably arranged for the instrument. Chappell's "Harmonium Journal," full music size, will also be found useful, as including rather more secular-music arrangements. All these works can be adapted to the American organ. Of collections specially made for that instrument, there is no need to mention anything but "The American Organ Journal," edited by J. M. Coward (Metzler). Thirty numbers of this excellent work have been published so far, and there is nothing of its kind better or more comprehensive.

Song Accompaniments. In addition to its use for the church service, for which it is so well adapted, the harmonium is also equally adapted, from the extent of its orchestral resources and power of expression, for the drawing-room or concert-room. "The harmonium," says Berlioz, the great composer, "is at once a church instrument and a theatre instrument, a drawing-room and a concert-room instrument. It occupies but little space, and it is portable. It is therefore a servant of indisputable utility for composers and amateurs." It is not necessary to enlarge upon this, but a word or two must certainly be said about the harmonium as an accompaniment to the voice and in conjunction with other instruments. With regard to the first-mentioned use, if heard properly, as the late Dr. Rimbault said, the harmonium will be pronounced not only capable of producing some of the most charming effects of accompaniment, but to possess powers of assisting the voice of the highest possible order. One practical hint: in accompanying songs from a piano copy, alterations will of necessity be made to suit the peculiar nature of the sustaining instrument. Octaves in the bass must be used sparingly, as the lower registers of the harmonium are powerful. When octaves are required in the right hand, it is generally best to get them by drawing the *Clarionet* stop. Again, repeated notes in piano copies should, as a rule, be held when played on the harmonium. But no fixed rules can be given. Much must depend upon the knowledge and acquirements of the performer.

Combination with other Instruments. As regards combination with other instruments, the chief thing to aim at, when an artistic effect is desired, is contrast of tone. Thus the flute does not "go" nearly so well with the harmonium as the violin. The best, as it is the most generally available combination, is that of harmonium and piano. "We cannot conceive," says Dr. Rimbault, "a more perfect drawing-room orchestra than the piano and harmonium when used in concert. Nothing can be more admirable than the combination of the strings of the former with the reeds of the latter, the one imitating the whole tribe of the violin class, the other the entire wind band, and forming together a *tout ensemble* capable of giving effect to orchestral works of the highest class." Special arrangements are, of course, required for this duet playing.

Any good music-seller will show a selection of such arrangements, but the student might ask to see some of those published by Messrs. Chappell and Messrs. Novello, particularly the latter's six duets of L. Engel and the "Transcriptions of Favourite Airs" of C. L. Krug. There is also a considerable quantity of music for harmonium with other instruments, such as violin, 'cello, clarinet, etc. Harmoniumists should lose no opportunity of practising with any suitable instrument available, such practice being of the highest value, not only from an artistic point of view, but also for cultivating the sense of *tempo*. When you are playing with another, you *must* "keep time."

Practice Hours. A few general hints, in closing, on the best method of practice: It must not be desultory. Three hours to-day and ten minutes to-morrow and nothing at all for a week can never mean any real advance. Let practice be regular and systematic. The precise amount of time will, of course, vary according to circumstances. The minimum for the amateur should be about an hour and a half daily. Whatever it is, the time should be well apportioned among the different kinds of work undertaken. The student should draw up a table specially for his own use (and rigidly adhere to it), but the following proportions for an hour's practice will generally be found advantageous:

	Minutes
Finger exercises, scales, etc.	20
New piece	20
Piece already learnt	10
Sight reading	10

Above all, let your practice be in thorough earnest, that no moment may be wasted. And always remember the words of Schumann: "Whenever you play, let it be as though a master were listening."

Driving. Employment in the Various Departments of Public Vehicles. Motor Omnibuses. The Livery Stableman in Business

Group 29
TRANSIT
15

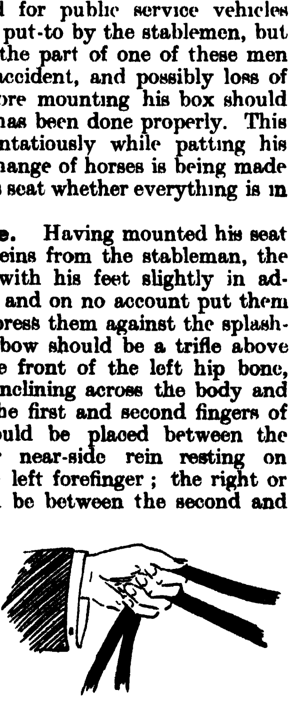
Continued from page 3981

By HENRY CHARLES MOORE

THE desire for an outdoor life is very strong in young men, and many to whom the thought of having to earn a living in shop, factory, or office is distasteful enter the service of the various public carriage companies. And now that motor traction is competing successfully with horse-drawn vehicles, the aspirant for an outdoor life has the choice, assuming that he wishes to be a driver, of becoming a "whip" or a motor man In the latter capacity his prospects of regular and long service will be greater than if he became a coachman, as the proprietors of horse-drawn vehicles are already reducing the number of their drivers, and in three years' time will need the services of very few of such men. There are, however, men who have a strong dislike for engines and machinery of any kind, and they will probably prefer to drive a pair of horses as long as such employment is obtainable.

The horses used for public service vehicles are harnessed and put-to by the stablemen, but as carelessness on the part of one of these men may result in an accident, and possibly loss of life, the driver before mounting his box should see that the work has been done properly. This he can do unostentatiously while patting his horses. When a change of horses is being made he can see from his seat whether everything is in order.

How to Drive. Having mounted his seat and received the reins from the stableman, the driver should sit with his feet slightly in advance of his body, and on no account put them under the seat or press them against the splashboard. His left elbow should be a trifle above and a little to the front of the left hip bone, with the forearm inclining across the body and the wrist bent. The first and second fingers of the left hand should be placed between the reins, the left or near-side rein resting on the knuckle of the left forefinger; the right or off-side rein should be between the second and third fingers. The third and fourth fingers should press the loose end of the reins on the palm of the hand. The whip should be in the right hand, held at the top of the handle, and lying in the palm of the hand and over the thumb When held thus the fingers are free to take the reins should it be necessary to use two hands.



The rule of the road is to keep to the near-side when meeting another vehicle; on overtaking one, the driver must pass on the off side of it, unless the vehicle overtaken be a tramcar, when it must be passed on the near side. Obelisks, street refuges, and other erections in the centre of the road must be passed on the near side.

Horse-drawn Omnibuses. The applicant for employment as driver of a horse-drawn omnibus must be accustomed to driving. This statement is not superfluous, for it is made with the knowledge that men who cannot drive frequently apply for work as omnibus drivers, believing that if they are promised employment they will soon be able to learn to drive a pair of horses It is also imperative that, before making an application for work, the would-be driver should possess a police licence, as omnibus proprietors do not entertain applications from unlicensed men, no matter how excellent their recommendations may be.

When the police have satisfied themselves as to the respectability of an applicant for a licence, they test his proficiency as a driver by setting him to drive an omnibus, which they keep for this purpose, through some of the most crowded parts of London A police inspector accompanies the applicant on his trial drive, and decides whether or not he shall be granted a licence. If the inspector considers that the applicant is not sufficiently experienced, he tells him that he must undergo another driving test, in two or three weeks, before a licence can be given to him In these circumstances the applicant will he wise if, in the meanwhile, he has some practice on a heavy pair-horse vehicle, and obtains advice from an experienced omnibus driver.

When the driver has passed the test he has to pay 5s. for his police licence and 2s. 6d. deposit for his badge. The latter sum is returned to him on his giving up his licence, but the 5s. has to be paid annually.

Securing Employment. The newly licensed driver may succeed in obtaining work from the first company to which he makes application, but it is quite possible that he will have to undergo the unpleasant experience of being told time after time that no drivers are wanted In that case all he can do is to leave his name and address at the various offices, and wait until a vacancy occurs. When at last he is given work he will be surprised to find that, although he holds a licence, his employers do not consider it to be a guarantee that he is thoroughly competent, and therefore he has to make several trial journeys. On these occasions an experienced and trusted driver sits on one of the front seats to watch him, with a view of reporting to his employers whether or not he is a capable coachman. In addition to this, he tells him where the "points" or stopping places are, and gives him other information which it is necessary he should possess. If the report be satisfactory, the new driver is engaged as an "odd man," which means that when a regular driver, or "service man," is absent through illness, or some other cause, he takes his place. Very probably he will get only one or two days' work during the first week; but he may be fortunate and begin with several weeks of unbroken work. When at last a vacancy is caused by the death, resignation, or discharge of a regular driver, the "odd man" gets his "service," and henceforth he has regular employment. "Odd men" are not, however, always new hands; a "service man" is sometimes reduced to an "odd man" for carelessness, or breaking the rules of his employers. Drunkenness while on duty is an offence which is punished by instant discharge.

Wages. Omnibus drivers are paid 6s. for a day of, on an average, twelve hours. Each man uses between ten and twelve horses a day, according to whether the road be hilly or not, the distance travelled by each pair being about sixteen miles. Sometimes a man who is a good driver is careless about the condition of his horses, but coachmen of this type do not remain long in the employ of an omnibus proprietor. It may be said, too, that if a man has any showy mannerisms, such as squaring his elbows when driving, he will be wise to break himself of them as quickly as possible, as the proprietors have a strong objection to "flashy" drivers. The left hand, it has been said, was made for driving, and the man who makes a practice of using both is another type which does not find favour with employers. For the driver who proves himself to be a good judge of horses there is the chance of promotion to the position of district horse-superintendent, with a salary of from £3 to £4 a week.

Conductors. It is as necessary for a would-be conductor as for a driver to obtain a police licence before applying for work. This is by no means difficult to obtain if the applicant be a respectable man, a few questions as to his knowledge of the main thoroughfares being the extent of the examination he has to undergo. For his licence he has to pay the same as a driver, and he, too, begins as an "odd man." But before becoming even an "odd man" he must take one or two journeys, unpaid, to learn his duties, his instructor being a reliable and experienced conductor. The novice watches the conductor on the first journey, learning the extent of the various fares, the sections in which to punch the tickets, and how and when to enter the unissued ones on the waybill. On the second journey the old conductor hands over to the learner his tickets and bell punch, but watches to see that he charges the right fares, and punches and issues tickets of corresponding value.

At the close of each day the conductor pays out of the takings the driver's and his own wages. The balance he delivers, on the following morning, at the district office, handing in at the same time his box containing the bell punch that he used on the previous day and the unused tickets. The box and its contents are then forwarded to the chief traffic office to be checked. A fresh bell punch, set of tickets, and waybill is issued to the conductor every evening, so that he can begin the following day with a fresh outfit. On the back of each waybill is printed a money table, and if the conductor has issued during the day 151 penny tickets, 47 twopennies, and 23 threepennies, he can see at a glance that he has to pay in 12s. 7d. for the first, 7s. 10d. for the second, and 5s. 9d. for the third.

Hours and Pay. Conductors work the same number of hours as the drivers, and are paid 4s. 6d. a day. Many of the ticket inspectors are drawn from the ranks of the conductors, but, from a monetary point of view, this is scarcely promotion, as the wages of the inspectors begin at 30s. a week, rising to 35s., for which they are on duty eight hours a day. One week they begin work at about seven o'clock in the morning, the following week they go on duty at about four in the afternoon. Another and more profitable position to which conductors can rise is that of road inspector, with wages of from £3 to £4 a week. Timekeepers, many of whom are old drivers or conductors, are paid from 30s. to 35s. a week; horsekeepers receive about 28s. a week; and the 'bus washers, whose work has to be done at night, are paid from 35s. to 40s. a week.

Motor Omnibuses. The old-established omnibus companies being naturally desirous of retaining as many as possible of their old servants, take their motor omnibus drivers from the ranks of the coachmen and conductors of their horse-drawn vehicles. Most of the companies have, at the present time, a long list of men who are being taught, or are waiting to be taught, motor omnibus driving. Usually they are taught at the expense of their employers, but in return are required to sign an agreement binding themselves to remain in their service for a specified period, in most cases a year. It will be seen, therefore, that for some years to come the old-established companies will be able to obtain from among their own servants all the motor drivers they require, and that consequently the man who is not already in their employ has little chance of entering their service as motor man. But with the new companies it is different. Having no horse-drawn omnibuses, they have no old servants to whom they feel bound in justice to give preference, and consequently they are able to consider the application of any man, qualified or unqualified, who wishes to enter their service. Both the old and the new companies have their own instructors, by whom the men are thoroughly taught driving and mechanism before being sent to New Scotland Yard to undergo their police examination.

Examination for Motor Omnibus Drivers. In the interests of the public, the examiner, an inspector of the Public Carriage Office, subjects each applicant for a licence to a very thorough set of tests. First he is examined in backing and turning the omnibus, and if he comes through this ordeal successfully he is told to drive out into the street. The examiner sits beside him, and decides the route he is to take during the hour's run. A part of the time is spent in crowded streets, and if the driver be unfortunate enough even to graze another vehicle he is put back for two or three weeks; if, however, he satisfies the examiner that he can drive carefully in the midst of traffic, there is the hill test to be undergone. He is told to drive to a fairly steep hill, and as he is ascending it he must stop the omnibus, and start it again, whenever the examiner commands. The same test is applied while descending the hill. If the examiner be satisfied that the man is thoroughly competent he is given a licence to drive an omnibus of that particular type; but if, after a time, he wishes to drive an omnibus of another make he must undergo another examination. This is an excellent police regulation, for there are many types of motor omnibuses in use, the châsses of which differ considerably in many respects.

Licences. For his licence the motor omnibus driver must pay 5s. to the police, 2s. 6d. deposit for his badge, and 5s. to the London County Council. After receiving his licence the driver soon obtains his "service," for qualified motor-'bus men are not yet so plentiful that they have to remain long as "odd men." Moreover, as motor omnibuses are on the streets from eighteen to twenty hours a day, it is necessary to have two drivers and two conductors to every 'bus, one pair of men working the first half of the day, the other relieving them after about nine hours, and working until the 'bus is taken into the garage for the night. Drivers are paid 7s. a day, and conductors 5s. Mechanicians, who overhaul the motor omnibuses every night, are paid 35s. a week, and 'bus washers 30s.

The Motor Omnibus Business. To start business as a motor omnibus proprietor it is necessary to have plenty of capital, for £1,000 barely covers the cost of one vehicle Moreover, the man who possesses only one or two motor omnibuses has little chance of competing successfully with the large companies, who can, of course, work at a lower cost per vehicle than is possible for a proprietor in a small way of business. Competition between the old and the new companies will become keener every month, and the result will be a cutting down of fares that will make it absolutely impossible for the owner of only one or two vehicles to run them at a profit. If, however, a man has plenty of capital, and decides to build up a fleet of omnibuses, he should endeavour to discover the various types of châsses that are giving satisfaction to their owners, and should restrict his choice to them. It will be much safer to do this than to purchase, even at a much lower figure than is demanded by makers of repute, a type of omnibus that has not undergone the test of some months' work on the public roads. When he has bought his châssis, it will have to be taken to a coachbuilder's to have a body built and fitted to it, for the makers of châsses do not, as a rule, build the bodies, that being quite a separate business.

Motor Omnibus Regulations. When the body has been fitted to the châssis, the omnibus is ready to be licensed; but it is useless to submit it for police inspection unless the following regulations have been observed in every respect:

"Carriages must be submitted for inspection in a thoroughly good condition, and no carriage will be certified fit for public use unless it is newly painted and varnished"

The following conditions must also be strictly complied with:

1. Stage carriages propelled by mechanical means, and subject to the Light Locomotives Act (59 and 60 Vict., Cap. 36), and Motor Car Act (3 Edwd VII., Cap. 36), must comply with the requirements of those Acts, and of the Orders of the Local Government Board in pursuance thereof

2. Each new type of motor-car intended for licensing must be presented at New Scotland Yard for inspection. The proprietor must at the same time produce the certificate of registration, and also one from the maker stating the machinery to be safe, and in every way fit for use in a public carriage.

If, on inspection, the car is approved, such approval may extend to all cars of that description, and cars of that type need not be again presented at New Scotland Yard, but may be taken to the usual passing station, provided a certificate from the maker is submitted with each car for licensing, stating that it is in every respect similar to the type already approved.

A certificate from the proprietor, stating there has been no alteration in the design of the machinery since the previous inspection and date covered by the maker's certificate, must be presented with each car submitted for renewal of licence

Should an alteration be made, the same course may be required as for a first inspection.

Should it be deemed necessary, an expert will be employed to advise on the subject. The fee for the expert examination to be deposited by the proprietor with the Commissioner, which fee will be returned if the car is passed without alteration being required.

There are specific regulations governing the construction of motor omnibuses, and licences are granted only for vehicles in the construction of which those regulations have been followed. The regulations specify the sizes of the various parts of the vehicles, and their details may be learned upon application to the licensing authority.

The fees to be paid to obtain a licence for a motor omnibus are £3 18s. to the Inland Revenue, £2 to the Metropolitan Police, and £1 to the London County Council. The last-mentioned fee is paid on the first year only; the other two are payable annually.

Cabs and Cabmen. The applicant for a cabman's licence, having satisfied the police as to his respectability and topographical knowledge, has to undergo a driving examination, usually on a four-wheeler, and with a police official sitting beside him on the box seat. The regulations, being subject to the local police arrangements, vary in different places. The London candidate, if passed by the police, is given a licence, renewable every twelve months, for which he has to pay 5s., and a deposit of 2s. 6d. His next step is to obtain a cab to drive. Cabmen differ from omnibus and tram men in not being the servants of the proprietors of the vehicle they drive. They hire them from a proprietor, paying a certain price per day. The average price per day for a hansom works out at 11s. 3d.; for a four-wheeler at 10s. 6d. Two horses are supplied for each cab. Drivers of "privileged" cabs have to pay an extra fee. The "privilege system" is an arrangement between the railway companies and certain cab proprietors, whereby a specified number of vehicles belonging to the latter are permitted to enter the various London termini and stand there for hire. As this ensures the drivers getting more "fares" than they would obtain if plying for hire in the streets, it is reasonable that they should have to refund to the proprietors the price paid per vehicle to the railway. At some railway stations the charge is 1s. per cab per day; at others it is as high as 4s.

Cab Fares. The following are the London cab fares. The cab radius is four miles from the statue of Charles I., at Charing Cross:

By Distance.	s.	d.
If hired and discharged *within* the radius, for any distance not exceeding two miles	1	0
For every additional mile or part of a mile	0	6
If hired *outside* the radius, wherever discharged, for the first and each succeeding mile or part of a mile	1	0
If hired *within*, but discharged *outside* the radius, the whole distance, not exceeding one mile	1	0
But exceeding one mile, then for each mile ended *within* the radius	0	6
And for each mile or part of a mile outside	1	0
By Time.		
Within the radius, four-wheeled cabs, for one hour or less	2	0
Hansoms, per hour	2	6
For every additional quarter of an hour, or part of a quarter, four-wheelers	0	6
Hansoms, per hour	0	8
Four-wheelers or hansoms, if hired *outside* the radius, wherever discharged, for one hour or less	2	6
If above one hour, then for every quarter of an hour or less	0	8
If hired *within* but discharged *outside* the radius the fares are according to the two preceding paragraphs.		
Luggage.		
For each package carried outside	0	2
Additional Persons.		
For each person above two (two children under ten years of age are regarded as one person)	0	6
Waiting.		
By distance only. For every fifteen minutes completed, if hired *within* the radius:		
Four-wheelers	0	6
Hansoms	0	8
When hired *outside* the radius, four-wheelers or hansoms	0	8

Unless the cabman is told when hired that he is engaged by time, fares must be paid according to distance. A driver can refuse to be hired by time between 8 p.m. and 6 a.m.

A cabman hired by distance must, unless prevented by the traffic, drive at the rate of six miles an hour; if hired by time, four miles an hour. Should he be requested to drive above the latter speed, he may demand, in addition to the time fare, for every mile, or any part of one, exceedin four miles, the fare regulated by distance.

The Taxameter. Disputes between cabmen and riders concerning the fare to be paid will continue to be numerous until some distanc registering apparatus is affixed to every cab The taxameter was tried on a few London cabs in 1899, but owing to the opposition of the cabmen as a body, the experiment was short-lived At the present day the objection to the taxameter is not nearly so widespread among cabmen, and there is every probability that before long it will be given a fair trial; a commission of inquiry into the subject has, indeed, reported this year (1906) in favour of its adoption. Somewhat resembling a clock in appearance, it is fixed over the off-side wheel, and records at the end of every journey the distance that has been travelled and the fare to be paid, including extras for luggage and waiting. It registers also the number of journeys the cab has made, the miles travelled, and the total takings of the day. When the cab is plying for hire, a little red flag projects from the side of the taxameter, and the words "Not engaged" appear on the dial. When a passenger enters the cab, it is the driver's duty to press down a lever, which causes the flag and "Not engaged" to disappear, the latter being replaced by the tariff. On arriving at the passenger's destination, the driver pulls up the lever, whereupon a record of the distance travelled and the fare to be paid appears on the dial.

Many cabmen are the proprietors of the cab they drive. In the majority of cases the man originally drove for some other proprietor, but having saved money, started business on his own account. A hansom or four-wheeler can always be obtained on the hire purchase system, and a couple of cab horses can usually be bought at a low figure if a man is prepared to spend some days at the horse repositories waiting for an opportunity to buy cheaply.

Cab Radius. As already stated, the London cab radius is four miles from the statue of Charles I. at Charing Cross. Its extension has been advocated frequently, but it is unlikely that any alteration will be made while horse-drawn cabs are in vogue. When motor cabs are plentiful, the proprietors and the drivers of the latter will probably ignore it if it be not considerably enlarged. An important section of the drivers of horse-drawn cabs—the men who ply for hire in the City and the West End—are very rarely engaged to go beyond the radius, and consequently it is a matter of indifference to them whether it be extended or not. The cabmen who do object to any alteration are those who stand for hire just outside the four-mile limit, for they appreciate being able to charge a person who hires just outside the radius "outside" fares for the whole distance travelled inside the radius. Their reply to the fact that if they charged "inside" fares they would carry more people to the West End is that they would then lose their most profitable jobs—the short shilling journeys from railway station to private houses.

Motor Cab Regulations. The conditions to be complied with before submitting a motor cab for police inspection are, to a great extent, similar to those framed for motor omnibuses; but the following are some of the special regulations. The height of the body of a hansom inside, from the top of seat cushion to the roof at the lowest part, or where the front window-frames fold up toward the roof to the lowest part of the frame, must not be less than 40 in., the width inside at any point, not less than 40 in., the width from the back squab to the nearest point of door pillars, not less than 26 in., and for knee space, not less than 28 in. The height of body of a brougham or landaulette, from the top of seat cushions to the roof at the lowest part, must not be less than 40 in., the width between the hinge pillars or shutting pillars, not less than 40 in., the width of door, not less than 21 in., and it must be so constructed that it opens to the fullest extent, and causes no inconvenience to passengers. Where the carriage is provided with front and back seats, the measurement between the front edges of cushions must not be less than 19 in., the width of front seat not less than 14 in., and of back seat not less than 16 in.

Tramways. The London County Council being the proprietors of the majority of the tramway services in the metropolis, the man who is desirous of becoming the driver or conductor of a tramcar, horse-drawn or motor, cannot do better than apply for employment to the chief officer of L.C.C. Tramways, 303, Camberwell New Road, S.E. Both drivers and conductors of the horse-drawn tramcars work six days a week, the rate of pay being for each 4s. 9d. a day on entering the service; 5s. 3d. after six months, or on obtaining a service car; 5s 9d. after six months on a service car; and 6s. 3d. after twelve months on a service car. Men are promoted from "spare" men to "service" men, as far as possible, according to seniority of service. Every driver and conductor receives also a uniform coat, overcoat, and two hats a year. Stablemen are paid 26s. a week; washers, 25s. to 30s.; farriers, 39s. to 43s. 6d.; track cleaners, 25s.; pointsmen, 24s.; trace boys, 14s. to 18s.; ticket inspectors, 42s.; regulators, 42s.; and night inspectors, 42s. All the above-mentioned work six days a week, the total number of hours per week being 60, except in the case of farriers, who work 54 hours. The only men who work seven days a week—total number of hours 70—are the foremen and deputy foremen, whose pay respectively is from 42s. to 64s. 6d., and 42s.

The drivers and conductors of motor tramcars receive the same pay as the drivers and conductors of the horse-drawn cars, but they work 56 hours per week instead of 60.

When any of the L.C.C. tramway employees are requested to work during their "stand off" or "resting" time they are paid at the rate of time and a quarter.

The conditions of employment under tramway companies and on the municipal tramways of the provinces vary, but the conditions in London may be regarded as typical.

Jobmasters. Any man who is energetic and a good judge of horses should be able to work up a profitable jobmaster's business. Two or three hundred pounds would be sufficient capital for a man starting in a very modest way, as broughams and landaus can be obtained on the purchase by instalment system, and the hay and corn merchants will give him credit, if he is a respectable man. Sometimes the hay and corn merchant will advance money to a man desirous of starting business as a jobmaster, but it is advisable to dispense with this assistance if possible, and be free to buy hay and corn in the cheapest market.

For every vehicle which a jobmaster lets out he has to pay 15s. for a licence. His coachmen are paid from 23s. to 35s. a week; but as their duties include the ordinary stable work, horse-keepers are not necessary. Many jobmasters do a good business with commercial travellers' broughams, which they let out at about £12 a month, this sum including horse and coachman. The wages of the coachman are about 23s. a week, but this sum is augmented by tips which he receives from the commercial traveller, the amount varying according to the prosperity and generosity of the donor.

No licence has to be paid for the letting out of saddle horses, and in some neighbourhoods this branch of a jobmaster's business is very profitable.

On important State occasions, when the nation's guests are numerous, the Royal stables are unable to meet the demands for carriages, with the result that some of the leading jobmasters receive orders to supply a certain number of broughams, landaus, and, occasionally, hansom cabs. The jobmasters naturally appoint their best coachmen to drive these carriages, and the selected men usually receive a handsome gratuity from the distinguished persons whose coachmen they become for the time being.

Carmen. Of all drivers, carmen are the worst paid, their wages ranging from 16s. to 32s. a week, the higher sum being received by the men who drive a pair of horses. They work on an average 14 hours a day, but, unlike most workers, have no settled times for meals, and must get them when and where they can. Whenever a carman leaves his vehicle to obtain a meal he runs the risk of being summoned by the police for leaving it unattended, and having to pay a fine of from 2s. 6d. to 15s. and costs. The London carmen, of whom there are some 45,000, are endeavouring to get Parliament to sanction the provision of registered stands where they could leave their vehicles in safety when they wish to obtain food. Such stands are very badly needed.

THE REPORTER & HIS WORK

First Years of Reporting. Shorthand. Telegraphing Copy. Longhand Abbreviations and Press Corrections. The Reporter's Environment. Helpful Qualities

By ARTHUR MEE

WE have reached the door of the newspaper office, and the work of him who steps inside will begin to take definite shape. He may never have been in a newspaper office before, and his first impression, perhaps, will be one of surprise at the utter simplicity of everything he sees.

He will remember what a wonderful thing a newspaper is; how it reaches to the very ends of the earth, and how it brings, or how it should bring, the beating heart of all the world to our own firesides. He will know that nothing can happen in any far-away corner of the world which will not some time, in some way, make itself known in the room he has entered. Yet all that he will see before him will probably be a few chairs and tables at which men are writing or reading telegrams. He will find, no doubt, his first encouragement in this. The simpler the conditions, the more hopeful he should be; and the man whose work needs no other tools than a fountain pen and a pad of paper can hardly wish for an environment more free from mystery and technicality.

The Reader's Room. Journalism has many destinies, and the time will soon come when our candidate must make up his mind which of these he will choose. He will have to decide whether he would like to be a reporter or a sub-editor, or whether he would rather aim for one of the other various posts a newspaper has to offer. But that time is not yet, and for practical purposes his work will be, for the first year or two, precisely the same whatever ultimate goal he has in view. The first business of the journalist is to be ready to do anything.

It should have been pointed out before, perhaps, that journalism may be very easily entered through a department of the composing room. One of the most important figures in a newspaper office is the reader, to whom is entrusted the business of correcting proofs. The reader's room, one of the busiest corners in a newspaper office, affords an excellent opportunity for an introduction to newspaper work, and a boy may enter this department as a copyholder much earlier and more easily than he can possibly enter the reporter's room. It will be his duty here to read copy aloud to the reader, who will compare it with the proof and make any necessary corrections. The training in this work will help considerably to prepare him for journalism, and this way of beginning may, indeed, be strongly recommended from many points of view. A year in the reader's room will enable a boy to form an opinion as to his liking for journalism as a career, will make him careful and quick to detect error, and will in many ways help to put him on the road he is anxious to tread.

The Journalist's First Work. But, whether with or without this experience, he will begin his real journalism in the reporter's room, and the first few years of his life here will be decisive of his place in his profession. He should never forget that his first duty to himself as well as to his paper is to gather experiences wherever he can, whenever he can, however he can; and he must be prepared to think nothing of hard work, of long hours, of irregular meals, of weary miles of walking by night, of unexpected demands to begin again at the end of a trying day. Journalism has no room for the man who must go home when the clock strikes.

Only one thing is automatic in journalism—the hour of going to press. It is the irregular and ever-changing nature of his work which the young journalist will come to regard as its chief value and charm. But he will find that at first his work lies in a well-defined field, and that he is given the responsibility of "covering" several regular and necessary appointments.

He will have become an apprentice, no doubt, on the staff of a provincial paper in a town such as, say, Nottingham. We may quite safely assume that he is in the provinces, because it is utterly impossible for a reporter to begin his career on a London newspaper. It is, indeed, impossible to begin newspaper journalism at all except in the provinces. It will be helpful, therefore, to take a swift survey of the ordinary work of a reporter in a typical provincial town, in the office of a morning paper with an evening edition, and the reader should bear in mind that it is precisely this kind of work which the young journalist is sure to be called upon to do at the outset of his career.

The Reporter's "Calls." The day begins with a series of calls which, though made by the junior member of the staff, are of the greatest importance. The coroner's office, the fire station, the police station, the hospital, must be called at early every morning; at 9 or 10 o'clock, or earlier, according to the time at which the paper appears. Let us go with the reporter on his round.

At the coroner's office he learns of some fatal accident, some sudden death, or some death by violence, and the brief statement of particulars which the coroner's officer allows him to see gives the essential facts. If an inquest is to be held the reporter notes down the time and place. At the hospital he may glean particulars of some street accident which has not proved fatal, and has therefore not come to the notice of the coroner; and there are many kinds of information which he may acquire by keeping in close touch with the hospital authorities.

So, too, at the police and fire stations, usually close together. The reporter may learn here of some probable development in the local courts that morning, of some interesting arrest, or of some outbreak of fire. With the necessary information about these things in his notebook he returns to the office and presents his report to his chief. If the matters are of minor importance he may be asked to write paragraphs concerning them, and this may be considered adequate treatment of the circumstances. Should there be any special interest, however, in any of the cases, the chief reporter will enter the event in a diary to be "followed up," either by the junior himself or by one of the senior reporters.

The Reporter's Diary. The diary is the most important and exciting book in the office. It is the genesis of the next edition of the paper so far as local events are concerned, and there are times in every reporter's life when he approaches this book in fear and trembling. He may find himself marked to take the next train to Manchester, or Birmingham, or Exeter, or Cardiff, to send a special account of a railway accident, a description of a political meeting, an interview with a man who has suddenly become of local interest, an investigation of some commercial enterprise closely concerning the readers of the paper. He may find himself sent away for a week to follow a candidate through a by-election, perhaps in some remote constituency in the depth of the winter. His fate for the day, whatever it may be, is settled by the diary.

It is the duty of every reporter to see that every interesting event that takes place in town is entered in the diary, and the junior may make himself very useful to his chief by keeping his eyes wide open for public announcements. It will be his duty also to familiarise himself with the dates of regular meetings which must be attended, and to see that these are carefully entered. The monthly meetings of the local authorities, the meetings of the town and county councils, the education authority, the parish and district councils, the annual meetings of societies, are all stock engagements which should never be left to casual recollection, but should be entered in the diary a year ahead. Notifications of most events are sent to the office by those concerned in them; but the vigilant reporter never relies on secretaries, and every day events occur of which no notification is sent. It is the duty of the reporter to see that these functions are not missed.

What the Reporter Should Know. The wise reporter will know something about most of the things that happen in the town. He will know not only when an annual meeting is to be held, but what is likely to be discussed at it. He will be friendly with all sorts and conditions of people, with employers of labour, with working men's leaders, with social workers, with ministers and clergymen, with lawyers, shopkeepers, police officers, builders, doctors, workhouse officials, town councillors and poor-law guardians, librarians, and a host of other people in all sorts of posts and places. The whole world is his idea-box, and the reporter never knows when there may be a column of "copy" in the most casual remark of somebody he meets. He may be attending a public meeting in a neighbouring village, and may find himself chatting with the chairman, who is, let us say, the local estate agent and valuer. Has the reporter ever thought of the copy that lies unused in a valuer's office? If he is used to seizing opportunities, he will discover that his valuer friend knows the ins and outs of all the little businesses in the neighbourhood—how they pay, their market value; what kind of business succeeds and what kind fails, and why; the factors that make one tradesman's life prosperous and happy and another a tragic failure. He will find a veritable mine of information of economic value and great public interest in the man whose business it is to know the comparative values of things in our villages and towns.

The Value of Shorthand. It will have been gathered already that a reporter's life does not by any means consist in the mere writing of shorthand and the transcribing of his notes. With the development of journalism the reporter has become largely merged in the descriptive writer. There will, no doubt, always be a demand for notetakers; but there is no demand for men who can merely take notes.

One of the most successful journalists of our time, Mr. T. P. O'Connor, has said that a journalist will succeed better without shorthand than with it. What he means is, probably, that the journalist is better without shorthand *when he has gained experience.* It is undoubtedly true that the man who succeeds in journalism without the use of shorthand is the best journalist, because his journalism is the sheer triumph of his own native ability without any mechanical aid such as shorthand gives; and in succeeding without shorthand he develops qualities a thousand times more valuable to him than shorthand could ever be.

But we live in a world where journalists are not born with a T.P. pen in their hands, and it is still true that the broad way that *leads to* journalism is by Pitman's shorthand. No ordinary young man has the slightest opportunity of joining a newspaper staff unless he learns shorthand, and this great fact is in itself an answer to those who declare that shorthand is unnecessary. While, therefore, the young journalist will fight against any inclination to trust to his shorthand as to a crutch, he will not fail to use it as a walking-stick—if one may adopt Sir Walter's famous simile

We have considered some of the duties which will make demands upon the reporter's notebook, and there are countless others. Every day there may be police courts sitting in which the reporter must make careful notes of the evidence of witnesses and legal statements. Not a day passes in which a careless reporter would not run the risk of involving his paper in an action for libel. Even such simple matters as the use of the word "prisoner" for "defendant," and the necessity of guarding a report in accordance with the theory that a man is innocent until he has been proved guilty, will cause the reporter much anxiety at first.

Pitfalls in the Reporter's Path. He must take care to realise the many pitfalls that lie in his path. He should never, when learning his work, resent the advice of a more experienced colleague. He should never allow himself to lose the sense of responsibility, to forget that the thing he writes is given to the world and cannot be recalled. The clerk who makes a mistake in his books to-day can rectify it to-morrow; even next week or next month the mischief may be stopped before it has gone too far. But a mistake in a newspaper paragraph goes on for ever. No correction can make it good.

A full sense of this truth will save the journalist from many slips. It will save him from such an experience as befel the writer when, in a mood of unpardonable indifference to all that he is now contending, he betrayed the paper which trusted him. There was in his town a place of entertainment so vulgar that he would not go to it, and his generous chief saved him the pain of rebellion by not marking him for the engagement he held in such contempt. There came a busy night, however, when there was no way out, and the sensitive junior reporter was marked to "cover" the fatal engagement. He would not go. On an electric switch by the fireplace in the reporter's room hung the weekly bills of the music hall; every week the new bill was put in its place on the top. Taking down the top bill, the rebel junior, guarding himself by an assurance over the telephone that the programme was being "satisfactorily performed," wrote a paragraph saying so for the next morning's paper. It appeared, a tame little paragraph in which nobody would have looked for a bombshell, until the manager of the music hall called to know what subtle reason the paper had for declaring that a programme five weeks old had been received the night before with great applause! There are obvious morals to the story, which every junior reporter may apply.

Experience of "Copy." The reporter should strive to create the feeling in the mind of his chief that he can be relied upon. It will be necessary at first for his copy to be revised, but the time will come when he himself will be given opportunities of revising the copy of a newer apprentice, or of the country correspondents who, invaluable as they are to any paper, have sometimes a genius for missing essentials and for writing tediously, in very bad grammar, about trifling things. The value of the good local correspondent can hardly be exaggerated, but the chief value of the bad correspondent is that his copy is a means of teaching sub-editing to those who deal with it. The reporter who is called upon, as all reporters are, to practise sub-editing, will find this experience so useful to him that he should do as much of this work as he can; it will help him to see defects in style, and to achieve a free style of his own.

The bulk of the reporter's work is, however, of a very different kind. His own copy should, after one or two years' experience, be ready for press without any sub-editing. He will learn in these first years much more than any book can teach him. He will have been called upon to test himself at almost every possible kind of function. He will have learned the value of every minute, the use of the telephone and telegraph, the importance of being able to make up his mind quickly how to act, the necessity of utilising time spent in travelling, and of writing with a rapidity he has not thought possible before. He will have found that newspaper work is not all flower-shows and weddings; but he will have found, also, that constant application and organisation make the most difficult things easier.

Reporting a Speech. There is a great difference in the styles of reporting which will come under his notice. The reporter will discover these things for himself, but we will take one example. There was a fine passage the other day in a speech by Mr. Winston Churchill, in which he drew the line between individualism and collectivism. Here is a first-person extract from his speech:

> That is where the Socialists make a mistake. Let us be careful not to fall into it. We have an Army and Navy collectively. Collectively we maintain a Government, police, and Post Office. But we do not make love collectively. We do not die collectively, and it is not collectively that we suffer, and hope, and win, and lose, in a world of accidents and storms.

The reporter who has to report this in the third person need only alter the first two lines: "That *was* where the Socialists *made* a mistake. Let *Liberals* be careful not to fall into it." In ordinary third-person reporting, however, this degenerated into:

> That was where the Socialists made a mistake. Let them be careful not to fall into it. We had an Army and Navy collectively. Collectively we maintained a Government, police, and Post office. But we did not make love collectively, we did not die collectively, and it was not collectively that we suffered, and hoped, and won, and lost, in a world of accidents and storms.

This, of course, is full of absurdities, almost worthy of the reporter who put a quotation from Tennyson into the third person by saying: "The speaker said that kind hearts were more than coronets, and simple faith was superior to Norman blood."

It is unfortunately true that in third-person reporting the practice of unnecessarily altering the present to the past tense is ordinarily adopted, but it is rarely done without spoiling the report, and sometimes quite perverting the meaning, as, say, in the case of a speaker who says: "London is greater than Manchester, and its streets are wider than the streets of Manchester."

This in the third-person style of reporting now common would become: "London *was* greater than Manchester, and its streets *were* wider than the streets of Manchester," the effect of which, of course, would be to give the reader the impression that London was greater than Manchester in the past, whereas what the speaker meant was that it is greater than Manchester now.

Reporting by Telegraph. The reporter will some day be called upon to send his copy by telegraph, and he will find this quite simple.

The first thing necessary is to obtain from the post-office, free of charge, a supply of Press telegraph forms. On the front slip (Form 1) are the places for the names and addresses of the papers to which the message is addressed; Form 2 is merely for the continuation of the message. Up to 6 p.m. on any day on which the office is open the reporter may hand in a message at any post-office in the kingdom at the rate of 75 words for a shilling. After 6 p.m. the rate is 100 words for a shilling.

There are still telegraph offices in the kingdom where no Press message has ever been seen, but the Post Office rarely disappoints the journalist. It is a condition that notice shall be given of any messages over 200 words, but where this is impossible the rule is readily relaxed. By writing to the secretary of the Post Office, giving him twenty-four hours' notice, the reporter may have any office in the kingdom kept open on payment of a minimum fee. When the message is to be sent to various papers, all that is necessary is to write the names and addresses on the front slip of his message, or to pin a list to this slip, and to pay 2d. instead of a shilling for each subsequent address—that is to say, a message sent after 6 p.m. from London to ten different newspapers in ten towns will be charged for once at the rate of a shilling per 100 words, and nine times at 2d. per 100 words, and it may be sent any number of times at this rate.

Rapid Writing. It is not possible for us to consider here, even in this brief fashion, all the practical things that a reporter must know. He will come to learn them as he goes along. He should never be satisfied with himself so long as it takes him more than an hour to write out a thousand words in longhand from his notes. The reporter's ideal is the House of Commons Gallery man who once wrote three columns of the TIMES (over 6,000 words) in three hours.

To facilitate rapid writing of longhand a series of abbreviations is recognised in every printing office and in every post-office. They are:

/ =the, fm=from, f=for, wd=would, o=of, shd=should, t.=that, h=have, wl=will, w=with, wh=which, cd=could.

Many other abbreviations will readily suggest themselves—such as, for instance, *g* for *ing*; *n* for *tion*—that is, *speak*^{g} for *speaking*; *terminat*^{n} for *termination*.

Of even greater importance is it that the journalist should learn how to correct proofs.

δ/	Delete (take out)	≡ or *cap.*	Capital letters
ɔ	Turned letter	= or *s.c.*	Small capital letters
∧	Caret (insert)	□	Indent line one "em"
❜❜/	Quotation marks	L	Reduce space
-/	Insert hyphen	*n.p.*	New paragraph
⁀	Close up	×	Broken letter
#	Insert a space	*w.f.*	Wrong fount of type

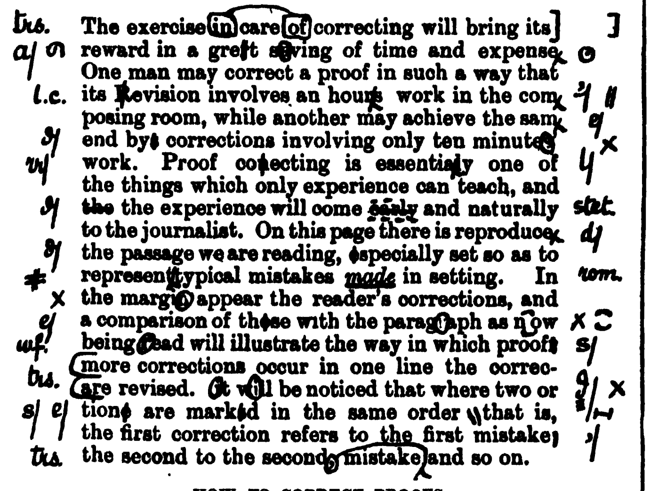
trs.	Transpose words or letters	*l.c.*	Lower case (small letters)

SIGNS USED IN CORRECTING PROOFS



The exercise in care of correcting will bring its
reward in a greft saving of time and expense
One man may correct a proof in such a way that
its Revision involves an hours work in the com
posing room, while another may achieve the sam
end bys corrections involving only ten minutes
work. Proof coecting is essentially one of
the things which only experience can teach, and
the the experience will come early and naturally
to the journalist. On this page there is reproduce
the passage we are reading, especially set so as to
represent typical mistakes *made* in setting. In
the margin appear the reader's corrections, and
a comparison of these with the paragraph as now
being read will illustrate the way in which proofs
more corrections occur in one line the correc-
are revised. It will be noticed that where two or
tions are marked in the same order that is,
the first correction refers to the first mistake,
the second to the second, mistake and so on.

HOW TO CORRECT PROOFS
This passage appears in its revised form on this page as part of this article, and the actual passage should be compared with the above

The exercise of care in correcting will bring its reward in a great saving of time and expense. One man may correct a proof in such a way that its revision involves an hour's work in the composing room, while another may achieve the same end by corrections involving only ten minutes' work. Proof correcting is essentially one of the things which only experience can teach, and the experience will come early and naturally to the journalist. On this page there is reproduced the passage we are reading, specially set so as to represent typical mistakes made in setting. In the margin appear the reader's corrections, and a comparison of these with the paragraph as now being read will illustrate the way in which proofs are revised. It will be noticed that where two or more corrections occur in one line the corrections are marked in the same order—that is, the first correction refers to the first mistake, the second to the second mistake, and so on.

The Reporter's Difficulties. The reporter should learn to write in almost any conditions. He may have to take notes in a crowd, holding an umbrella, or hanging on to a lamp-post. He will find great difficulty at times in obtaining names at meetings; will suffer much inconvenience from the neglect of secretaries, the mistakes of speakers, the bad manners of many people who ought to know better. He will be insulted by people who imagine that every reporter has his price—from the poor woman who, knowing no better, offers him sixpence to keep her boy's name out of the paper, to the man who, knowing better, is not ashamed to tempt him into evil by offering him gold.

The good reporter is oblivious of the difficult or unpleasant circumstances in which he may find himself at times. He will think nothing of having to write in trains—that, if he will sit facing the engine and write on a stiff board, letting his back come into contact as little as possible with the carriage, is easy. He will accept a difficult engagement quite readily, knowing that the experience will make the same work easier when it comes again, until difficulties cease to trouble him, He will learn to have a contempt for such men as the reporter on a London morning paper who, having been engaged in the office for some time, was told to do outside work. "But I am no good at outside work," he said. "Well," said the editor, "that is all I have for you." "Well, I had better take my pay and go," said the stupid reporter, and one of the most go-ahead halfpenny papers in London was well rid of him. The reporter who is "no good at outside work" is no good for anything to a newspaper, and it is a most unfortunate day in a journalist's career when he refuses an engagement for reasons of that kind.

A Royal Road to Information. There are many things that the reporter must teach himself. Only his own experience can teach him the priceless value of the gift of holding his tongue and of never expressing surprise.

There is a familiar story of a representative of the TIMES dining with a physician, who mentioned that a statesman had that day asked him if India would suit him. He had answered, "Yes." The TIMES reporter exhibited no surprise and no unusual interest. Knowing that the Viceroyalty was vacant, he went to the office and wrote a paragraph saying that the statesman was to be the new Viceroy of India. He was right. A casual remark at dinner had contributed what may have been the most interesting paragraph in the next day's papers. It was a creditable achievement, and it depended upon four qualities on the part of the journalist. He knew his facts; the Viceroyalty was vacant. He had cultivated his natural powers of deduction; it was not likely to be a mere coincidence that one of the probable candidates for the Viceroyalty should ask at that particular moment if India would suit his health. He had the astuteness not to seem unusually interested; he had all the information he wanted, and knew that any expression of surprise might cause the physician to pledge him to secrecy. He had the courage without which no man ever succeeds in journalism; he did not wait to make further inquiries, which would have lost him the distinction of making an exclusive announcement.

The Man Who Always Knows. It is one of the surest and wisest rules in journalism never to manifest surprise. It is the business of the journalist to *know*, and he should give the impression of a man who knows wherever he goes to seek information. The quickest way of closing a man's lips is to express surprise at anything he has said. He hesitates, pauses to ask himself if he is wise, and at last regrets having revealed a secret. The natural reluctance of men and women to say anything which may involve them in trouble or publicity makes the work of the journalist often unnecessarily hard; and the journalist can smooth the way for himself by taking a startling statement as a matter of course, as if he had been familiar with it all the time. It is not necessary, of course, to point out the difference between a piece of confidential information and information which it is quite legitimate to publish, though the man who can give it is unreasonably nervous about doing so. No reporter worthy of the name will break faith by publishing something he has promised to keep secret. We are discussing now the method of obtaining information or opinions in a quite legitimate manner from persons who, either because of their own nature or because of the circumstances, may be very easily frightened and stricken dumb by the way in which the journalist receives their statements.

The Value of Sympathy in Reporting. The reporter's life brings him into contact with that side of things which is not always the best, but he will, if he is wise, take care that his experiences make him not a worse but a better man. He need not be ashamed of having emotions even as other men. The chief reporter who knows his work well and knows how to get full value from his staff will do his utmost to see that his reporters are sent to sympathetic engagements, and he will do all that he can to encourage rather than repress any enthusiasm the reporter may manifest. The reporter is too often regarded as something apart; a necessary, but not an integral, piece of machinery. He should make it his business to become an integral factor in things, to feel himself a part of, and let others feel that he is a part of, whatever is happening. It is inevitable that the reporter should find himself in the company of people he dislikes, in an environment that is intolerable to him, doing work that he detests; but it is a good thing to bear in mind that the man who will describe a movement best is the man who feels the spirit of it, who knows the aim of it. There was a wonderful article describing a Salvation Army meeting in a London paper not long ago. It was written by a reporter who calls himself a Freethinker, but who had the greatest difficulty to keep away from the penitent form as he listened to Miss Eva Booth. It is not astonishing that he wrote a wonderful article. The reporter who puts his soul into his work will carry everything before him.

DRESS FOR LITTLE BOYS

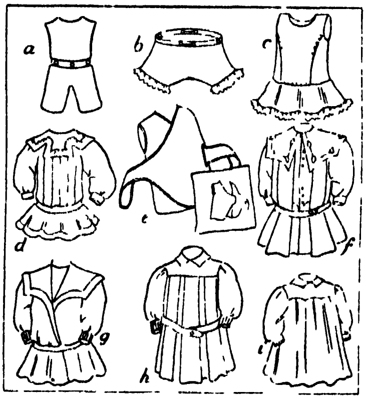
A Set of Garments for Little Boys. Tunic and other Suits. The Popular "Man-o'-War." A Scotch Kilt

continued from page 4054

By AZÉLINE LEWIS

IT has already been remarked that, although both boy and girl babies at first wear petticoats, there is some slight difference in shape, as those for the boys are generally cut with long waists, the skirt part consisting of a shaped or straight-gathered frill. The little frocks, too, even the kilted style, could be made on the same lines.

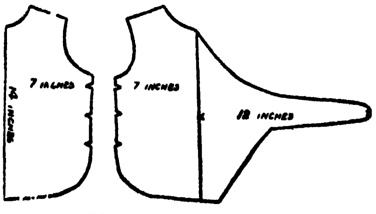
Diagram 33 shows a set of boy-baby garments for the first stage: (*a*) is the small combination, consisting of two parts, the leg portions of which, made a little larger, will afterwards do for pants. At this very early stage, however, a little knitted vest, cut up sufficiently deep to form legs, will answer the purpose admirably. (*e*) is an American vest or shirt, made of very finest flannel, which may be worn up to four years of age under a tunic or suit.



33. BABY-BOY GARMENTS

The small drawers are shown at (*b*). These are made all in one, the fastening consisting of tape passed through eyelet-holes, as in the sketch, which are drawn up and passed round the buttons of the bodice. (*c*) is the petticoat, which differs only from that shown in 47 in having the seams from the armholes, and one instead of two shaped frills for the skirt.

The frock, made of white flannel, Viyella, or wincey, is shown in (*d*). (*g*) is a cross-over tunic, with vest and collar; (*h*), a pleated tunic frock. For quite small boys these are better arranged in a short yoke, but for older boys the pleats should come from the shoulder. (*i*) shows a smock, or overall, of holland or linen, and (*f*) a neat variation of the tunic suit, with an added waistcoat.



34. AMERICAN SHIRT

Tunic Suits. Nearly all these garments can be cut with the aid of the draftings already given, with slight alterations. The bodice of the petticoat and frock, for instance, is the same as in 25, only a few inches being added to the length, and seams made to come from front of armhole. Directions have already been given in DRESSMAKING for cutting circular and shaped flounces, the little skirt sketched being of this shape, as it sets out so much better at the lower edge than the straight-cut one.

The little frock is exactly the same shape, minus the seams at side of front, the pleats being arranged on the pattern before cutting out. If made in washing material the bodice need not be lined, but the pleats should be stitched down at each edge; if of woollen goods, a lining is needed. The petticoat will take ½ yd. of 36-in. material, and the frock from 1 to 1¼ yd. of 27-in. goods.

Diagram 34 shows the shape of the American shirt, which can also be adapted from the bodice pattern, with the necessary extension for the belt part. This vest should be cut selvedge ways of the flannel, as it is then much less likely to stretch. The edges are bound with lute ribbon, care being taken not to stretch the cross-way edges, whilst the seams must be neatly herringboned with fine cotton. Three-quarters of a yard of flannel are required.

In 35 we have the drafting of a tunic which will serve for (*f*), (*g*), (*h*) and (*i*) in 33, as well as for (*d*) and (*f*) in 36. These can be evolved from 35 by adding on the requisite length and width to the lower portion. The plain tunic measures about 1¼ yd. round the lower edge.

The double broken line at (*a*) in 35 shows the direction to be taken for the fronts of the cross-over tunic in (*g*) of 33 for a very little boy; whilst the single row of broken lines indicate the direction for the plain double-breasted affair, with a diagonal closing, as in (*d*) of 36.

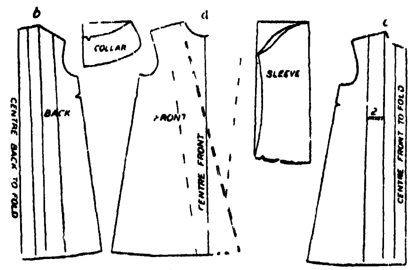
The pattern will also serve as model for the pleated tunic, shown in the same diagram [33], by modelling the pleats, as described for the pleated skirt, as shown in diagram 30, and also in TAILORING FOR GIRLS [page 2468]. The box pleats are about 2 in. wide. If a yoke be needed, cut this from the upper part, as shown by the notches, and model the pleats for the lower part as described.

This tunic may fasten at centre-back or front, as preferred; if in front, the opening must be made to come under the middle pleat.

Directions for drafting the collar have already been given, whilst that for the crossover tunic of

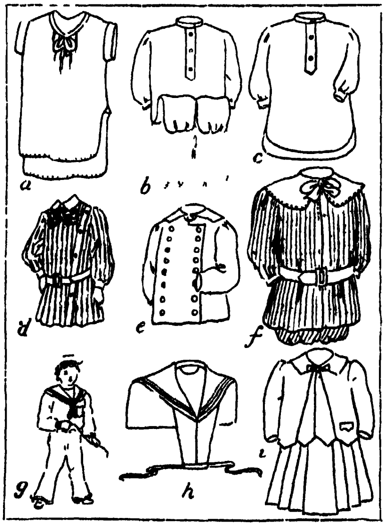
33 must be shaped to fit the neck and front opening. The vest can be cut to the directions of the singlet shown in the boy's man-o'-war suit, in 41, with the addition of a collar, or not, as fancy may dictate.

Little Boys' Suits. The ideal suit for small boys, advocated by many doctors, is the kilt. This provides the necessary leg covering and gives freedom, whilst ensuring warmth to encourage a proper blood supply to the knee and leg. The kilt can be worn with either coat and waistcoat—the making of both of which have been already described [31]—or a sailor blouse.



35. TUNIC

Diagram 36 shows the various garments suited to the second stage of the small boy's existence. (c) is the small first shirt, to be made of either flannel or shirting. Combinations would, however, still be retained, and knickers or pants would be the same as those in 33, with a slight increase of size. (b) and (a) depict two French shapes for the small boy, which may be commended to the notice of mothers. The first is a cross between a chemise and a shirt, which may be recommended for summer, whilst the latter, combining the advantages of the shirt and combination, is advisable for winter wear. This latter shape, with the leg portion further lengthened, forms the sleeping-suit.



36. LITTLE BOY'S GARMENTS

In (d) is shown a Russian tunic, which is worn over small knickers, and can be plain or pleated, as preferred. (f) depicts the same pattern, only made to fasten in the centre. This is a very suitable style for boys from four to six years of age.

Three things are necessary to this suit—*viz.*, the collar, tie, and the belt, whilst a fourth may also be added—the cap, which is of the "Tam" order, for outdoor wear. The suit may be made of any material, and any suitable colour. The suit can also be worn by older boys, when a plain Eton collar is best. The belt should be of leather, with a large plain buckle.

In (*i*) we have a Scotch kilt suit. For the making of this, see directions for kilt in the previous course [page 4053]. It may, however, be remarked that the kilt should be fuller, and can well have three widths of material. (A kilt for an adult Scot measures, on an average, seven yards round.) If made with a plain front it should be made to lap over the full width of this plain part, and thus be double where required.

For the making of the coat and waistcoat, see Tailoring for Women and Children [page 1110], all that is necessary being to cut the pattern without allowing inlays, if required for the smaller size.

A Man-o'-War Suit. In (*g*) we have the suit cut exactly on the lines of that of a Jack Tar From a hygienic point of view this is by far the best sailor style for the tiny boy, because the blouse, or "jumper," as it is technically known, is cut somewhat long, so as to be tucked into the waist part of the trousers, which are cut with a fall-front, and thus affords more warmth than the ordinary blouse gathered into an elastic.

(*e*) shows a blouse fastened over in the manner of a short Breton coat, which makes a warm wrap. In the American fashion it fastens over in the opposite direction. (*h*) illustrates a removable sailor collar, the semi-circular piece at the back keeping this in position. From six years of age and onwards the coat and knickers, as well as the Norfolk and other suits which are described in Tailoring [page 1752], can be worn. With regard to his out-of-door attire, the small boy looks very well in a tunic coat, cut on similar lines to that sketched in 36, made of cloth, velveteen, or corduroy velvet, with leather belt and large square buckle. Another style would be the sacque coat, cut the same as in 32, only less full in the skirt portion, and made single or double-breasted, as preferred. This can be accompanied by two or three graduated capes, highwayman fashion, and a tricorn hat.

The reefer coat is a very suitable accompaniment to the man-o'-war suit shown in 36.

Later on the little boy may quite well be clad in an overcoat with a step-collar, with Chesterfield or double-breasted fronts, for which full description as to drafting and making are given in Boys' Suits [page 1754]. The system of drafting there given will answer for this with the necessary alterations of chest and length measure. In many cases the drafting will do perfectly for the smaller size, if cut without allowing inlays. The making of such an overcoat will be exactly the same as for the larger size. If required double-breasted, and to fasten with buttons and buttonholes instead of a fly-front, an extra two inches must be allowed for the lap-over, whilst the fronts would be made as described for the Norfolk coat.

AN ARMY COMMISSION

Entrance Examination and Conditions. Cadetship. Promotion. Emoluments and Expenses. The Indian and Egyptian Services

ARMY
continued from page 4032

By C. DUNCAN CROSS

We have seen how a man may rise from private to warrant rank. We now come to the career of a soldier who joins the Service as an officer.

To be eligible, the young man must attain to certain physical requirements. His chest measurement and height must accord with the figures given in the following table; his eyesight must be good, and his hearing perfect. His teeth are carefully examined. More than ten lost or decayed will disqualify him, though a decayed tooth well stopped is counted as sound.

Age last birthday	Height without shoes.	Chest.	
		Girth when fully expanded.	Range of Expansion.
18	62 and under 65	34½	2
	65 ,, 68	35	2
	68 ,, 72	35½	2
	72 and upwards	36	2½
19	62½ and under 65	35	2
	65 ,, 68	35	2
	68 ,, 70	35½	2
	70 ,, 72	36	2
	72 and upwards	36½	2½

He will choose first of all which of the two great divisions of the Army he desires to enter. If he has a strong taste for engineering, for mathematics, and for the applied sciences, he will do well to choose the Royal Engineers or the Royal Artillery, through the Royal Military Academy. Or, if he prefer, he will enter the Cavalry, the Infantry, or the Army Service Corps, through the Royal Military College, Sandhurst.

The Royal Military Academy. We shall consider first the Royal Military Academy, or, as it is called, "the Shop."

Admission is gained by open competitive examination (fee, £2 in London, £3 in Dublin), held in June and November each year. The candidate must be between 18 and 19½ years of age. He must produce either a leaving certificate from one of the accepted sources, such as the Oxford and Cambridge Schools Examination Board, the Universities of London or Birmingham, the Oxford or Cambridge Local Examination Board (in Scotland the Scottish Education Department, and in Wales the Central Welsh Board for Intermediate Education), or he must produce a "qualifying" certificate, for which he is examined by an Army qualifying board in English, English history and geography, elementary mathematics, and two out of the following three subjects: Science; French or German; Latin or Greek. Or he can produce an "exempting" certificate showing that he has passed certain other Civil Service examinations of an equal or greater severity.

The subjects of the entrance examination are as follow:

COMPULSORY SUBJECTS

English. Essay, précis writing, and reproduction of passages read.

French or German. Translation into and from, conversation, and an essay.

Mathematics I. Arithmetic, geometry, Euclid I. to VI., algebra, a knowledge of simple trigonometry, simple statics and dynamics.

And two of the following:

OPTIONAL SUBJECTS

Mathematics II. Including mathematics I. (above), with solid geometry, Euclid (Book XI.), advanced algebra, differential and integral calculus, coordinate geometry, elementary statics of liquids and gases.

History. A general paper, a period or a general paper on ancient history, a military biography.

German or French. Other than the language selected in compulsory subjects.

Latin or Greek. Translation into and from, Latin verse or Roman literature.

Science. An examination to test a general knowledge of physics and chemistry.

Physical Standard. Should the applicant prove successful in the examination, it will be necessary for him to pass a severe medical test before he can be accepted. To minimise the possibility of failure now, with its consequent waste of time and money, he may apply to the Secretary, War Office, for a preliminary medical examination (fee, £2 2s.), in which case arrangements will be made with a medical board at the military station nearest to the applicant's residence. This preliminary examination is in no way final, and binds the War Office neither to take nor reject the candidate, the final examination being the report on which his physical condition is considered. Should the final medical examination be unsatisfactory, an appeal may be made for a further inquiry into the applicant's health, in which case a fee of £4 4s. must be deposited in advance. This will be returned should the appeal be found to be justified.

Cadetship. The medical board safely passed, the candidate is then entered as a cadet. The fees range from £40 to £80 for the sons of officers, retired officers, and a few privileged persons, according to the rank of the father; for the son of a private gentleman the fee is £150. A few King's cadets (sons of officers who have died on service) are educated free of charge. Beyond this, for other than King's cadets, at the beginning of the course a sum of £35 must be paid for uniform, books, etc., and again at the beginning of the third term a further sum of £15.

An allowance of 3s. a day is made to each cadet in aid of expenses of uniform, messing, washing, etc., but a further allowance from the parent is necessary. With economy on the part of the cadet, £50 a year will suffice for pocket-money, travelling and other expenses.

The course of instruction extends over two years, divided into four terms, and includes the following subjects:

Mathematics and mechanics, artillery, military engineering, practical geometry, military topography and freehand drawing, military history and tactics, electricity and magnetism, chemistry and physics, French and German, military law and interior economy, infantry drill, riding, gymnastics, signalling, workshops.

Every half-year the cadet is examined by the staff of the Academy, and by outside examiners at the end of each year. A certain percentage of marks must be gained or the cadet loses the term and forfeits all claim to choice of corps, and, if the same thing should happen again he is removed from the Academy.

A Commission. At the end of two years, supposing him to have reached the Fourth Class and passed his final examination successfully, the cadet is gazetted to a second lieutenant's commission in the Artillery or the Engineers.

The Royal Military College (Sandhurst) is an institution similar in character to "the Shop." Its function is the training of officers for the cavalry, the infantry, and the Army Service Corps. The qualifications and certificates are the same as those necessary for the Academy and the course consists of four terms normally, though, pending the enlargement of the college, a temporary two-term course has been adopted. The course is less strenuous than that of the Military Academy, gunnery, chemistry and physics, and workshop practice being omitted, and the cadets go into camp for three weeks in the summer.

Passing Out. When the final examination is passed and the candidate passes out of the Academy, the choice of corps, so far as vacancies permit, is given to those who have passed out highest in the order of merit at the final examination; but those candidates who are recommended for the Royal Artillery are given the opportunity of choosing whether they prefer the Field Artillery or the Garrison Artillery. Provided he has distinguished himself in riding, horsemanship, and Field Artillery drills, the cadet who desires it will be posted to the Field Artillery, from whose ranks are selected the best riders and the smartest officers for the Horse Artillery.

In passing from the Military College, selection is made among the successful candidates as follows. The cavalry cadets are appointed to British cavalry, and after their claims have been satisfied, the remaining commissions are thrown open to other cadets who desire them, and are allotted in order of merit. As to the infantry, cadets having special or territorial connection with certain regiments should apply before the examination to the Military Secretary through the commandant of the College. Occasionally, if the claim is a very strong one and no vacancy exists, the cadet is allowed to wait, but in no case may he wait more than six months. Candidates without special claims may apply for special regiments, but they are not allowed to wait should there be no vacancy. In due course the successful candidate's name appears in the "Gazette," he receives from the Military Secretary a confirmation by letter, and from the Adjutant-General orders to join his battalion.

The case of a cadet joining the Indian Army is treated separately.

University Men. A certain number of commissions are given to students at the great universities who are between the ages of twenty and twenty-five and who have graduated in any of the approved subjects (except theology, medicine, music, or commerce). A student passing with first-class honours is entitled to count one year's seniority for it. A candidate for the Royal Artillery must show that he has qualified in the same mathematical subjects as are required in the entrance examination for the Royal Military Academy. The further qualifications required of all university students are that they shall have been attached for training to a Regular unit during the previous two years, and that they can obtain qualifying marks (·5 in the aggregate) in military history and strategy, tactics, military engineering and topography, military law, and military administration.

* In addition, "Engineers' Pay," Lt.-Col., 14s.; Major, 9s.; Capt., 6s.; Lieut. and Second Lieut., 4s. a day.

† In addition, "Guards' Pay," Col., £250; Lt.-Col., £200; Major, £170; Capt., £140; Lieut. and Second Lieut., £70 a year.

‡ Rising 1s. 6d. a day for every five years served.

¶ In addition, A.S.C. "Corps Pay," Lt.-Col., 6s.; Major, 5s. 4d.; Capt., 4s.; Lieut., 3s. 6d.; Second Lieut., 2s. 6d. a day.

Officers of the Militia and the Imperial Yeomanry are also admitted on similar conditions, provided they have served for two annual trainings, have been attached to a Regular unit for instruction in drill, discipline, interior economy, musketry, signalling, and practical tactics, and are recommended by their commanding officers. Further, they must produce the "leaving" or qualifying certificate before mentioned.

Equipment. The cost to a newly appointed lieutenant, including private clothes, etc., in a Line regiment of infantry will be not far short of £100, and in the cavalry close upon £250. The equipment, such as revolver, field-glasses, saddlery, etc., can be bought either at Government price from the Ordnance Department, or privately. In the Foot Guards and Household Cavalry the outlay is naturally greater. It may be said that a second lieutenant in the Infantry of the Line should have at least £100 and in the cavalry £200 a year of his own. Even this will mean cutting down personal expenses to a minimum.

Promotion. As second lieutenant he must, before promotion to lieutenant, pass a simple professional examination in regimental duties, which is based on the "King's Regulations," the Army books and forms in use, the Pay Warrant, "Equipment Regulations," and, in the case of foreign service, on the special Army Regulations laid down for the particular country in which he is serving. The examination divides itself into four heads:

1. DISCIPLINE. General instructions; administration; courts of inquiry; deserters; and disposal of prisoners.
2. DUTIES. Roster of duties; garrison and field duties; compliments; guards and sentries; military funerals; duties in aid of civil authorities.
3. INTERIOR ECONOMY. Officers and N.C.O.'s; system of keeping accounts, books, and returns for squadron, battery, or company; system of payment, messing, and supply of necessaries for same; pay of N.C.O.'s and transfer and discharge of soldiers.
4. MISCELLANEOUS INFORMATION. The method of supplying troops in quarters and in the field; a junior officer's duties in connection with the movement of troops by land and sea; detail of carrying arms and equipment (for the cavalry, the detail of saddlery, the fitting of saddle and bridle, etc.).

Practical Test. In addition, there is a practical examination in the field to be passed. The candidate is required, in addition to giving the words of command, to explain clearly and simply the movement he orders to be performed. In the cavalry, the examination is based on "Cavalry Training" and the "Musketry Regulations," and comprises a knowledge of

DRILLS. Military equitation; the instruction of a soldier mounted and on foot; and the capacity to command a squadron on parade or in the field.

MUSKETRY. Instruction of the recruit; preliminary drill and practice; field firing and dismounted practice with horses; musketry returns.

Miscellaneous subjects from "Cavalry Training."

Artillery. In the Artillery the examination is rather more complicated. The range of books required is also wider. It includes "Cavalry Training," "Field Artillery Training," "Rifle Exercises and Infantry Training," "Infantry Training," and the "Handbook of the Gun," "Instruction for Practice, Horse, Field, and Mountain Artillery."

Here is the syllabus of the examination:

DRILLS AND EXERCISES. Instruction of dismounted men; equitation, stable duties, and driving; drills, manœuvres, and ceremonial observances; rifle and pistol exercise; guards; section gun drill; gun-laying—sights, tangent, and telescopic; indirect laying and the use of the clinometer; care and adjustment of sights; the laying of a gun under competition conditions.

EQUIPMENT. Taking to pieces fittings of guns and carriages, and the explanation of their uses; a knowledge of the parts of gun-carriages likely to suffer from wear, ill-usage, or service conditions; explanation of the construction and action of various projectiles; the action of fuses; preparation charges and the setting of the fuse.

PRACTICE. A general knowledge of Chapter IV. of "Field Artillery Training."

The examination for coast defence companies is similar, but deals more with the work of a coast defence section of artillery—the construction of heavy guns, their fitting and adjustment, and so forth. The books on which the examination is based are "Infantry Training," parts I. and II.; "Handbook of the Gun"; "Garrison Artillery Training," Vols. I., II., and III.; and "Instruction for Practice Seawards."

For siege companies and heavy batteries the examination is much the same as for coast defence companies, but in relation to siege guns particularly. The books required are "Infantry Training," "Siege Artillery Drill," and "Heavy Artillery Training."

Engineers and Infantry. For engineers and infantry the examination is quite simple, and is based on "Infantry Training," "Combined Training," and the "Musketry Regulations." The following are the subjects:

DRILL. Squad and company drill; to command a company in battalion drill.

EXERCISES. Rifle and firing exercises; advanced guards and rear guards; outposts and skirmishing; the company in attack and defence; ceremonial.

MUSKETRY. Instruction of the recruit; preliminary drill and practice; the making up of drill and practice returns.

The Army Service Corps examination is practically the same as that for infantry and engineers, except that under the heading of "Drills" comes knowledge of corps duties from "A.S.C. Training," and instead of "Exercises" is carbine exercise and manual and firing exercises.

Promotion to Captain. The next stage in the lieutenant's career is promotion to captain. This comes by seniority, with a certain amount of selection in the case of a particularly desirable officer. It is possible to prepare for this, but more usually a tutor is employed for a month at a cost of twelve to fourteen guineas. In any case, he must pass a searching test in (i.) Practical military topography; (ii.) practical military engineering; (iii.) practical tactics; (iv.) riding; and, if he belong to a mounted branch, (v.) horsemastership, which includes horsebreaking, veterinary knowledge, and, indeed, a comprehensive knowledge of the whole subject. Beyond this lies a theoretical acquaintance with military law, engineering, tactics and topography, administration, organisation and equipment, and military history. A candidate for a captaincy in the artillery must in addition pass in artillery, and in the A.S.C. will be tested in the varied duties which fall to the officers of that branch.

Higher Staff Appointments. As captain he will, if he be an ambitious man, try to enter the Staff College, which, after a two-years' course, will make him eligible for higher staff appointments. There is also the recently created general staff which will attract the most brilliant soldier to its ranks. To prepare for the entrance examination a tutor (cost about £40) is necessary. On the other hand, he may prefer to remain with his regiment, in which case seniority will carry him to senior major. Before promotion to lieutenant-colonel he will have to show in the field his ability to handle mixed forces of all arms of the Service which will be placed under his command, to take part in staff rides and war games, and generally to prove by practical demonstration that he can not only command men, but that he has also those higher qualities which make the successful tactician and strategist.

Among the side avenues of the Army the Royal Army Medical Corps, the Veterinary Service Corps, the religious, and the scholastic branches offer many advantages to men of special training. As these are of purely technical interest, and appeal only to men with special civilian training they may be dismissed with the statement that to enter them a proof of professional capability is required in the form of a diploma, and that promotion comes by seniority and length of service.

The Indian Army. On passing out of the Military College the cadet is gazetted as second lieutenant on the unattached list, and is appointed to a British regiment serving in India. From the date of his first commission to the date of his arrival in India he receives the British pay of his rank. At the expiration of one year's actual duty with the British regiment, should he prove satisfactory, he is admitted to the Indian Army with the rank of second lieutenant, and appointed to a native regiment. Here his position is infinitely more responsible than that of second lieutenant in the British Service. He has native officers of many years' service under him, and his pay—considering the cheapness of native servants, and the lower standard of expense generally obtaining in the Indian Service—is more adequate. Within two years and three months from his first commission he must pass an examination in Urdu by the lower standard, and he will then be promoted to lieutenant. Within three years of his admission to the Indian Army he must pass the higher standard of Urdu, for until that is done he is not eligible for any higher appointment than squadron or double company officer. When the direct supply of officers from Sandhurst fails, officers are drawn direct from volunteers from British regiments.

In addition to the Urdu examination, officers are required to pass another examination in the language chiefly spoken by the men of their regiments. There is also a simple professional examination.

Promotion. Promotion in the Indian Army (subject to the passing the examination) is regulated by length of service. As we have seen, after 27 months a second lieutenant is promoted to lieutenant; after nine years he becomes a captain; after 18 years, a major; and after 26 years a lieutenant-colonel. It may, however, be accelerated with luck by a brilliant man. A major may be promoted to lieutenant-colonel when he is appointed to command a regiment or battalion, or an appointment which would carry the substantive rank of colonel if the officer were qualified for that rank; and in one or two other cases.

A lieutenant-colonel reaches the rank of colonel in similar fashion on completion of three years' service in command of a battalion or regiment, on completion of six years' service as brevet lieutenant-colonel in a military appointment, or by holding certain analogous positions.

Promotion to the rank of major-general is made by selection. In the same fashion is promotion to one of the five lieutenant-generalships. Last of all, above this come the three generalships by seniority after three years or more as lieutenant-general.

The Egyptian Army. Officers of the British Army desirous of joining the Egyptian Army must apply through their colonel to the Adjutant-General of the Egyptian Army, Khartoum. Officers must be over 25 years of age, unmarried, must be good horsemen, and must obtain a medical certificate that their health is equal to service in a tropical climate. They must have had five years as commissioned officers, and must have passed for the rank higher than that which they hold.

On acceptance they join the Army as bimbashis (majors), or a higher rank if their position in the British Service warrants it. After three months' probation with a native regiment their pay is at the rate of £540 a year. They then sign an agreement for two years, during which time they learn Arabic and the vernacular spoken by their command. The agreement on expiration may be extended by two years, later by three years, and again by three years up to 10 years, by which time the rank of kaimakam (colonel) will have been reached with salaries of £720 a year.

For men who can stand the strain of the climate, and who are willing to cut themselves off from home and friends, the Indian and Egyptian Armies offer exceptional chances both in the good rate of pay and the opportunities of civil and staff appointments to which they lead.

TECHNICAL DRAWING continued from page 4005

By JOSEPH W. HORNER

Design Drawings. We give in this lesson a series of drawings illustrating the art of machine design. Fig. 133 is a design drawing of a 1,200-horse power mill engine. It is a typical example of the class of drawing usually made to accompany a tender, for no attempt is made to show details or sectional views, the object aimed at being to produce an attractive-looking drawing made to scale, and from which the over-all dimensions may be taken. In actual practice such a drawing is set out by an experienced draughtsman; but the student has much to gain by copying it and studying the proportions and positions of the various parts, for it is from such design drawings that the working, or detail, drawings are deduced. Foremost will be noticed the rope wheel, with its 30 grooves for the driving ropes [see page 3428 for section of groove], and the opening cut in the ground for the reception of the wheel. It is necessary to provide a bearing for the shaft on the outside of the wheel in order to avoid the tremendous load which would otherwise come on the shaft, due to the over-hang of the wheel. There are three cylinders, A, B, and C, supported upon front and back columns from the bedplate; the front columns are circular, but the back ones are shaped to carry the crosshead guides, and are cast in hollow rectangular section. The upper ends of the columns have flanges cast on to meet the feet of the cylinders. The lower ends are splayed out in order to clear the connecting-rod heads, and have flanges to meet facings on the bedplate. The lever D is for working the air-pump E. It receives motion from one of the piston-rod crossheads, and is pivoted on a bracket bolted to one of the back columns. The air-pump itself is bolted to the bedplate, and also to the column. The air-pump is connected with the low-pressure cylinder C by the pipe F, and its function is to maintain a vacuum for that cylinder to exhaust into. A note on air-pump levers will be found on page 828 in Mechanical Engineering.

The outline of the cylinders themselves does not appear, as they are surrounded with lagging strips. *Lagging* consists of wrapping the cylinder with asbestos mattresses, or similar non-conducting material, in order to prevent loss of heat, the mattresses being kept in place by strips of wood and brass bands, or alternatively by thin sheets of steel. The valve-chests are similarly lagged. Relief valves, G, H, I, are shown on the cylinder covers, and also upon the high pressure and intermediate valve-chest covers J and K. The relative positions of the cranks are seen in the end elevation, and are projected in the side elevation. A bearing is arranged upon each side of each crank, and a solid forged coupling, L, connects the crank-shaft to the pulley-shaft. The working floor level is raised above the foundation line, so as to give easy access to the bearings and cranks. Two platforms are built around the engine at suitable levels to facilitate attention to the working parts, the upper platform serving for the cylinder and valve covers, etc., while the lower platform is for

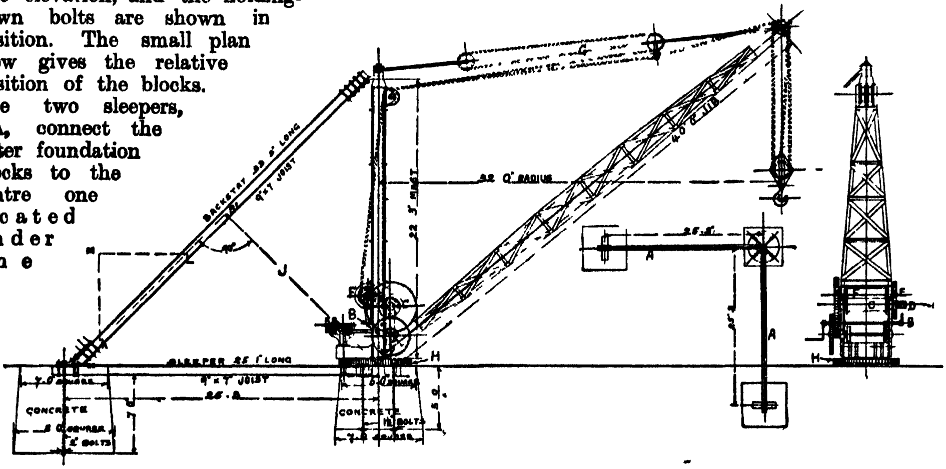
the glands and bottom covers. Ladders and handrails are provided as shown in drawing.

General Drawings. Another class of drawing is shown in **184**, which is very similar to the preceding example, but presents much more detail. It is a *general arrangement drawing*, made after the details have been worked out on separate sheets, and it serves as a guide for the complete assembly and erection of the machine. The foundation blocks are fully dimensioned in the side elevation, and the holding-down bolts are shown in position. The small plan view gives the relative position of the blocks. The two sleepers, AA, connect the outer foundation blocks to the centre one located under the crane-mast; such a foundation is substantial and permanent, but very frequently, however, this type of crane has only temporary foundations, such as timber seatings and weights simply laid across the ends of the sleepers. The mast is furnished with top and bottom pivot pins, and the back stays support the top pivot. The crane gearing is seen in position at the lower end of the mast; there is a train of spur gear from the handle shaft B, connecting to the barrel C, which coils the hoisting-chain. A clutch, D, and gears, E, couple the hoisting barrel C to the barrel F, upon which is coiled another chain, which varies the radius of the jib by altering the length of the ties G, this movement being termed *derricking*, or *luffing*, the jib. The revolving, or slewing gear is arranged behind the mast and consists of spur and bevel gear, connecting to the curb ring H, which is bolted to the bedplate underneath the mast.



184. GENERAL ARRANGEMENT OF 15-TON DERRICK CRANE

Detail Drawings. The drawings from which machines are actually manufactured are termed *detail drawings*, each part of the machine being fully delineated and dimensioned upon one or more sheets. Castings have a sheet to themselves, forgings have a separate sheet, plating another, and so forth, the object being to provide each work's department with drawings that concern the department alone. The principal detail drawing is the one which depicts the main framework of the machine. Framings are made of various metals and in various forms. Machine tools and engines are invariably built with cast-iron frames, although exceptions are to be found, the chief virtue in such frames being rigidity, a factor that cannot be calculated in anything like an exact manner. There is perhaps no other part that requires so much sound judgment and experience in order to produce satisfactory results. The earlier designers of engine frames, etc., aspired to architectural outlines and ornamentations; but increasing steam pressures, greater outputs, and closer economy, have resulted in the adoption of scientific lines of construction. Smooth outlines, easy curves, and even disposition of metal are now aimed at. The same may be said of machine tools generally. Other frames, such as cranes and overhead travellers, are built of mild steel; and, although experience is necessary in order

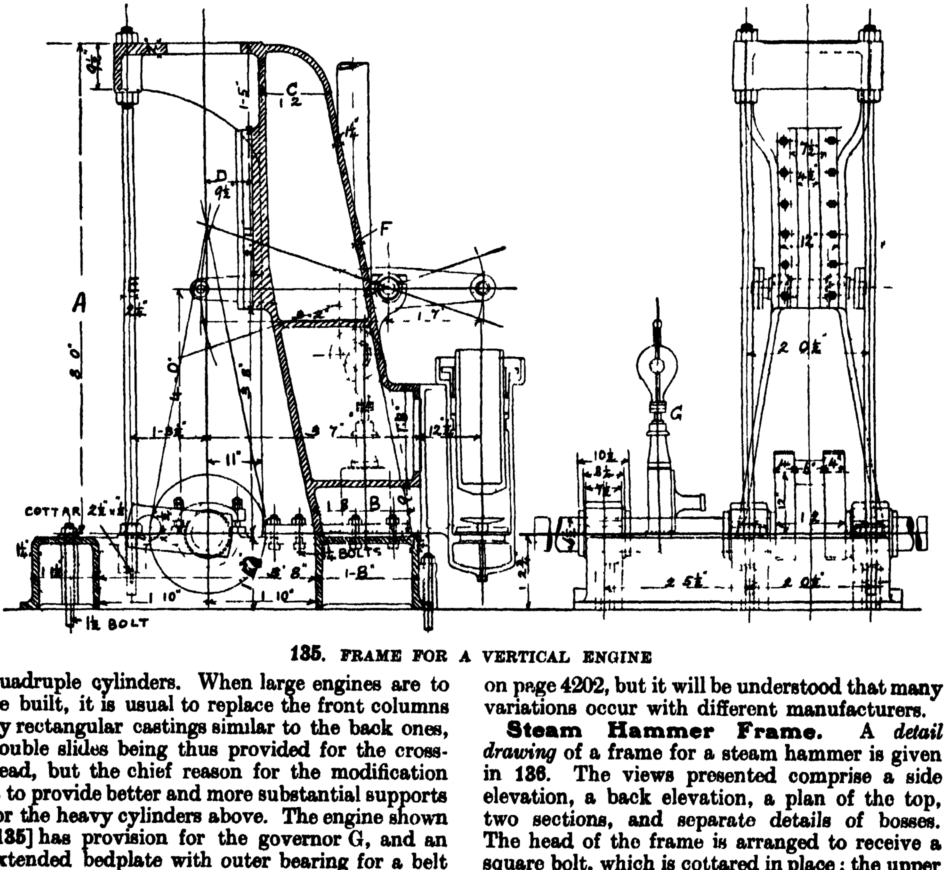
to design them, their proportions can be definitely calculated by estimating stresses, etc.

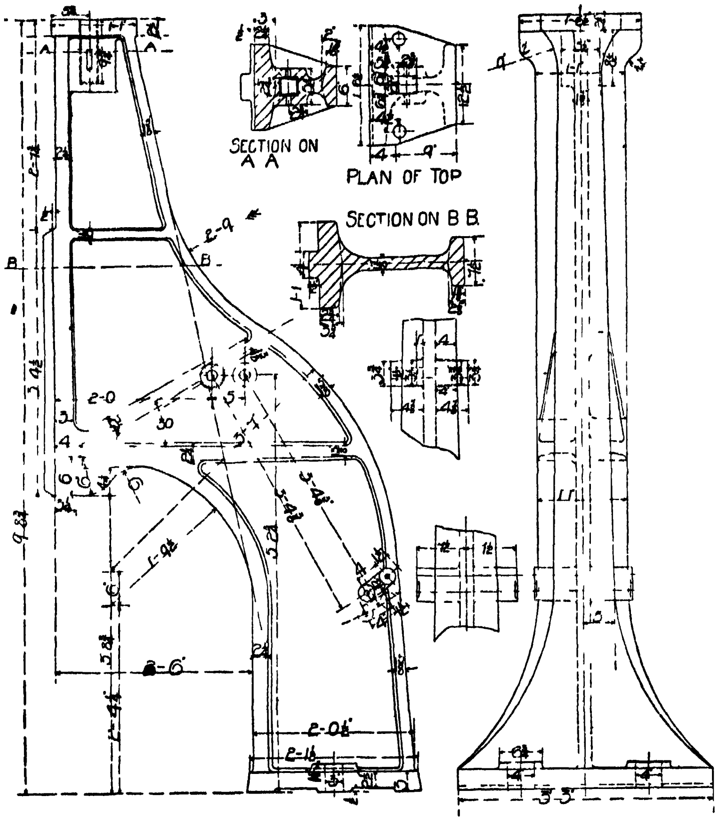


135. FRAME FOR A VERTICAL ENGINE

Vertical Engine Frame. Two views taken from a *detail drawing* of a vertical engine frame are given in **135**; the construction is similar to **133**, but is for a smaller engine. The front supporting columns are of mild steel, and are cottared into a boss cast on the bedplate. The back column is shown in section, as well as in face elevation, the bearings for the air-pump lever and the bracket for the air-pump itself being shown in position. A table is given on page 4202 of the approximate leading dimensions of this class of engine frame, which will be useful to the student. There are many variations in the outlines and sections of such frames; they are also made for single, doub'e, triple, and quadruple cylinders. When large engines are to be built, it is usual to replace the front columns by rectangular castings similar to the back ones, double slides being thus provided for the crosshead, but the chief reason for the modification is to provide better and more substantial supports for the heavy cylinders above. The engine shown [**135**] has provision for the governor G, and an extended bedplate with outer bearing for a belt drive; the cylinder is 16 in. in diameter by 24 in. stroke.

Horizontal Engine Frame. Fig. **133** illustrates a *detail drawing* of a pair of frames for a horizontal compound engine. Each frame consists of a single member, rectangular in section and of cast iron; the guides are formed in the same casting, and are cylindrical, having openings on each side. The left hand frame is for the high pressure cylinder, and the right hand for the low pressure, each cylinder being supported from foundations, as well as being held by the ends of the guides. The main bearings are formed in the frame in a similar manner as they are formed in the bedplate of the previous example. It is usual to detail the bearings separately. The piston-rod glands are arranged in the ends of the guides, but they are also frequently made part of the cylinder casting. Bosses are formed for the foundation bolts, and extend the full depth of the framework, wherever they occur; the centre bosses are provided with ribs connecting them to the side walls. Bolt bosses are also made on the end of the frames for coupling up to the cylinders. The guides have facings top and bottom, bored out for the crosshead to bear against. We give a table of approximate over-all dimensions for this class of frame on page 4202, but it will be understood that many variations occur with different manufacturers.

Steam Hammer Frame. A *detail drawing* of a frame for a steam hammer is given in **136**. The views presented comprise a side elevation, a back elevation, a plan of the top, two sections, and separate details of bosses. The head of the frame is arranged to receive a square bolt, which is cottared in place; the upper end of the bolt passes through the foot of the hammer cylinder, as well as the two outer bolts, and holds it down with a nut in the usual way; there are two such frames, one on each side of the hammer block. The section of the frame is different to the preceding engine frames, it being what is termed H section instead of a hollow rectangle; the inner flange throughout is heavier than the outer one, it being subjected to severe compressive shocks; three cross ribs are arranged to tie the flanges together, and to stiffen

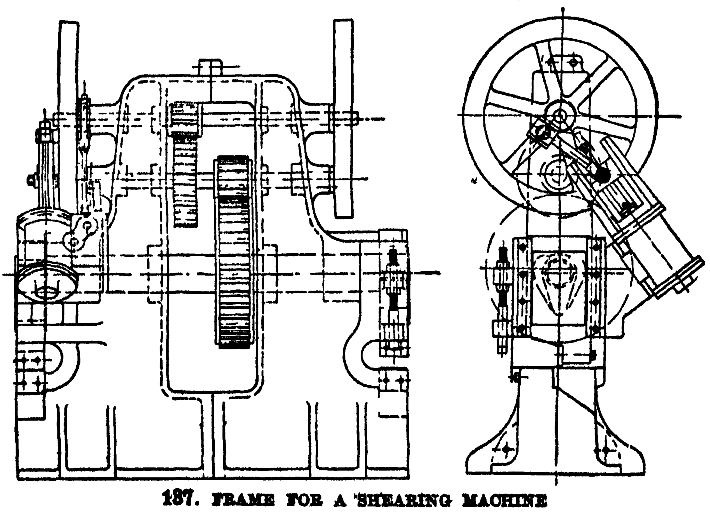


186. FRAME FOR A 25-CWT. STEAM HAMMER

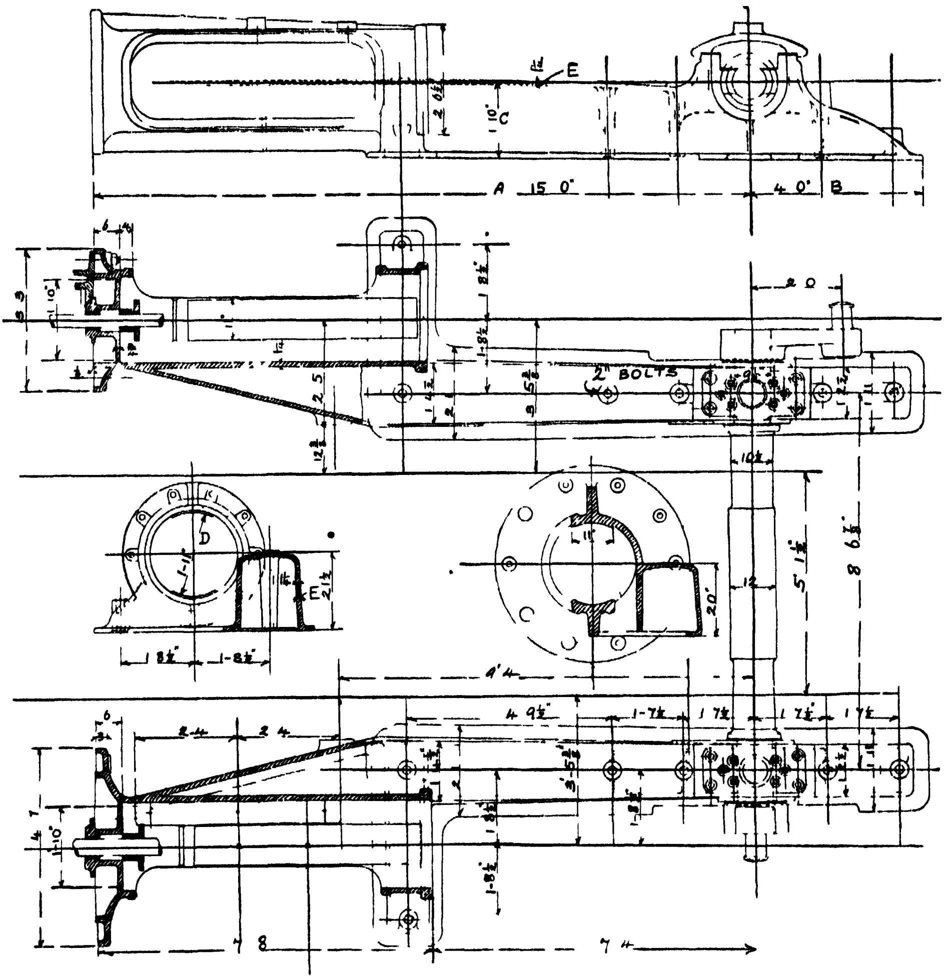
the web plate The taper allowed on the flanges is considerable, and large radii are put in the corners. This is done in order to ensure a sound casting, free from initial stress due to contraction, and also to enable the pattern to be drawn easily from the mould, and so produce a smooth outline. The front of the frame at the bottom of the hammer guides is specially heavy, to prevent fracture at this point. The bosses are for the pivot pins of the working levers. The base of the frame is provided with facing strips and bosses for the foundation bolts, and the holes are slotted so as to permit adjustment endwise. The slope of the upper part of the frame is obtained by prolonging the line, as shown [186], until it forms a tangent with the inside radius of the lower part. The drawing is reproduced from an actual working drawing supplied by Messrs. Thwaites Bros., of Bradford, Yorkshire.

Machine Tool Frames. Outlines of machine tool frames will be found on pages 206 and 207 in Mechanical Engineering, and further examples are given under Machine Tools. We amplify these by 137, which is a drawing of a bar shearing machine, driven by an engine carried upon the framework. The frame is in halves, bolted at top and bottom, and is in hollow form, with an opening at the centre for the gearing ; bosses are cast on the upper part to carry the engine shaft, which is shown in position with the two fly-wheels. There are two spur-gear reductions from the engine shaft to the eccentric shaft, which operates the moving cutter. The metal is massed around the jaw which receives the cutters, the top and bottom of the jaw having enormous strength to withstand the reaction of shearing without yielding. A bracket and facing are provided for the steam cylinder, which is 8 in. diameter by 12-in. stroke. The machine will shear up to 2-in. square bars on either side.

Mild Steel Frames. Mild steel frames are not used for machine tools proper on account of their elasticity and consequent



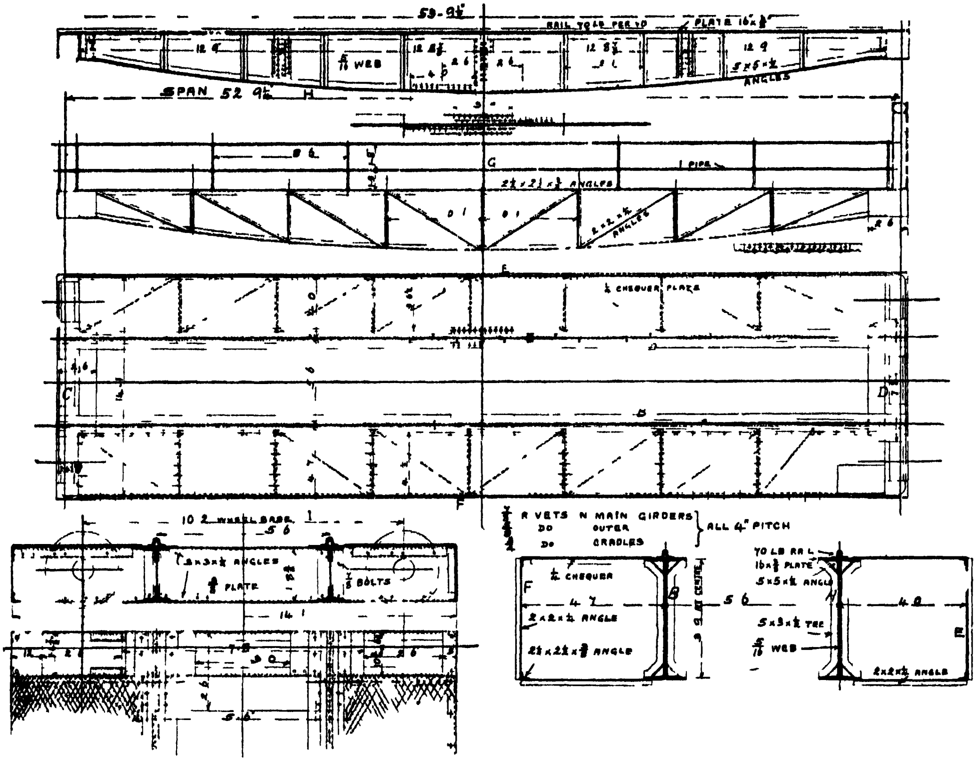
137. FRAME FOR A SHEARING MACHINE



138. FRAME FOR A HORIZONTAL ENGINE

lack of rigidity; they do, however, enter into the construction of many appliances used by engineers, and in such appliances have a far greater value than cast-iron frames. Locomotive frames, carriage frames, large crane frames, furnace charging machines, etc., are examples in which cast iron would be a failure. Fig. 139 illustrates the steel frame of an overhead traveller as used in most engineers' shops. It consists of a pair of girders, A and B, secured to two cradles, C and D, which are mounted upon double-flanged wheels. These wheels are set to run upon rails which are built on the side walls or columns of the shop. The girders A and B are provided with rails which form the track for a trolley or crab, which is fitted with hoisting mechanism and necessary tackle. The machine is driven electrically, a separate motor being applied to each movement. The example [139] is for a high-speed electric traveller, and it is therefore specially braced to meet the stresses due to inertia in starting and stopping. The auxiliary girders E and F are stayed to the main girders A and B by bracing bars on the lower boom in such a way as to afford them lateral support; the upper booms have chequer plates connecting them instead of bracing bars, and these incidentally form a platform for the attendant, and are protected by handrailing as shown at G. The distance from centre to centre of the main rails H is termed the span, and the distance apart centre to centre of the wheels I is the wheel base and is usually one-fifth of the span. The depth of the main girders at the centre of the span is generally one-fifteenth of the span.

The upper elevation shows the main girder with its joints. The web plate is made in four lengths for convenience, while the boom plates and angles are made in two lengths; the central joint is shown in plan. The next elevation is of the outer girder with the handrailing on top, the form of the bracing being known as the Linville and being economical of material.



189. FRAME FOR A 35-TON ELECTRIC TRAVELLER

The general plan view shows all the girders in position as well as the cradles and platform. The two bottom left-hand enlarged views are details of the cradles, while the right-hand bottom view is an enlarged section cut through the four girders at the centre.

Calculations. The main sections of the various members of such frames as 184 and 189 can be decided by calculations. In 184 the load on the jib and tie may be determined as described on page 415 of Mechanical Engineering. The tie-rods and chains are tension members, and can have sufficient area allowed to permit a factor of safety of 8 to 1; the jib is a column and should have a factor of safety of 6 to 1. The load on the backstay is found by taking moments about I; the forward moment is made up of the load multiplied by the full radius plus the weight of the jib multiplied by half the radius; adding these two moments together and dividing by distance J, we get the load on the backstay (B1). The backstay may be either in compression or tension, according to the position of the jib in plan; as it is weakest in compression it may be proportioned as a column with a factor of safety of 6 to 1. The load on the sleeper and the mast is easily obtained by a simple diagram. Mark off the load on the backstay as K L on a scale of tons, and draw a vertical line from K till it cuts a horizontal line from L, meeting at M, then K M scales the load on the mast and L M scales the load on the sleeper. Both mast and sleeper have alternatively tensile and compressive loads in a similar manner to the backstay, and they are proportioned for compression; the mast has to sustain in addition the load due to the hoisting and derricking chains, which also impose compressive loads.

Traveller Frame. In 189 we have the simple case of loaded beams or girders fully dealt with on page 540 in Mechanical Engineering and page 1984 in Materials and Structures. The load on the main girders is made up from the actual load lifted by the traveller plus the weight of the movable crab and half the weight of the girders themselves. The cradles may be regarded as beams of a length equal to the wheel base, and loaded at the two points at which the main girders are built in; each cradle has to sustain half the weight of the whole framework plus nearly the whole weight of the crab and load; the exact amount of this latter sum depends upon the nearness of the extreme position of the crab to the cradle. The outer girders have to sustain their own weight and half the weight of the platform, etc. When long spans are involved, the main girders as well as the outer girders are often designed as Warren or Linville braced members.

Definitions. 1. A limited portion of space is called a *solid.* A solid has three *dimensions*—*viz.*, length, breadth and thickness.

The amount of space occupied by a solid is called its *volume.*

2. The *surface* of a body separates it from the surrounding space. A surface has no thickness. It is therefore of two dimensions, length and breadth.

3. The intersections of surfaces are called *lines.* Since surfaces have no thickness, it is evident that their intersections can have neither breadth nor thickness. Hence a line has only one dimension, length.

4. The extremities of a line are *points.* Also, the intersections of lines are points. Points have neither length, breadth nor thickness. Thus, points have no dimensions.

It follows, then, that we can only *represent* a point. If we make a dot with a pencil, the dot will have *some* length and breadth, however sharp the pencil may be. In the same way, we cannot draw a geometrical line, but if we move the pencil point over the paper, the mark left will *represent* a line.

5. Lines may be *straight* or *curved.*

A *straight* line is traced by a point which moves so as to keep always the *same direction.*

A *curved* line is traced by a point whose direction of motion continually changes.

From the definition of a straight line we have the following *Axioms*, or self-evident truths:

(i.) *The shortest distance between two points is the straight line which joins them.*

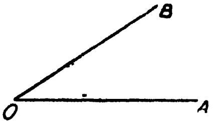
(ii.) *Two straight lines cannot enclose a space.*

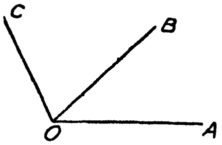
6. Surfaces may be *plane* or *curved.*

A *plane surface*, or, as it is generally called, a *plane*, is a *flat* surface. The flatness is tested by taking any two points in the surface and joining them by a straight line. If the surface is flat, the straight line will lie on the surface. Notice that we must be able to take *any* two points; it must not be possible to find two points on the surface such that the straight line between them does *not* lie on the surface.

7. When two straight lines meet at a point they are said to form an *angle.* The point is called the *vertex* of the angle, and the straight lines are called the *arms.*

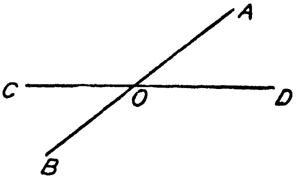
The *magnitude* of an angle may be measured thus. Suppose a straight line rotates, in a plane, about the point O. Let it start from the position OA and rotate into the position OB. Then, the *amount of turning* which the line does in moving from the position OA to the position OB measures the angle. The angle is called the angle AOB, the letter at the vertex being placed between the letters at the other end of the arms. Notice that the *size* of the angle does not depend on the lengths of the arms; the size of the angle AOB remains the same when OA and OB are lengthened.



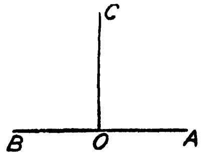


Two angles which lie one on each side of a common arm are called *adjacent* angles. Thus, the angles AOB and BOC, which lie on either side of the arm OB, are adjacent angles.

When two straight lines cross one another, such as AB and CD in the figure, the angles AOD and BOC are called *vertically opposite angles.* So, also, AOC and BOD are vertically opposite angles.



8. If one straight line stands on another straight line and makes the adjacent angles equal, each of the angles is called a *right angle.* Each line is said to be a *perpendicular* to the other. Thus, if OC stands on AB and makes the angle AOC equal to the angle BOC, each of these angles is a right angle.



It is clear that, if a straight line revolves about the point O, starting from the position OA and finishing in the position OB, it must pass through a position in which it is at right angles to AB. Hence, we have the axiom

Through a point in a straight line one, and only one, perpendicular can be drawn to the straight line.

At this stage we do not know how to find the exact position of the perpendicular; we can only estimate it roughly. But in the meantime, if it is required in the course of any other investigation, we are quite justified in saying, "*Let* OC be the straight line which is perpendicular to AB," since we know that there *is* a line which is perpendicular.

Another axiom following from the definition is *All right angles are equal.*

Note. A right angle is divided into 90 equal parts called *degrees ;* a degree into 60 equal parts called *minutes ;* a minute into 60 equal parts called *seconds.*

9. An angle less than a right angle is called an *acute* angle.

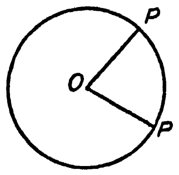
An angle greater than a right angle but less than two right angles is called an *obtuse* angle.

Two angles whose sum is *one* right angle are called *complementary angles,* and each is the *complement* of the other. Two angles whose sum is *two* right angles are called *supplementary angles,* and each is the *supplement* of the other.

10. A *plane figure* is any portion of a plane surface bounded by one or more lines.

11. A *circle* is a plane figure contained by a line traced out by a point which moves so that its distance from a given fixed point is always the same.

For example, if P moves so that its distance from O is always the same, then the line traced by P encloses a circle.



The line itself is called the *circumference* of the circle.

The fixed point is called the *centre* of the circle.

A straight line drawn from the centre to the circumference is called a *radius.* Hence, all radii of the same circle are equal.

A straight line drawn through the centre and terminated both ways by the circumference is called a *diameter.*

An *arc* of a circle is any portion of the circumference.

A *semicircle* is the figure bounded by a diameter and the portion of the circumference which it cuts off.

12. To *bisect* a thing is to divide it into two equal parts. It is clear that

(i.) Every terminated line has a point of bisection. For, if a point be supposed to move from one end of the line to the other, it must at some instant be exactly half-way.

(ii.) Every angle has a line of bisection. For, in the angle AOB, if a straight line start from the position OA and revolve about O into the position OB, it must pass through a position in which it divides AOB into two equal parts.

The Postulates. It is taken for granted that the three problems stated in the following postulates, or demands, are possible with the help of a straight ruler and a pair of compasses.

1. *A straight line may be drawn from any one point to any other point.*

2. *A terminated straight line may be produced, i.e., made longer.*

3. *A circle may be described with any centre and any radius.* This enables us to transfer distances from one part of a diagram to another; so that, from the greater of two straight lines we can, with the aid of compasses, cut off a part equal to the less.

Problems and Theorems. The propositions discussed in geometry are of two kinds, *Problems* and *Theorems.*

A *problem* requires something to be constructed, such as the drawing of a line which will bisect a given angle.

A *theorem* requires the proof of the truth of some geometrical statement.

The general statement of what the proposition requires us to do is called the *Enunciation.*

The *particular enunciation* is the same statement referred to a diagram.

In the enunciation the *Hypothesis* is that which is assumed to be true; the *Conclusion* is that which has to be proved.

If we have two propositions in which the hypothesis and conclusion of the one form the conclusion and hypothesis respectively of the other, the one proposition is called the *Converse* of the other.

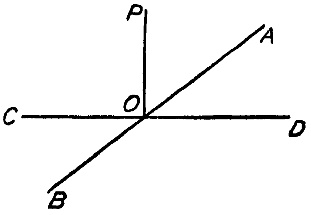
For example. "If two sides of a triangle are equal, the angles opposite to them are equal." The hypothesis here assumes that two sides of a triangle are equal; the conclusion is that the angles opposite to them are equal. Hence, the converse of the proposition is "If two angles of a triangle are equal, the sides opposite to them are equal."

A *Corollary* to a proposition is a statement whose truth follows readily from the result established in the proposition and generally requires no further proof.

Proposition 1. Theorem

If two straight lines cut one another, the sum of the angles on the same side of either line is equal to two right angles.

Let AB and CD be two straight lines which intersect at O.



It is required to prove that

$$\angle DOA + \angle COA = 2 \text{ right } \angle\text{s.}$$

Proof. If $\angle DOA = \angle COA$ then each is a right angle (Def. 8); so that their sum is two right angles. But, if $\angle DOA$ is not equal to $\angle COA$, let OP be the straight line through O which is $\perp$ to CD. Then

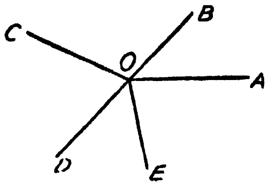
$\angle DOA + \angle COA =$ the 3 $\angle$s DOA, AOP, POC

and

$\angle DOP + \angle COP =$ the same 3 $\angle$s.

$\therefore \angle DOA + \angle COA = \angle DOP + \angle COP = 2$ right $\angle$s.

In the same way it can be shown that any other pair of angles on the same side of either of the lines AB, CD, are equal to two right angles.



Corollary. If any number of straight lines meet at a point, the sum of the consecutive angles is equal to four right angles.

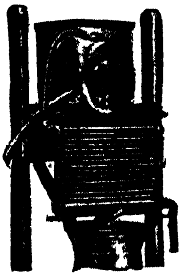
DAIRY FARMING
continued from page 4088

By Professor JAMES LONG

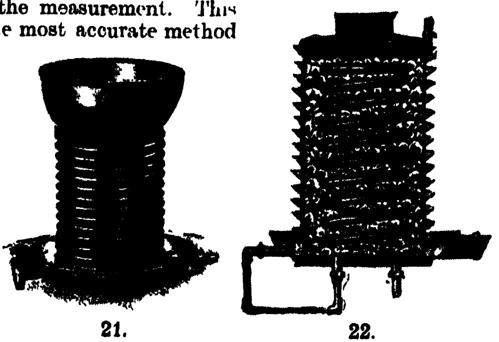
THE SALE OF MILK

From Farmer to Retailer. The bulk of the milk supplied to our large population is produced by farmers who contract to supply wholesale and retail buyers under conditions which are rearranged every half year. There are, however, in or near all towns cowkeepers who retail the milk they produce. The usual prices paid to the farmer are from 13d to 17d. per barn gallon from March to October, and from 1s. 6d. to 1s. 9d. from October to March; a barn gallon consists of 17 pints, or two imperial gallons and a pint, which, originally thrown in to make up for waste or loss in vending, is now adhered to by the trade, although this particular measure, the "barn," is not a legal one The farmer is required to deliver his milk twice daily, well cooled, aerated, and sweet, containing at least 3 per cent. of fat — the Government standard — or slightly more in some cases, where firms require high quality. The milk is sent by rail, carriage paid, in metal railway churns, which usually hold 17 gals. imperial. In some parts of England, especially in the North, however, smaller churns or cans are employed for the purpose. The cost of the transit varies with the distance from ½d. to 1½d. per imperial gallon, while the prices realised are higher in the South than in the Midlands. The churns are gauged, and in course of time the constant bruising interferes slightly with the measurement. This principle is wrong, for the most accurate method of buying or selling milk is by weight, although this is difficult in practice.



20. HORIZONTAL COOLER
(Showing the new rotary self-cleaning strainer above Invented by the Dairy Supply Co)

Keeping Milk Cool. The cooling of milk is imperative, for unless reduced to a temperature of about 50° F. in hot weather it will scarcely keep half a day, or sufficiently long to arrive sweet upon the breakfast or tea table. The system of cooling adopted also provides for the aeration of the milk. There are two forms of cooler—one, which is horizontal [20], consisting of a number of tubes which cold water enters at the bottom and passes out at the top, while the milk runs from a receptacle above over the outside of the tubes, and passes into the churn as it leaves the bottom of the cooler. It will thus be observed that when the milk is coldest it leaves the refrigerator at its coldest point, and thus with sufficiently cold water it may be reduced from a temperature of 90° F. to 50° F. in less than a minute. There is, however, a lenticular cooler [21 & 22], in which the principle adopted is similar, although ice may be packed within the interior in those made for this particular purpose. In both cases the milk passes over the cooler in the form of a thin film, and is therefore well exposed to the air, and its temperature more easily reduced. If cool milk be retailed in vessels which are covered with a white cloth, it should keep sweet during the hottest weather; but on many farms it is impossible to obtain water of sufficiently low temperature, with the result that whole churns of milk occasionally arrive at their destination in an imperfect condition, being for this reason generally returned by the purchaser. Such milk, however, is not valueless; it may still be churned for the production of butter, although the pecuniary result will not be so satisfactory.



21. 22.
LISTER'S LENTICULAR COOLER
In 22 the cooler is packed with ice

Precautions against Contamination. Milk vendors and dealers in general naturally object to the mixing of the milk of two milkings—the morning's with the evening's—which many farmers practise during cold weather in order to avoid two journeys to the railway station; nevertheless, there are many cases in which this practice is permitted. Still stronger objections are made against the milking of cows by persons who are suffering from any disease or who are members of a household in which any infectious or contagious disease exists. For this reason some farmers retain the services both of a veterinary surgeon and medical officer, who from time to time visit the farms, inspect the cattle, and interview the farmer himself. Some of the larger firms of milk vendors refuse to allow members of their staff to enter their premises, or to retail milk under similar conditions, their practice being to pay them their wages until a clean bill of health can be shown. The reader is referred to the article on the Trade of the Dairyman, on page 2215, in which the question of milk contracts and cognate subjects are more fully treated.

It is obvious that where milk is delivered, as it is by almost every firm in the country, twice daily, the labour involved is considerable, and it is chiefly for this reason that there is so large a difference between the price paid to the farmer and that obtained from the consumer, 4d. a quart being the average figure demanded in this country.

Bad Milk. From the retail dealer's point of view it is important that milk should be produced by cows which are not fed upon improper foods, such as strong-smelling ensilage, half-rotted brewers' grain, turnips, and swedes, which, given in large quantities, convey an ill flavour to the milk, and certain other foods known as distillers' sludge, or even large rations of cabbage. There is, however, a good deal of imperfect, and even impure milk retailed in large cities at 3d. a quart; but whatever may be the desire of the consumer for cheap food this milk should be strictly avoided, for it is impossible, whatever it may have been like as it left the farm, that it could have been handled properly by the retailer.

23. MILK OR CREAM CAN

During very hot and dry weather, milk frequently reaches famine price, and retailers are sometimes compelled to pay as much as 1s. 4d. per imperial gallon in order to satisfy their customers. Milk sold to hospitals and other charitable institutions is naturally sold at lower prices than where it is retailed in large quantities to the public. The wholesale vendor is required to take very little more trouble in the conveyance of 50 or 100 gallons per day than in delivering a few quarts to a number of different houses, but this contract milk is frequently poor in quality, and sometimes impure, although of all places the hospital and the children's home are those where the quality demanded should be of the highest.

Milk Delivery. If milk be *pasteurised* —and the remark equally applies to cream—and suddenly cooled, it will keep longer than when it is simply cooled. In all cases, however, it is the wisest and most business-like plan to deliver milk immediately after it has arrived from the station—servants and customers being advised wherever possible to take care that the vessels in which they receive it are perfectly clean and that it is always kept in the coolest dry apartment in the home. In Paris and many foreign cities milk is delivered daily in bottles which are sealed, and in this way its quality is secured; this plan has been already adopted in this country, and will probably extend far and wide. Similarly, milk which has been sterilised, in hermetically-sealed bottles, is delivered, but only once per week or fortnight, sterilisation ensuring its keeping properties during any reasonable period, and in this way a great deal of labour is saved on the part of the retailer. Milk, however, should never be placed in bottles which have not been cleaned; nothing but actual scalding either with steam or boiling water is efficacious.

In many cases retailing firms send out their milk in locked metal churns, the man in charge drawing it from the tap as his customers require it; but, making every allowance for the shaking which the milk undergoes, the quality at the bottom of the churn is always lower than that at the top, owing to the fact that the cream ascends; the ascent of cream, however, is very slow and slight in milk which is cold. In spite of all precautions, milk carriers occasionally manage to introduce water into the milk they deliver; for this reason inspectors are sometimes employed by large firms to look after them. Such firms take samples of the milk they send out by their servants and are, therefore, able to check them in case a sample was watered before it reaches a customer.

BUTTERMAKING.

Butter made directly from milk, or from cream removed from milk, contains about 86 per cent. of fat, 12½ per cent. of water, and 1½ per cent. of casein, sugar and salt. The more heavily salted the butter, however, the larger the last percentage. The finest butter may contain less than 12 per cent. of water, while in imperfect samples the water present may reach 20 per cent. or even more. In commerce a material is frequently sold which is known as "milk-blended butter;" this sometimes contains as much as 30 per cent. of water which has been worked into it through the medium of milk. Imported butter is usually employed.

The Best Butter. The finest butter is the produce of Channel Islands' cattle—Guernseys and Jerseys—or of herds of which these animals chiefly form part; they add both richness of flavour and colour. Fine butter should be tough, dry, a rich primrose in colour, with a fine, mild, sweet, nutty flavour and a delicate aroma. If a roll be taken in the hands and gently bent it should break gradually and exhibit a grain resembling that of a piece of broken cast steel. If the grain exhibit numbers of drops of water the fact is indicated that it usually contains too much water—although butter may look dry and still contain a high percentage of moisture, for, as shown by Storch, the Danish chemist, a cubic millimetre of butter which has been well worked may contain from 3,000,000 to 4,000,000 globules of water. Heavily-watered butter is soft or brittle, while pickled butter, common to Ireland, perhaps the most inferior product in the British Islands, is not only heavily salted but heavily watered—the result of the process adopted.

Although butter is washed while in grain in the churn, washing should not be overdone, for while it removes the impurities such as curd and sugar, which, if allowed to remain, cause rapid deterioration in quality, flavour and aroma, it is possible to reduce both flavour and colour.

Colour and Flavour. The colour of butter is chiefly due to the breed of cattle employed, but partly to the food supplied, to sunlight—hence, the paleness of the butter produced in winter—and to excessive washing. The flavour of butter also depends in a large measure upon the breed of cows, upon the food supplied to them, and to the condition of the cream at the time that it is churned. The finest mild butter is the product of sweet cream, and this realises the highest prices in the French market, where we have known it to reach 2s. 8d. a pound. The fullest flavour is obtained when ripened or soured cream is employed, but flavour should not be masked by the employment of too much salt. In the production of a fine mild sample less than a quarter of an ounce to the pound should be used. Storch believes that the flavour of butter is largely derived from the solid materials in the serum of milk and not from the fat; but there is reason to suppose that it is, in part at least, owing to the presence of the volatile fatty acids. Food, however, necessarily affects flavour; hence the change which occurs when turnips, swedes, sour grains and strong smelling herbs are consumed. All difficulties on this score, however, are obviated where cows feed upon fine pastures in summer or are supplied with the best sweet hay, bran, crushed oats, parsnips, and carrots in winter. The fine flavour of butter is not developed until 24 to 48 hours after its manufacture; hence, the mistake often made of judging butter fresh from the churn. At the National Dairy Show, where prizes are sometimes awarded for the best samples on the last day of the Exhibition, while some prize samples are found to have lost both flavour and aroma, others become more perfect.

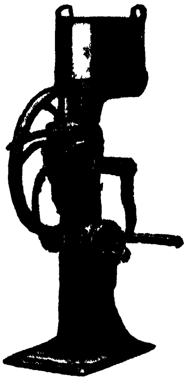
The Aroma. The aroma of butter is due to similar causes to those which affect the flavour. When exposed to air and light the aroma, like the flavour of the outside, changes rapidly, the more so where it is placed in contact with any strong smelling material. The aroma of the interior of a sample is as indicative of quality and even of age as the flavour, but both are affected by heat, which induces decomposition and the development of rancidity. According to Duclaux, than whom no one was more competent to speak, the aroma of butter possibly proceeds from the result of fermentation in the cream; perhaps, indeed, to ethers, the products of caproic or butyric acid, which are found in all samples of butter in a free state.

Amount of Butter to be Made from Milk. The quantity of butter obtainable from a given quantity of milk may be estimated with much accuracy if the quality of the milk be known. Thus, if we take a sample of milk containing 4 per cent. of fat, which represents milk of high quality, and suppose that a sample of butter contains 14 per cent. of water, we shall find that the milk should produce 4·4 lb., assuming that the separator be employed for the extraction of the cream. The process of skimming would be followed by a loss of ·15 per cent. of fat, and the process of churning by ·05 per cent., or ·20 per cent. in all, leaving 3·8 per cent. of fat with which to deal. If we add to this the water, apart from impurities which ought not to be present—and this we can do by dividing 3·8 by ·86—we get 4·41 lb. of butter to the 100 lb. of milk; that is if the work be performed skilfully throughout.

How Butter is Made. The systems under which butter is now made are as follows:

1. From soured or ripened milk churned at 66° F. This practice, still existing in both Scotland and Ireland, especially where buttermilk is readily saleable, is usually followed by the production of a large yield of butter of fair quality.
2. From cream skimmed from milk set in shallow vessels or pans.
3. From scalded cream. In this case the milk is set in similar but slightly deeper vessels. This practice is common in the three western counties—Somerset, Devon, and Cornwall—the *scalded milk*, as it is termed, being easily saleable.
4. From cream skimmed by the mechanical separator.

In every case in which butter is made from cream it may be the product of sweet cream or matured cream, the latter being sometimes described as ripened or soured, either naturally or artificially. The employment of soured cream necessitates either accurate skill and judgment on the part of the maker, who must determine how far acidity should go by experience and taste, or the aid of a chemical test by which the quantity of acid present is indicated. This quantity may vary in accordance with the character of the butter produced or with the milk employed. Sweet cream produces a smaller quantity of butter than ripened cream, with the result that the buttermilk contains more fat. The butter, however, is milder and sometimes realises a higher price. Most of the butter in the British market is the product of ripened cream, whether it be home produced or imported from foreign countries or our Colonies. The flavour of such butter is fuller, and it is generally believed to keep longer.



24. LAVAL CREAM SEPARATOR

A Model Dairy. In a well-managed dairy, the head of which is highly skilled, the butter produced is practically always the same in character. The dairy and all its utensils and plant should be thoroughly cleansed with boiling water throughout. If the milk, the produce of cows properly fed, be then drawn into clean vessels by clean hands, and the cream removed in perfect condition, the result should be satisfactory; but satisfaction may be practically ensured by the addition to the cream of a small quantity of fresh buttermilk obtained from an adjacent dairy where butter of the finest quality is produced. In this way it is inoculated with friendly bacteria. Thus in most factories and creameries where milk or cream are obtained from large numbers of farmers, the cream is pasteurised with the object of destroying all bacteria, and subsequently inoculated with what is termed a "pure culture" of bacteria, which are responsible for the production of fine flavour.

Pans versus Separators. In the past, and especially before the introduction of the separator, the system of cold setting of milk was common, especially in the three Scandinavian countries, and in parts of Germany and America. The two systems employed were known as the *Swartz* and the *Cooley* systems. The warm milk was plunged in deep pans in very cold or iced water, with the result that the cream was thin and large in volume, while, being but little in contact with the air, it was not sufficiently oxidised. The system of *shallow* setting in pans already referred to possesses the distinct advantage that the cream is practically all brought into contact with the air, with the result that oxidation is perfect, and the flavour much finer. Cream is also raised in jacketed shallow pans of rectangular form. The jackets are filled as occasion demands with either hot or cold water, and when the cream has risen the skimmed milk is withdrawn from beneath it. All systems of the past are, however, giving way before the separator, and yet no finer butter or cream can be produced than by the simple method of shallow setting.

Points for Buttermakers. There are certain principles involved in butter production which may be formulated as follows:

(1) Cream is extracted from milk by the separator by centrifugal force. The effect of this force is to throw the heavier portions of the milk to the wall or periphery of the cylinder or drum, and thus to keep the lighter fat globules in the centre.

(2) Cream is extracted by shallow setting for the reason that, as already mentioned, being lighter than the serum, it rises to the surface.

(3) Cream rises best in a falling temperature, the larger globules rising first. As the temperature falls, the fat, being a non-conductor, does not feel the change to the same extent as the serum, with the result that the difference in the density of the two materials is widened, and it rises all the quicker in consequence.

(4) If milk be cooled before setting, the cream rises imperfectly.

(5) Cream should be aerated that it may part with any objectionable odour or flavour, and be the better oxidised. The higher the temperature at which milk is set after coming from the cow at, say, 95° F., and the lower the temperature of the apartment in which it stands for the cream to rise, placing 40° F. as a minimum, the better the cream rises.

(6) If milk be re-heated before setting for cream there is a loss involved.

For the purposes of raising cream on the shallow system, the vessels employed are usually of metal, glass, porcelain, or earthenware. They are round, and vary from 18 in. to 24 in. in diameter. Where the cream is scalded, however, they are slightly deeper than under other conditions, and furnished with handles on either side to facilitate manipulation to and from the stove. In no case should the dairy in which cream is set in these vessels be higher than 60° F., or the cream rises less perfectly, while acidity is induced by the heat before the fat globules have had time to reach the surface. Where the system of scalding is practised, a pan of milk having been set in the dairy for twelve hours, or longer, if in the judgment of the dairymaid, the cream has not all risen, it is placed upon the stove—preferably into a vessel of water that it may not burn—until the cream be covered with a film, and has reached a temperature of 175° F. If by accident the milk be allowed to boil, a small quantity of cold water should be immediately added, but this will not altogether remedy the mistake. This heating process is practically pasteurisation, with the result that bacteria are killed, and both cream and butter keep sweet longer.

The Separator. The important modern machine known as the *cream separator* is now made in many forms [24], but in all cases the same principle is adopted. The milk passes into a receptacle, usually a bowl or cylinder, the heavier solids it contains being repelled from the centre, around which the lighter portions—the fat globules which form the chief portion of the cream—gather. As the inflow continues, the pressure it exerts is followed by a corresponding outflow, the cream finding its way through one orifice and the separated milk through another, both being conveniently placed for the purpose. All the best machines are now provided with discs of different forms, which divide the milk into layers, and thus facilitate its separation, with the result that much larger quantities are handled than was possible formerly. The thickness of the cream is regulated not only by the size of the orifice, but by heat, the temperature of the milk being now controlled to a great nicety in all large butter-making establishments, with the result that much better work is performed; but the separation of the cream from the milk is only perfect—which means that not more than ·15 per cent. of the fat is left behind—when the conditions are perfect. The speed—that is, the number of revolutions—must be correct, while the temperature of the milk and its inflow must be carefully regulated. Whatever instructions may be provided by the makers of a separator, the skilful operator will ascertain for himself how many revolutions per minute, what temperature, and what inflow will enable him to obtain the best results. The separated milk, as it leaves the machine, is sometimes cooled rapidly that it may be kept for sale or for return to the farms; or, if not heated to a high temperature before separation, it may be first pasteurised and subsequently cooled, plant being now obtainable for that purpose. Sour or imperfect milk cannot be separated with good results. The scum adhering to the sides of the separator should be removed by thorough cleansing after each day's operation. Since the first public trials in Denmark and Hamburg, in 1883, and subsequently in Paris, separation by centrifugal machines has been improving until the work of to-day is as nearly perfect as possible; yet we look forward with confidence to something still greater—the production of the butter direct from the cow. This will involve the invention of a more perfect milking machine from which the uncontaminated milk will pass into the separator, and from the separator into an instantaneous buttermaker—a machine which, if still imperfect, has already been invented.

Strainers. All cream should be strained before churning. Many forms of strainer have been invented, but none are really perfect, with the result that cloths are still employed. A hair strainer, however, may be used for straining the butter, the buttermilk, and the water or brine as each leaves the churn. For butter production in a private dairy, the cream, as it is skimmed, should be mixed and stirred after each skimming, a glazed earthenware vessel being kept for the purpose; but churning should never begin until twelve hours have elapsed since the last cream was added; nor, if the best product is to be obtained, should any cream be more than twenty-four hours old if it has been kept, as it should be, in a dry apartment at 60° F. At this temperature, cream skimmed from a shallow vessel while perfectly sweet should be quite mature or ripe in 24 hours. Where cream is churned under these conditions it produces butter of finer flavour, chiefly owing to its more perfect oxidation, than anything which is produced in the creamery or factory—or, indeed, wherever the practice of inoculation be carried out. If cream, when ready for churning, be too small in volume for the churn employed, that volume may be increased by the addition of a portion of the skimmed milk from which subsequent cream has been removed, conditionally upon its being clean and pure; but this method is not applicable to the factory. Ripe or mature cream is thick, owing to the production of lactic acid, and the resulting coagulation of the casein. Such cream produces from 15 per cent. to 25 per cent. more butter than perfectly sweet cream which has been raised, for example, in twelve hours at a temperature of 60° F. If sweet cream be mixed with ripe cream, there is a corresponding loss; in other words, the loss will be in proportion to the quantity of sweet cream employed. In no case should cream—or, indeed, milk—be set in a badly-ventilated, dark, or damp apartment; it is practically certain to be spoiled in flavour and to produce ill-flavoured butter, owing to the fact that it is attacked by organisms which are peculiar to such apartments, but which are seldom if ever found in sunlight.

Regulating the Temperature. When cream is ready for churning it should be brought to the required temperature, otherwise there may be loss both of quantity and quality; in summer, 55° F. to 56° F. will be found the most convenient, while in winter the temperature may be raised to 64° F. It depends, however, upon the temperature of the apartment in which the work takes place. In winter the churn should be scalded, and thus prepared, so that after the cream has been placed within it its temperature may not fall. Similarly, in summer, the churn may be cooled after scalding, to prevent a rise in the temperature of the cream. The object should be to obtain small, well-formed, crisp granules of butter which are easily washed and brined. If the granules be too large or too soft, washing is necessarily imperfect—the large granules enclosing buttermilk, which cannot be removed, while those which are soft resist the action of water. In a private dairy, where churning is not practised at least every other day, it is difficult to obtain butter of the finest quality; therefore, whatever care be exercised in feeding the cattle, in milking cows, in setting and skimming the cream, we must look for imperfect results if that cream be kept too long. It is indispensable that a tested thermometer should be used in every operation; it will indicate the suitability or not of the temperature of the dairy, of the cream, and of the water employed in washing the butter. It is still more necessary where milk or cream is pasteurised.

Avoidance of Sudden Changes. In order to obtain the required temperature of the cream before churning, usually it is necessary to heat it in winter or to cool it in summer; either process must be gradual, sudden heating or cooling, or heating or cooling too many degrees at one time, being fatal to success, and here the ingenuity of the maker will be tested. Neither hot nor very cold water, nor ice, should be added to cream on any consideration; nor should it be heated or cooled more than three or four degrees at one time, and this only by the addition of pure water, or by standing the cream vessel in hot or cold water, and keeping it gently stirred. In factory and creamery work the temperature is regulated by heating the apartment in which the cream is placed, and by arrangements so carefully made that it is churned immediately it is fit for the purpose. In buttermaking the operator should on all occasions note the aroma and flavour of cream before churning, and compare the subsequent aroma and flavour of the butter produced from it. In this way he will be able to indicate with great accuracy precisely when cream is ready to churn. If cream has been pasteurised on milk in an open vessel, or clotted, as in the Western Counties, it may be churned at a temperature of 58° F., although it is quite a common practice among many makers to stir clotted cream into butter, and subsequently to work the butter with the naked hand—both of which methods are carefully to be avoided.

IRREGULAR VERBS

Second Conjugation

VERBS IN **ère** (long)

Sapére, to know (I know *something*)

Ind. Pres.—So, sai, sa, sappiamo, sapete, sanno.

Imperf.—Sapevo, sapevi, etc.

Past Defin.—Seppi, sapesti, seppe, sapemmo, sapeste, sèppero.

Future—Saprò, saprai, saprà, sapremo, saprete, sapranno.

Imperat.—Sappi, sàppia, etc.

Pres. Subj.—Sàppia, sappia, sappia, sappiamo, sappiate, sàppiano.

Imp. Subj.—Sapessi, sapessi, etc.

Conditional—Saprei, sapresti, saprebbe, etc.

Past Part.—Saputo.

Dovére, to owe, to be obliged

Pres. Ind.—Devo (*debbo*), *devi, deve, dobbiamo, dovete, dèvono* ((*dèbbono*), I must, etc.

Imperf.—Dovevo, dovevi, etc.

Past Def.—Dovei and *dovetti, dovesti, dovette* (*dovè*), *dovemmo, doveste, dovèttero* (*dovèrono*).

Future—Dovrò, dovrai, dovrà, etc.

Pres. Subj.—Debba, debba, debba, dobbiamo, dobbiate, dèbbano.

Imp. Subj.—Dovessi, dovessi, etc.

Conditional—Dovrei, dovresti, etc.

Past Part.—Dovuto.

Volère, to be willing

Ind. Pres.—Voglio (*vo'*), *vuoi, vuol*(*e*), *vogliamo, volete, vògliono.*

Imperf.—Volevo, volevi, voleva, etc.

Past Def.—Volli, volesti, volle, volemmo, voleste, vòllero.

Future—Vorrò, vorrai, vorrà, vorremo, etc.

Pres. Subj.—Vòglia, vòglia, voglia, vogliamo, vogliate, vògliano.

Imp. Subj.—Volessi, volessi, etc.

Conditional—Vorrei, vorresti, vorrebbe, etc.

Past Part.—Voluto.

Vedére, to see

Pres. Ind.—Vedo (*let. veggo*), *vedi, vede, vediamo, vedete, vèdono.*

Imp.—Vedevo, vedevi, etc.

Past Def.—Vidi, vedesti, vide, vedemmo, vedeste, vìdero.

Future—Vedrò, vedrai, vedrà, etc.

Imperat.—Vedi (*ve'*), *veda,* etc.

Pres. Subj.—Veda (*vegga*), etc., *vediamo, vediate, vèdano.*

Imp. Subj.—Vedessi, vedessi, etc.

Conditional—Vedrei, vedresti, vedrebbe, etc.

Past Part.—Veduto and *visto.*

The compound *prevedére* (to foresee), *provvedére* (to provide), and *travedére* (to see indistinctly), in the future and conditional are regular: *prevederò, prevederei, provvederò,* etc.

Potére, to be able

Pres. Ind.—Posso, puoi, può, possiamo, potete, pòssono (I can).

Imperf.—Potevo, potevi, etc.

Past Def.—Potei, potesti, etc.

Future—Potrò, potrai, potrà, etc.

Pres. Subj.—Possa, etc.; *possiamo, possiate, pòssano.*

Imp. Subj.—Potessi, potessi, etc.

Conditional—Potrei, potresti, etc.

Past Part.—Potuto.

Tenére, to hold, to keep

Pres. Ind.—Tengo, tieni, tiene, teniamo, tenete, tèngono.

Imperf.—Tenevo, tenevi, etc.

Past Def.—Tenni, tenesti, tenne, tenemmo, etc.

Future—Terrò, terrai, terrà, etc.

Imperat.—Tieni, tenga, teniamo, tenete, tèngano.

Pres. Subj.—Tenga, etc.; *teniamo, teniate, tèngano.*

Imp. Subj.—Tenessi, etc.

Conditional—Terrei, terresti, etc.

Past Part.—Tenuto.

Conjugate like *tenere*: *appartenére,* to belong, *contenére,* to contain, *ritenére,* to retain, *sostenére,* to sustain, etc.

ESERCIZIO DI LETTURA

. . . Dovete dunque sapère che, in quel convento, c'era un nostro padre, il quale era un santo, e si chiamava il padre Macàrio. Un giorno d'inverno, passando per una viòttola, in un campo d'un nostro benefattore, uomo dabbene anche lui, il padre Macàrio vide questo benefattore vicino a un suo gran noce; e quattro contadini, con le zappe[1] in aria, che principiàvano a scalzàr[2] la pianta, per mètterle le radici[3] al sole. Che fate voi a quella pòvera pianta? domandò il padre Macàrio. Eh! padre, son anni e anni che la[4] non mi vuol far noci; e io ne fàccio legna. Lasciàtela stare, disse il padre: sappiate che, quest'anno, la[4] farà più noci che fòglie. Il benefattore, che sapeva chi era colui che aveva detta quella parola, ordinò sùbito ai lavoratori, che gettasser di nuovo la terra sulle radici; e, chiamato il padre, che continuava la sua strada, padre Macàrio, gli disse, la metà della raccolta sarà per il convento. Si sparse la voce della predizione; e tutti corrèvano a guardare il noce.

Infatti, a primavera, fiori a bizzeffe,[5] e, a suo tempo, noci a bizzeffe. Il buon benefattore non ebbe la consolazione di bacchiarle ;[6] perchè andò, prima della raccolta, a ricèvere il prèmio della sua carità. Ma il miràcolo fu tanto più grande, come sentirete.

1, pick-axe ; 2, to bare ; 3, root ; 4, it ; 5, in abundance, plenty ; 6, to shake.

PERSONAL PRONOUNS—continued

Tu, Voi, Lei. In addressing a person we may use the pronoun of the second person singular, *tu* (*dare del tu*); or the pronoun of the second person plural, *voi* (*dare del voi*) ; or the feminine pronoun of the third person singular, *lei* (*dar del lei*).

1. *Tu* is used in addressing children, relatives, very intimate friends. Examples : Where are you going, Peter ? *Dove vai, Pietro ?* Speak, my child, *Parla, bambino mio.*

2. *Voi* is used in addressing a person to whom we desire to show a *certain* deference, or with whom we do not wish to be too familiar.

Examples : You have not studied enough to-day, *Voi non avete studiato abbastanza oggi* ; You are a good man, *Voi siete un buon uomo.* The adjective referring to *voi* (sing) is in the singular. You are very kind, *Voi siete molto gentile.*

3. *Lei* is the usual form of address (except in the cases mentioned above) : for the plural, *loro* is used. Example : You must excuse me, *Lei mi deve scusare* ; You (plural) are right, *Loro hanno ragione.*

4. The verb must, of course, agree in person and number with the personal pronoun used in addressing a person. The pronouns also in this case are generally omitted : *entra, entrate, entri, èntrino.*

5. In addressing a man in the third person the adjective referring to the pronoun *may* be in the feminine, as *lei* stands for the feminine *Vossignoria* (your lordship) ; *Lei sarà contento* (or *contenta*) *di sapere,* You will be pleased to know.

6. *Your, yours* when speaking in the third person must be translated by *suo, sua, suoi, sue, loro* ; *suo padre,* your father ; *le sue sorelle,* your sisters ; *i loro amici,* your friends. In writing, *Ella* may be used instead of *lei*, as, *Scrivo sùbito perchè Ella ne sia informata,* I am writing at once in order that you should be informed of it.

7. For you (*obj.*) the conjunctive forms *la, le* must be used. If a conjunctive pronoun is used the adjective must be feminine. Example : *La prego di scusarmi,* I beg you to excuse me. So the forms to be used when speaking or writing in the third person, whether the person addressed be a man or a woman, are as follow :

you (*subj.*)—*lei*, or *Ella* (sing.), *loro* (plural)
you (*obj.*)—*la* (sing.), *le* plural)
to you—*le* (sing.), *loro* (plural)
it, him, them, etc. to you—*glielo,-a,-i,-e*
of it, of him, of them, etc. to you—*gliene*

Exercise XXXII.

1. Noi si parlava di lei. 2. Lei è gentilissima. 3. Mi fàccia il piacere di darmi quello spillo. 4. Mi scusi se non glieli ho mandati più presto. 5. Le prometto che fo uno spropòsito se lei non mi dice sùbito sùbito il nome di colui. 6. Amico mio, tu hai torto ; domanda un po' a tua sorella ; non è vero, signorina, che lei è informata di tutto ? 7. Siete ben pronta a parlare senz' èssere interrogata. 8. Lei è la più cara persona che io àbbia mai conosciuta ; come fa a èssere sempre così allegra ? 9. Suo fratello mi disse che lei era ritornata in città, e mi sono affrettato a venire a strìngerle la mano. 10. Si è divertita questi lunghi mesi d'inverno ? 11. Perchè stanno sulla porta al freddo ? èntrino. 12. Lei non sa, non saprà mai quanto sincera fosse la mia amicìzia per suo fìglio. 13. Àbbia la gentilezza di mèttere questa lèttera alla posta quando va fuori. 14. La ringràzio tanto tanto dei bei fiori che mi ha mandati. 15. Loro crèdono che tutto si possa fare a tambùr battente ; ci vuol tempo per tutte le cose. 16. Le sue amiche la prègano di volère andàr giù in giardino, se non le dispiace. 17. Glieli mostrerò.

Conversazione

Chi le ha detto che l'affare non si farà ?

Lo so ; e vedrà che ho ragione.

La ringrazio della sua gentilezza e la prego di comandarmi in tutto ciò che posso.

Non si dia pensiero di me ; saprò come regolarmi.

Ho saputo che i suoi lavori sono stati accettati ; gliene faccio i miei complimenti.

Grazie, ma non dica niente a mio padre, perchè voglio fargli uno sorpresa.

E loro stanno sempre in campagna ?

Sì, e forse ci resteremo per due o tre mesi ancòra. Speriamo che ci farà l'onore di una sua visita un giorno o l'altro.

Da quanto tempo non vede il signor N ?

Lo vidi in casa Sarti due mesi fa (*ago*).

Dov'è il mio giornale ?

Scusi tanto, signorina, non ci ho pensato ; ma le prometto che stasera al più tardi glielo farò avere.

Se non vuol farlo, ce lo dica.

Non è che non voglio, non posso. Loro non sanno quanto sia difficile di ottenere qualche cosa da quella gente. A ogni modo proverò, e gliene farò sapere qualche cosa.

Key to Exercise XXIX.

1. We had thought to sell him some tickets, but he has not wished to buy any. 2. They have shown me some of different qualities. 3. If I had some more, I would give some to you. 4. Where is your aunt ? 5. There she is ; speak of it to her. 6. These little pictures are very beautiful ; if you go to Italy do not forget to buy some for me. 7. I have bought some beautiful toys for this little boy, but I have forgotten to bring them to him. 8. Do not bring them to him, because he has been naughty all day. 9. If the dressmaker has

finished my dress, tell her to send it to me directly. 10. I shall not fail to tell her of it.

KEY TO EXERCISE XXX.

1. Non vedete che la fàccia di questa bambina è tutta sporca di fumo? lavàtegliela. 2. Se avete delle rose e dei garòfani freschi, fàtene un bel mazzolino e mandàtelo a questo indirizzo. 3. Vi avevo pregato di non dirle niente, e voi le avete raccontato tutto. 4. Ecco la lèttera che abbiamo vicevuta, leggètegliela e vedete che impressione le fa. 5. Se avesse detto a noi tali parole, avremmo saputo come rispònderle per le rime. 6. Questo telegramma vi è stato rimesso alle sette e venti, come va che me lo date dopo più di due ore? 7. Se volete andare a teatro, andàteci; io preferisco di non uscire. 8. Lo tratterò come un mio fratello, ve lo prometto. 9. Ecco il telegramma che abbiamo ricevuto: "Ricevuto biciclette: spedirèmovele." 10. È in Italiano, non lo capisco; traducètemelo, per piacere.

KEY TO EXERCISE XXXI.

1. That boy was saved by a miracle. 2. To-day the new railway time-table has been published. 3. The workmen are paid every five days. 4. We were invited, but we did not go (there). 5. He is loved and esteemed by all who know him. 6. I am sorry I cannot accept your invitation, because I must soon start for Rome, where I have been summoned by telegram. 7. Stick no bills. 8. It is said that war between the two countries is now inevitable. 9. They say that General N. has been wounded in the last battle. 10. Don't be tiresome, otherwise thou wilt be avoided by everybody. 11. This little story has been related to us by a friend of ours. 12. The miser is attracted by gold, as iron by the magnet. 13. The fire has been finally isolated; but twenty houses and two coal-stores have been entirely destroyed. 14. The thief has been arrested.

VERBS—continued

Pronominal Verbs Conjugated Interrogatively

Pronominal verbs are conjugated interrogatively:

1. In simple tenses, by putting the pronoun subject after the verb.
2. In compound tenses, by putting the pronoun subject after the auxiliary verb.

These verbs may, like all other verbs, be conjugated interrogatively by prefixing *est-ce que* without inversion. This form is most commonly used in the case of the first person singular of the simple tenses, and is the only one that will be given here:

Se flatter, conjugated interrogatively

INDICATIVE

Present

Do I flatter myself?
est-ce que je me flatte?
nous flattons-nous?

Imperfect

Did I flatter myself?
est-ce que je me flattais?
nous flattions-nous?

Past Definite

Did I flatter myself?
est-ce que je me flattai?
nous flattâmes-nous

Future

Shall I flatter myself?
est-ce que je me flatterai?
nous flatterons-nous?

COMPOUND TENSES

Past Indefinite

Have I flattered myself?
me suis-je flatté, or *flattée?*
nous sommes-nous flattés, or *flattées?*

Pluperfect

Had I flattered myself?
m'étais-je flatté, or *flattée?*
nous étions-nous flattés, or *flattées?*

Past Anterior

Had I flattered myself?
me fus-je flatté, or *flattée?*
nous fûmes-nous flattés, or *flattées?*

Future Anterior

Shall I have flattered myself?
me serai-je flatté, or *flattée?*
nous serons-nous flattés, or *flattées?*

CONDITIONAL

Present

Should I flatter myself?
est-ce que je me flatterais?
nous flatterions-nous?

Past

Should I have flattered myself?
me serais-je flatté, or *flattée?*
nous serions-nous flattés, or *flattées?*

Pronominal Verb Conjugated Interrogatively and Negatively

INDICATIVE

Present

Do I not perceive?
est-ce que je ne m'aperçois pas?
ne nous apercevons-nous pas?

Imperfect

Did I not perceive?
est-ce que je ne m'apercevais pas?
ne nous apercevions-nous pas?

Past Definite

Did I not perceive?
est-ce que je ne m'aperçus pas?
ne nous aperçûmes-nous pas?

Future

Shall I not perceive ?
est-ce que je ne m'apercevrai pas ?
ne nous apercevrons-nous pas ? —

Compound Tenses

Past Indefinite

Have I not perceived ?
ne me suis-je pas aperçu, or *aperçue ?*
ne nous sommes-nous pas aperçus, or *aperçues ?*

Pluperfect

Had I not perceived.
ne m'étais-je pas aperçu, or *aperçue ?*
ne nous étions-nous pas aperçus, or *aperçues ?*

Past Anterior

Had I not perceived ?
ne me fus-je pas aperçu, or *aperçue ?*
ne nous fûmes-nous pas aperçus, or *aperçues ?*

Future Anterior

Shall I not have perceived ?
ne me serai-je pas aperçu, or *aperçue ?*
ne nous serons-nous pas aperçus, or *aperçues ?*

Conditional

Present

Should I not perceive ?
est-ce que je ne m'apercevrais pas ?
ne nous apercevrions-nous pas ?

Past

Should I not have perceived ?
ne me serais-je pas aperçu, or *aperçue ?*
ne nous serions-nous pas aperçus, or *aperçues ?*

Exercise XXIX.

Of the pronominal verbs that have the second pronoun for their direct object, some take the preposition *à*, others the preposition *de*, before their indirect object. These prepositions are indicated in the following list of verbs that occur in the exercise :

s'aider, to help oneself
s'apercevoir de, to perceive
s'appeler, to be called
s'arrêter, to stop
se battre, to fight
se défendre, to defend oneself
se défier de, to distrust
se déguiser, to disguise oneself
se dévouer, to devote oneself
s'emparer de, to take possession of, to seize
s'ennuyer de, to weary of
se glorifier de, to be proud of
se méfier de, to mistrust
se mettre à, to set about, to begin
se plaire à, to take pleasure in
se ralentir, to slacken
se trouver, to find oneself, to happen to be
se vanter de, to boast of

1. It seems to me that I have already seen that lady. What is her name ? (How does she call herself ?)

2. The vanquished (*vaincu*) have not fought less well than the victors (*vainqueur*).

3. The enemy (singular) have taken possession of the town, after a long siege, during which the inhabitants defended themselves as courageously (*courageusement*) as the soldiers.

4. We distrust others too much, and we do not mistrust ourselves sufficiently.

5. There are men who are prouder (glorify themselves more) of their defects (*le défaut*) than of their good qualities.

6. "Help thyself, heaven will help thee," says the proverb.

7. They (f.) perceived their error, but it was too late.

8. A writer (*écrivain*) has said that if we often boast of not wearying, it is because we are so conceited (*glorieux*) that we do not wish (*voulons*) to consider (find) ourselves (*de*) bad company (*la compagnie*).

9. At what time do you usually (*ordinairement*) get up ? We usually get up at half-past seven, and we rarely go to bed before half-past eleven.

10. Great motives may (*peuvent*) induce (*engager*) us to humble (*humilier*) ourselves, none to demean (*avilir*) ourselves.

11. The Romans, after having taken possession of Gaul (*la Gaule*), gave it in a short time their civilisation.

12. It is (*vaut*) better to expose oneself to ingratitude than to leave a wretched (man) (*malheureux*) without help (*secours*).

13. History tells us that there have been kings who devoted (*dévouer*) themselves to death for the safety (*le salut*) of their people.

14. There is a great deal of difference between (*entre*) taking pleasure (*se plaire*) in a (*à*) work and being suited (*propre*) for (to) it.

15. We are so accustomed (*accoutumés*) to disguise ourselves to others, that in the end (*enfin*) we disguise ourselves to ourselves.

16. It is as easy to deceive (*tromper*) oneself without perceiving it, as it is difficult to deceive others without their (that they) perceiving it.

Passive Verbs

1. Verbs in the passive voice, or passive verbs, as they are commonly called (*verbes passifs*), consist of the past participle of an active verb added to the verb *être*, to be. Thus, *aimer*, to love ; *être aimé*, to be loved ; *j'aime*, I love ; *je suis aimé*, I am loved ; *La mère a grondé l'enfant*, The mother has scolded the child ; *L'enfant a été grondé par sa mère*, The child has been scolded by his mother.

2. In passive verbs, the past participle always agrees with the subject : *Jeanne d'Arc fut brûlée sur la place publique de Rouen*, Joan of Arc was burnt in the public square at Rouen.

3. In conjugating a passive verb, it must be remembered that *je*, *tu*, *nous*, *vous* may stand for feminine subjects, and that in such a case the past participles must be feminine also.

4. As the conjugation of the passive voice presents no difficulty, it will suffice to give one simple tense and one compound tense as models :

Present Indicative

I am loved, etc.
je suis aimé, or *aimée*
tu es aimé, or *aimée*
il est aimé, elle est aimée
nous sommes aimés, or *aimées*
vous êtes aimés, or *aimées*
ils sont aimés, elles sont aimées

Past Indefinite
I have been loved, etc.
j'ai été aimé, or *aimée*
tu as été aimé, or *aimée*
il a été aimé, elle a été aimée
nous avons été aimés, or *aimées*
vous avez été aimés, or *aimées*
ils ont été aimés, elles ont été aimées

5. The subject of a verb in the passive voice can only be that which would be the direct object or accusative of the same verb in the active voice. The indirect object or dative of the active may never be the subject of the passive voice. Thus, the verb *dire*, to tell, requires the indirect object: *je lui dis*, I tell (to) him. Consequently, such a construction as "I have been told" is impossible in French. We must say, *on m'a dit*, one has told me, or *il m'a été dit*, it has been told me.

6. The passive construction is used far less frequently in French than it is in English. In the former language it is very commonly rendered by an active construction with *on* as subject, or by means of a reflexive verb: It is said that the enemy have taken possession of the town, *On dit que l'ennemi s'est emparé de la ville*; That word is not found in the dictionary, *Ce mot ne se trouve pas dans le dictionnaire*

Neuter Verbs

1. The neuter, or intransitive, verb (*verbe neutre ou intransitif*) is that which can never have a direct object or accusative, and which, consequently, has no passive voice.

2. Some neuter verbs are conjugated with *être* as their auxiliary, in the compound tenses. The more common of these are:

aller, to go
arriver, to arrive
entrer, to enter
mourir, to die
naître, to be born
partir, to go away
rester, to remain
sortir, to go out
tomber, to fall
venir, to come, and some of its derivatives.

By P. G. Konody and Dr. Osten

XCII. Attributive Clauses. The attributive clause represents the attribute to the subject in the principal sentence, and is generally joined to the other parts of the sentence by the conjunction daß, or by interrogative or relative pronouns. As a substitute for an attribute, the attributive clause, like the attribute, answers to the question was für ein? what sort of? In the sentence: Er gab mir den Beweis der Wahrheit ſeiner Darſtellung, He gave me the proof of the truth of his version, the substantive attribute answering the question Was für einen Beweis? is: Den Beweis der Wahrheit, etc. The attributive clause, by which it may be replaced, would be: Er gab mir den Beweis, daß ſeine Darſtellung wahr ſei, He gave me the proof that his version is true.

XCIII. Relative Clauses. Attributive adjectives can be replaced by attributive clauses connected with the principal sentence by the relative pronouns der, die, das, welcher, was, or by the conjunctions [see XLV., 2] wo, da, wie, wann, etc. The relative pronouns agree in gender and number with the corresponding noun in the principal sentence, but the case is determined by the predicate of the subordinate clause. In the sentence: Ein kahler Baum erquickt das Auge nicht, A barren tree does not please (refresh) the eye, the adjective-attribute kahl can be replaced by an attributive (relative) clause: Ein Baum, der kahl iſt, erquickt das Auge nicht, A tree that is barren, etc. Ich liebe nicht fehlerloſe Kinder, I do not like faultless children, and: Ich liebe nicht Kinder, die fehlerlos ſind. Dies iſt ein Mann, deſſen Hilfe ich bedarf, This is a man whose help I need. Dies iſt ein Mann, dem (3) nicht geholfen werden kann, This is a man to whom help cannot be given. Dies iſt ein Mann, den ich brauche, This is a man whom I want. Dies ſind Leute, die wir kennen, These are people whom we know. Dies iſt eine Frau, deren Hilfe ich bedarf, This is a woman whose help I want. In these examples it will be seen that gender and number of the relative pronouns are determined by the nouns to which they refer, whilst the case is influenced by the predicate of the relative clause. Sometimes the relative pronoun is dependent on the adjunct substantive, in which case it must be in the genitive (deſſen, deren): Dies iſt ein Mann, an deſſen Beifall mir liegt, This is a man whose approval I care for.

1. If the attributive clause refers to a substantive, the relative pronouns der, die, das, and welcher, welche, welches, are employed. The choice between the two groups is generally decided by euphony: Er brachte den Tiſch, welchen (or den) ich geſtern gekauft hatte, He brought the table which I [had] bought yesterday. But if the relative clause refers to a personal pronoun, only the relative pronouns der, die, das, are admissible: Wir ſahen ihn, der (not welcher) uns früher Auskunft gegeben hatte, We saw him who had previously given us information. Er beleidigte mich, den (not welchen) er zum erſten Male ſah, He insulted me whom he saw for the first time.

2. If the relative clause refers to the *neuter* of a demonstrative pronoun, or of a substantive, or of an indefinite numeral, it has to be introduced by the relative pronoun was, or its contraction with prepositions, like womit, wodurch, wozu, woraus, etc. Examples: Er ſagte mir Alles was er wußte, He told me all he knew. If the relative clause refers to a substantive, was and its contractions are usually not employed: Das Bett, das (not was) ich kaufte, The bed which I bought. The relative pronoun was is, of course, subject to declension.

3. Relative Adverbs are: wo (wohin), da (als, wenn)—wo referring to place, and da to time. Wo (wohin) is used instead of an dem Orte, an welchem . . . . (an den Ort, an welchen . . . .), in the place where . . . . ; and da (als, wenn) instead of

zu der Zeit, in welcher ..., at the time when ... etc. Examples: Kennſt du das Land, wo die Citronen blühn? (Goethe), Knowest thou the land where the lemons blossom? Am Tage, da wir uns zum erſten Male ſahen, On the day when we saw each other for the first time.

4. The contraction of relative clauses lends more vigour and terseness to the sentence. The relative clause in the sentence Der Graf, der ein vorzüglicher Reiter war, ſtieg in den Sattel, The count, who was an excellent horseman, mounted into the saddle, can be contracted by the omission of the relative pronoun „der" and the finite auxiliary (copulative) verb „war": Der Graf, ein vorzüglicher Reiter, ſtieg in den Sattel. The contracted part of the relative clause takes the case of the noun to which it refers: Der Rat des Arztes, der ein Freund unſerer Familie war, ſchien gut, The advice of the doctor, who was a friend of our family, seemed good; but Der Rat des Arztes, eines Freundes unſerer Familie, ſchien gut.

If the predicate of the relative clause is a verb in the passive voice, the relative pronoun is dropped and the verb takes the past participle: Er lebt in einem Dorfe, (welches) Gernhauſen genannt (wird), He lives in a village (which is) called Gernhausen.

XCIV. Adverbial Clauses. According to the different groups of adverbs there are adverbial clauses of place, time, manner, cause, etc., which can be placed at the beginning, at the end, or in the middle of the sentence. The adverbial clause must not be confounded with the ordinary adverbial phrase of place, time, etc. The former is a *complete* clause with subject and predicate. Thus, wo immer, an allen Orten, wherever, in all places, are merely adverbial phrases of place; whilst Wo immer ich auch bin, Wherever I may be, is an adverbial clause of place, with subject and predicate.

1. The adverbial clause of place answers to the questions Wo? Where? Wohin? Whither? Woher? Whence? by which conjunctions it is generally introduced; whilst the correlatives, da, dort, etc. frequently occur in the principal sentence: Wo Licht iſt, da iſt auch Schatten, Where there is light, there is also shadow. To distinguish between adverbial clauses and attributive clauses of place, which are introduced by the same conjunctions, it should be remembered that the former answers to the question Wo? etc., and the latter to Was für ein? Wo ich geboren bin, iſt meine Heimat, Where I was born is my home, is an adverbial clause of place. (Question: Wo iſt meine Heimat?) But in Der Ort, wo ich geboren bin, iſt meine Heimat. The place where I was born is my home, the relative clause is attributive. (Question: Was für ein Ort?)

2. The adverbial clause of time answers to the questions Wann? When? Wie lang? How long? Seit wann? Since when? Bis wann? Till when?

(*a*) If the actions in the principal sentence and in the dependent clause coincide, these clauses are introduced by the conjunctions als, wie, wenn, wann, ſobald, ſowie, während: Als er kam, ging ich fort, As he came, I went away. Er wollte einſteigen, während der Zug abging, He wanted to get in whilst the train was starting, etc. The predicates of both parts of the sentence take, of course, the same tense. If the conjunctions wenn and wann are omitted the sequence of words is the same as in an interrogative sentence: Wenn ich wiederkomme, wollen wir fröhlich ſein, When I return we will be merry; but: Komme ich wieder, wollen wir fröhlich ſein.

(*b*) If the action of the dependent clause precedes that of the principal sentence, the former is introduced by nachdem, after: Nachdem ich ihm meine Meinung geſagt hatte, beruhigte er ſich, After I had told him my opinion, he calmed down. Here the imperfect in the principal sentence corresponds with the pluperfect in the dependent clause.

(*c*) If the action of the principal sentence precedes that of the dependent clause, the latter is introduced by ehe, bevor, before: Tue es, ehe es zu ſpät iſt, Do it, before it is too late.

(*d*) The adverbial clauses answering to Wie lange? How long? Seit wann? Since when? Bis wann? Till when? are introduced by the conjunctions ſeit, since; bis, till; indem, während, whilst; indes, meanwhile; ſolange, as long as; and nun, now: Seit du da biſt, fühle ich mich wieder wohl, Since you have been (are) here, I feel well again. Bleiben Sie hier, bis ich komme, Stay here until I come.

3. Adverbial clauses of mode and manner answer to the questions Wie? How? and Auf welche Weiſe? In which way (manner)? These clauses can be (*a*) comparative, or (*b*) conclusive. In (*a*) the subjects of the principal sentence and of the adverbial clause are compared; in (*b*) a conclusion is drawn in the one from the other.

(*a*) The comparative clause is introduced by the conjunctions wie, als, wie — ſo, ſo — ſo, als daß, als ob, als wenn, wie wenn, indem, ohne daß, je nachdem, je — deſto, inſofern, inwiefern, inſoweit, inwieweit. The similarity of the objects compared is indicated by wie, the superiority or inferiority by als [see LV., 5, 6]: ſtark wie Eiſen, strong as iron; ſtärker als Eiſen, stronger than iron. If the principal sentence and the comparative clause have the same subject and predicate, these can be dropped in the comparative clause after the conjunctions als and wie: Er liebt ſeine Bücher, wie (er) ſonſt nichts auf Erden (liebt), He loves his books as he loves nothing else on earth. Comparative clauses introduced by ohne daß can also be contracted if they have the same subject as the principal sentence: Er ſtimmt zu, ohne daß er darüber ein Wort verliert can be contracted (with omission of daß, and with the prepositional infinitive of the verb) into: Er ſtimmt zu, ohne darüber ein Wort zu verlieren, He assents, without wasting [losing] a word about it. Comparative clauses introduced by indem are contracted by omission of the conjunction and subject, the verb being put in the participle present: Er ſtand auf, indem er dem Kellner eine Silbermünze zuwarf, and Er ſtand auf, dem Kellner eine Silbermünze zuwerfend, He got up, throwing a silver coin to the waiter.

(*b*) Conclusive clauses are introduced by ſo—daß, ſodaß, daß, zu—als daß, etc. Als daß is followed by the subjunctive: Ich war zu erregt, als daß ich ihm hätte antworten können, or contracted (with omission of the conjunction, and with the infinitive with um zu): Ich war zu erregt, um ihm antworten zu können, I was too excited to be able to answer him. Er war zu vorſichtig, als daß er dem Rat befolgt hätte, or contracted: Er war zu vorſichtig, um den Rat zu befolgen, He was too cautious to follow the advice. The contracted form is distinctly preferable and is generally employed.

4. Adverbial clauses of cause denote (*a*) the cause, (*b*) the purpose, (*c*) the condition, (*d*) the concession of an action expressed in the principal sentence.

(*a*) Clauses of cause are introduced by the conjunctions weil, indem, da, dadurch—daß, daran—daß, davon—daß, daraus—daß. Examples: Ich ging fort, weil Sie nicht kamen, I went away because you did not come. Da er nichts ſagte, ſprach auch ich nicht davon, Since he said nothing, I, too, did not speak about it. The clauses of cause introduced by the conjunctions da and weil can be contracted by the omission of the conjunction and the subject, the verb being put in the participle: Da ich mit dieſer Beſtimmung nicht einverſtanden war, brach ich die Verhandlungen ab, As I did not consent to this stipulation, I broke off the negotiations; or contracted: Mit dieſer Bedingung nicht einverſtanden, brach ich die Verhandlungen ab.

(*b*) Clauses of purpose are introduced by the conjunctions damit, auf daß, daß, etc. (sometimes with the correlatives darum, deshalb, zu dieſem Zwecke, in the principal sentence). The verb in these clauses takes the subjunctive mood: Er ſprach leiſe, damit ihn niemand höre, He spoke low, so that no one should hear him. The contraction is effected in the usual way, by omission of conjunction and subject, the verb taking the prepositional infinitive with zu or um zu: Sie ſcheute keine Mühe, damit ſie zu ihm gelange, or Sie ſcheute keine Mühe, um zu ihm zu gelangen, She shirked no trouble to get to him.

(*c*) Conditional clauses are introduced by falls, wenn, wofern, wo, im Falle daß, sometimes with a correlative ſo in the principal sentence: Falls es regnet, ſo komme ich nicht, If it rains I do not come. If the conjunction of the subordinate clause is dropped, the verb must precede the subject: Regnet es, ſo komme ich nicht. If a clause introduced by wenn is contracted, the conjunction and subject are omitted, and the verb takes the past participle: Wenn er getreten wird, krümmt ſich auch der Wurm, or contracted: Getreten, krümmt ſich auch der Wurm, Even the worm will turn when trodden on.

(*d*) Clauses of concession are introduced by wenn auch, wenngleich, wenn ſchon, ob auch, obgleich, obſchon, obwohl, wie auch, wiewohl, although, sometimes with a correlative ſo doch or ſo dennoch in the principal sentence. The conjunctions wenn, ob, are sometimes dropped for reasons of euphony, in which case the sequence of words is the same as in an independent interrogative sentence: Wenn auch das Unglück ihn tief gebeugt hatte, ſo ließ er doch den Mut nicht ſinken, Although misfortune had bent him down, he did not lose courage; or contracted: Hatte ihn auch das Unglück tief gebeugt, ſo ließ er doch den Mut nicht ſinken.

EXAMINATION PAPER XXIII.

1. To which question does the attributive clause answer, and for what reason?
2 How are relative clauses connected with their principal sentences?
3. What determines the gender and number, and what the case, of the relative pronoun in an attributive clause?
4. When is it necessary to employ the relative pronouns der, die, das; and what consideration decides, in other cases, the alternate use of these pronouns and of welcher, welche, welches?
5. Which relative pronoun must be used, when the relative clause refers to the neuter of an adjective in the superlative? Under what other circumstances is the same pronoun to be used?
6. How can relative clauses be contracted?
7. What are adverbial clauses, and how are they grouped?
8. How is it possible to decide whether dependent clauses introduced by the conjunctions wo, woher, wohin, are adverbial clauses of place or relative (attributive) clauses?
9. What is the difference between an adverbial clause of place and a mere adverbial phrase of place?
10. What tenses are used in the principal sentence and in the adverbial clause of time (*a*) if the actions of both coincide, (*b*) if the action of the dependent clause precedes that of the principal sentence?
11. What rule determines the use of wie and als in comparative clauses?
12. How can a comparative clause be contracted? And how are clauses of cause, purpose, and condition contracted?

EXERCISE 1 (*a*). Insert the missing relative pronouns:

Ich kaufte den Hut in dem Geſchäfte, ... ſich
I bought the hat in the shop [which
nebenan befindet. Dies widerfuhr mir, ... doch
is] next door. This happened to me who knew
den Weg genau kannte. Er ſtellte mir ſeine Frau vor,
the way exactly. He introduced to me his wife
.... ich vorher noch nie geſehen hatte. Dies iſt der Mann,
whom I had never seen before. This is the man
... Sohn uns hierher führte. Dies iſt die
whose son conducted us here. This is the peasant-
Bäuerin, ... Tochter uns den Weg gezeigt hatte.
woman whose daughter had shown us the way.
Das war Alles, ... ich erfahren konnte. Das ſagen Sie,
This was all I could learn. You say so,
.... dies doch beſſer wiſſen ſollte? Das ſagte der Mann,
who ought to know better? The man said so,
.... dies hätte beſſer wiſſen müſſen. Das Klügſte,
who should have known better. The best [wisest]
.... wir tun können, iſt, abzureiſen. Es gab nichts,
we can do, is to depart. There was nothing
.... er nicht wußte.
that he did not know.

(*b*). Form attributive (relative) clauses of the following sentences :

Ich kaufte den Hut in dem nebenan befindlichen Geſchäfte.
I bought the hat in the shop next door.
(See first sentence of exercise 1*a*.)
Alle daran gewandte Mühe war vergeblich.
All the trouble spent on it was wasted.
Ich befolgte den mir erteilten Rat.
I followed the advice given to me.
Sie ſchenkte ihm eine wunderbar duftende Roſe.
She presented him with a deliciously smelling rose.
Er zeigte mir den kürzeſten Weg.
He showed me the shortest way.

Exercise 2. Insert the correct conjunctions of comparison :

Ich fühle mich ſo wohl, ... ein Fiſch im Waſſer.
I feel as well as a fish in the water.
Ich fühle mich wohler, ... ein Fiſch im Waſſer.
I feel better than a fish in the water.
. . . . die Sonne aus den Wolken bricht, ſo trat die Fee aus dem Waldesdunkel hervor.
As the sun breaks forth from the clouds, so the fairy stepped out of the darkness of the forest.
Unſer Garten iſt weit ſchöner . . . . der ſeine.
Our garden is far more beautiful than his.
Er liebte ihn, ... ein Bruder den andern [liebt].
He loved him as one brother loves the other.

Key to Exercise in Examination Paper
Page 4076

Dem Kinde wurde befohlen, im Zimmer zu bleiben. Dem Kinde wurde befohlen dazu bleiben. Ich bat ihn mir zu helfen. Ich bat ihn mir mit einigem Gelde auszuhelfen. Ich bat ihn ſich einſtweilen ohne mich zu behelfen. Er erklärte nichts davon zu wiſſen, or: Er erklärte, er wiſſe nichts davon. Der Vater fürchtete, ſein Sohn würde ihm nichts mitteilen. Ich hoffe morgen früh abzureiſen, or: Ich hoffe, ich werde morgen früh abreiſen. Es war, ſagte er mir, ſchrecklich. Der König wurde, berichtete die Zeitung, glänzend empfangen. Den Truppen wurde der Befehl erteilt das Feuer zu eröffnen. Geſtatten Sie mir Ihnen alles zu erzählen. Erlauben Sie mir Sie nächſtens zu beſuchen. Gewiß, aber trachten Sie den Zug nicht zu verſäumen. Verhält es ſich ſo, dann bleibe ich noch. Wünſchen Sie es nicht, ſo wird es einfach nicht geſchehen.

CONVERSATIONAL EXERCISES

IX. Forms of Courtesy

Generally speaking, the Germans are far more formal and courteous in conversation than the English, and have many expressions and quaint forms of speech which do not exist in English. Thus it is customary to say „Guten Appetit“ (good appetite) before, and „Wünſche wohl geſpeiſt zu haben“ (I hope you have dined well) after a meal; or to exclaim „Zum Wohlſein!“ on hearing somebody sneeze. The custom of addressing people by their full title is carried to such extremes that the wife of a small government official is addressed by her husband's title: „Frau Steuereinnehmerin“ (Mrs. tax-collector). To make these forms clearly intelligible, they are here literally translated.

Good-morning! Good-day! Good-evening!	Guten Morgen! Guten Tag! Guten Abend!
How do you do?	Wie geht es Ihnen?
Quite well, thank you; and you?	Danke beſtens, ganz gut; und Ihnen?
Well, not particularly well; I have caught a slight cold.	Nun, nicht zum Beſten; ich habe mich ein wenig erkältet.
Good-bye! God be with you!	Adieu! Gott befohlen! Gott zum Gruße!
After you!	Nach Ihnen!
Your health!	Proſit! Auf Ihr Wohl! Ihre Geſundheit!
Farewell!	Leben Sie wohl!
May we meet again soon!	Auf Wiederſehen!
Good-night [gracious] madam!	Gute Nacht, gnädige Frau!
I am pleased to have made your acquaintance.	Es hat mich gefreut, Sie kennen zu lernen, (or: Ihre werte Bekanntſchaft zu machen).

X. Concerning Time

What o'clock is it?	Wie viel Uhr (wie ſpät) iſt es?
Eight o'clock. A quarter past eight. A quarter to nine. Five minutes past nine. Half past eleven.	Acht Uhr. Ein Viertel nach acht Uhr. Dreiviertel neun Uhr. Fünf Minuten nach neun. Halb zwölf Uhr.
The train leaves at 2.20, at 3.30 p.m.	Der Zug geht um 2 Uhr 20 Minuten, um halb vier nachmittags ab.
The fast train arrives at 4.45 a.m.	Der Schnellzug kommt um dreiviertel fünf Uhr morgens an.
I shall be with you at five minutes to six.	Fünf Minuten vor ſechs Uhr bin ich bei Ihnen.
I shall only wait for you till a quarter past six, then I shall go, as the performance begins at 7 o'clock sharp.	Ich warte nur bis ein Viertel nach ſechs auf Sie, dann gehe ich fort, da die Theatervorſtellung um präciſe 7 Uhr beginnt.

XI. Concerning Relationship

That young lady is a niece of the officer who travelled with us.	Jenes Fräulein iſt eine Nichte des Offiziers, der mit uns reiſte.
My nephew lived twelve months with his mother in London.	Mein Neffe lebte ein Jahr lang mit ſeiner Mutter in London.
I have a cousin at Breslau and an uncle at Magdeburg.	Ich habe einen Vetter in Breslau und einen Onkel in Magdeburg.

I think there were several brothers and sisters; has the child any brothers or sisters?	Ich glaube es waren mehrere Brüder und Schweſtern da; hat das Kind Geſchwiſter?
The grandparents took charge of the little girl.	Die Großeltern nahmen die Kleine zu ſich.
How many grandchildren has the Count?	Wie viel Enkel hat der Graf?
He is a stepbrother of my brother-in-law.	Er iſt ein Stiefbruder meines Schwagers.
Do you know my sister-in-law?	Kennen Sie meine Schwägerin?
The bridegroom and the bride came to see us.	Der Bräutigam und die Braut machten uns einen Beſuch.
The children are twin-sisters.	Die Kinder ſind Zwillingsſchweſtern.

SPANISH

Continued from page 4080

By Amalia de Alberti & H. S. Duncan

VERBS—continued

The Reflexive Verb. Reflexive verbs are so called because they are conjugated with a pronoun object identical with the subject. Examples:

alabarse, to praise oneself
me alabo, I praise myself
te alabas, thou praisest thyself
se alaba, he praises himself
nos alabámos, we praise ourselves
os alabais, you praise yourselves
se alaban, they praise themselves, etc.

Many neuter and passive verbs have only the reflexive form in Spanish. Examples:

alegrarse, to rejoice
arrepentirse, to repent
quejarse, to complain
burlarse, to mock
enfadarse, to get angry
levantarse, to get up
acostarse, to go to bed
llamarse, to be called

Verbs having only the reflexive form in Spanish, when active or neuter in English, may be conjugated with *se*, itself, and the dative pronoun to distinguish the person. Examples:

me alegro, or *se me alegra*, I rejoice
te alegras, or *se te alegra*, thou rejoicest
se alegra, or *se le alegra*, he rejoices
nos alegrámos, or *se nos alegra*, we rejoice
os alegrais, or *se os alegra*, you rejoice
se alegran, or *se les alegra*, they rejoice

Reciprocal Verbs. When reflexive verbs in the plural refer to two or more persons separately they are called reciprocal, and the pronoun object is rendered by *each other* when two are intended and *one another* when several are indicated. Example: *se aman*, they love each other, or one another.

As *se aman* may also mean they love themselves, when any doubt is possible such phrases may be strengthened by some addition. Examples:

se aman á sí mismos, they love themselves
se aman el uno al otro, they love each other
se aman los unos á los otros, they love one another.

The Passive Voice. The passive voice, as already explained, is formed by the simple and compound tenses of the auxiliary verb *ser* joined to the past participle of the verb to be. Examples:

soy amado, I am loved
fui amado, I was loved
seré amado, I shall be loved
haber sido amado, to have been loved

The passive voice is little used in modern Spanish, but is generally replaced by the reflexive construction. Example:

El libro se vendió muy barato, The book was sold very cheap; rather than *fué vendido*.

The passive voice is preferred in narrative of past events. Example:

Muchos soldados fueron matados en la batalla, Many soldiers were slain in the battle.

The Participle. The past participle is looked upon as an adjective, and agrees with the noun in gender and number when used as an adjective without the verb, and when conjugated with any verb as auxiliary except *haber*. With *haber* the participle is always invariable. Examples:

Ellos han leido las cartas, They have read the letters.

Las cartas están leidas, The letters are read.

Las cartas leidas, The letters read.

Participles are considered irregular when they do not end in *ado* or *ido*, according to their conjugation.

The following regular verbs have an irregular past participle:

Infinitive	*Participle*
abrir, to open	*abierto*, opened
cubrir, to cover	*cubierto*, covered
escriber, to write	*escrito*, written
imprimir, to print	*impreso*, printed

All the derivatives of the above verbs have the same irregularity. Examples:

descubrir, to discover	*descubierto*, discovered
encubrir, to conceal	*encubierto*, concealed
inscribir, to register	*inscrito*, registered

Impersonal Verbs. Impersonal verbs are those which can only be used in the third person singular, and whose subject in English is *it*. They are inflected according to their conjugation. True impersonal verbs refer to natural phenomena. Examples:

llover, to rain	*llueve*, it rains
nevar, to snow	*nieva*, it snows
helar, to freeze	*hiela*, it freezes
tronar, to thunder	*truena*, it thunders
amanecer, to dawn	*amanece*, it dawns
anochecer, to grow dark	*anochese*, it grows dark

The two last may be used personally. Examples:

Amanecí en Londres, I reached London at dawn.

Anochecimos en Paris, We reached Paris at nightfall.

The following are examples of the different methods of rendering the English impersonal "it is" in Spanish:

Es verdad, It is true

Así es, It is so

Está helando, It is freezing

Hace frio, It is cold

Hace sol, It is sunny

Hace tres dias, It is three days ago

Hay diez millas de aquí, It is three miles from here.

Mas vale tener poco que nada, It is better to have little than nothing.

NOTE. *Hace* is always used with reference to time, and *hay* with reference to distance.

Vocabulary	**Vocabulario**
A cowherd	Un vaquero
A watering-pot	Una regadera
A spade	Una azada
Shears	(Las) cizallas
A shearer	Un esquilador

EXERCISE XIV. (1)

Translate the following into Spanish:

1. Will you play chess? I cannot play as well as you. It does not matter, I will give you the queen and pawn.

2. Very good; but after finishing a game of chess we will play one of draughts. I think I know that game very well. Here is the board.

3. Take a cigar; they are good; they are Havanas. Thanks, I do not smoke. And your brother, [does he] smoke? My brother smokes cigars, cigarettes, and a pipe.

4. The Scotch play the bagpipes, and they are the only [people] in the world who can play them.

5. This water you see here is a spring of fresh water.

6. This is a rivulet in summer, and a voluminous river in the winter.

7. Calm comes before a storm.

8. He says he is a good horseman and he cannot manage his horse.

9. Do you use spurs? Never.

10. This saddle is old. You should buy a new one; and allow me to tell you that the stirrups are too long.

11. This horse is very spirited; it must be broken in. That is easy, I have a good trainer in my stables.

12. The harnessing will be quickly done.

13. It is not well to praise oneself so much, as he who praises himself runs risk of being mocked.

14. Let them mock; I do not care!

15. My heart rejoices at the sight of you.

16. We are very pleased at your good fortune.

EXERCISE XIV. (2)

Translate the following into English:

1. La guerra fué muy sangrienta; murieron muchos soldados.

2. Al recibir la triste noticia la pobre mujer se desmayó.

3. ¿ Puedo abrir esa carta? Está abierta desde esta mañana.

4. El cielo está encapotado; se deben cubrir esas flores, pues de seguro lloverá.

5. He escrito á su señor padre dándole parte de nuestro compromiso; verémos si se digna escribir.

6. ¡ Esas palabras están impresas en mi corazon!

7. Hay que imprimir este manuscrito.

8. La América fué descubierta por Colón.

9. Al descubrir la estátua, la derribáron al suelo.

10. Truena, llueve y hiela al mismo tiempo.

11. ¡ Vá á tronar!

12. Al amanecer salimos del pueblo incognito.

13. Amanece á las cinco de la mañana.

14. Al anochecer llegamos á nuestro destino; fué una jornada larga.

15. ¿ Es verdad que hay doce millas de aqui á San Juan de Luz?

PROSE EXTRACT XII.

Passages from an Essay by Mariano José de Larra, entitled "¿ Quién es el Público?" (Who is the Public?).

This word public which is always in every man's mouth in support of his opinions, this accommodating servant of every party and every opinion, is it a word void of meaning or is it a real and actual living being? According to the amount of talk there is about it, according to the prominent part it plays in the world, according to the titles lavished upon it, and the consideration

Esa voz pública que todos traen en boca siempre en apoyo de sus opiniones, ese comodin de todos los partidos, de todos los pareceres, ¿ es una palabra vacia de sentido, ó es un ente real y efectivo? Segun lo mucho que se habla de él, segun el papelon que hace en el mundo, segun los epitetos que se le prodigan, y las consideraciones que se le guardan, parece que debe de ser alguien.

shown it, it seems as if it ought to be somebody. The public is enlightened, the public is indulgent, the public is impartial, the public is respectable, there can be no doubt, therefore, that the public exists. Such being the case, who is the public and where is it to be found ?	El público es ilustrado, el público es indulgente, el público es imparcial, el público es respetable : no hay duda, pues, en que existe el público. En este supuesto, ¿ Quien es el público y donde se le encuentra ?
With a youthful and ingenuous countenance I leave my house to search for the public in these streets, and to take notes in my pocket-book of the character, or rather of the distinctive characteristics of this worthy gentleman.	Salgome de casa con mi cara infantil y bobalicona á buscar al público por esas calles, y á tomar apuntaciones en mi registro acerca del caracter, por mejor decir, de los caracteres distintivos de ese respetable señor. . . .
I gather up my notes more perplexed than ever as regards the object of my inquiries, and seek information from persons more learned than myself. To my question " Who is the public ? " an author who has been hissed replies, " Ask me rather how many fools are required to make a public."	Reuno mis notas y más confuso que antes acerca del objeto de mis pesquisas, llego a informarme de personas más ilustradas que yo. Un autor silbado me dice cuando le pregunto, " ¿ Quién es el público ?" " Preguntadme más bien cuántos necios se necesitan para componer un público."
An author who has been applauded replies, " It is the assembly of enlightened persons who decide upon the merit of literary productions in the theatre."	Un autor aplaudido me responde, " Es la reunion de personas ilustradas que deciden en el teatro del mérito de las producciones literarias."
Mariano José de Larra (1809-1837) was born with all the gifts of genius, marred by a bitter pessimism which drove him to suicide at the age of twenty-eight. He was the author of one historical novel and a few adaptations for the stage, but his fame rests chiefly upon the vigorous prose of his satirical essays, which appeared under a variety of pseudonyms. In spite of his early death he is considered one of the foremost authors of the century.	Mariano José de Larra (1809-1837) nació con todos los dones de un genio, dañados por sus sentimientos pesimistos que lo llevaron al suicidio á la edad de veinte y ocho años. Fué el autor de una novela historica y de algunas adaptaciones para las tablas, pero su fama está principalmente basada sobre la prosa vigorosa de sus ensayos satiricos, los cuales parecieron bajo varios seudónimos. Apesar de su temprana muerte está considerado como uno de los primeros autores del siglo.

KEY TO EXERCISE XIII. (1)

1. ¿ Desde cuando tiene el señor banquero M...... la cruz de . . . . ?
2. Le fué conferida despues de la guerra.
3. Me alegraré desmentir los rumores falsos que han corrido por la ciudad.
4. Fué herido de un pistoletazo en el brazo derecho.
5. ¿ Fué el derecho, ó el izquierdo ?
6. Ya he dicho que era el derecho.
7. Inferí que estaba malo, no le he visto por muchos dias.
8. Ese hombre es capaz de pervertir á la persona más sabia, sus doctrinas son escandalosas.
9. ¡ Vamos á la feria ! de seguro que podremos comprar buenos potros y caballos.
10. El salondo fumar está al fin del jardin.
11. Iremos mañana á la fundicion de cañones.
12. El ladron con la ganzúa abrió la puerta.
13. El centinela está en la garita.
14. Tiene Vd bastantes uvas para hacer la vendimia. No, no tengo bastantes, pero tengo hermosos racimos.
15. ¿ Tiene Vd viñas ? Tengo dos, una en Moguer y otra en Jerez.
16. El eje se rompió cuando los caballos iban al galope y el coche volcó.
17. Se representa á la muerte con una guadaña y un reloj de arena.
18. Los segadores tienen la supersticion de si al segar cortan algun animal, sea pájaro, conejo ó cualquier cosa animada, que han cortado su vida.
19. Despues de concluida la cosecha los segadores bailan en la era, es una costumbre que data de la edad media.
20. La fuente del jardin es de mármol y el agua muy limpia.

KEY TO EXERCISE XIII. (2)

1. I come to inquire into the details of the theft which took place yesterday.
2. We can say no more than what we have said already.
3. It would be possible to catch the thieves if we made haste.
4. It is not worth the trouble; what they took is of little value, and, after all, " live and let live " comes in well here.
5. He is a man of strong will, he has risen from nothing, and look at the position he holds ; think of all the difficulties he has had to conquer.
6. He is very distinguished.
7. Let us go to catch the train. It is late, and if you do not arrive in time you will not catch it.
8. Be careful; thou art scattering that seed, and there will be none left for the garden.
9. That woman is very frivolous and superficial.
10. Last night we went to the gallery of the " Theatre Royal." I did not like the tragedy ; the leading lady is too old, and the leading man cannot declaim.

THE MODERN LOCOMOTIVE

A. Four-cylinder compound "Atlantic" type express locomotive, G. N. R., built at Doncaster works, to the designs of Mr. H. A Ivatt. There are two high-pressure cylinders outside the frames, and two low-pressure cylinders inside. B. End view of same, showing smoke-box. C. End view of same, showing the fire-box, interior of cab, and controlling gear, injectors, etc. D. "Consolidation" type (2—8—0) mineral locomotive, G.W.R., built at Swindon works, to the designs of Mr. J. G. Churchward

RAILWAY MANAGEMENT

Division of the Railway Administrative Staff into its Several Departments, and the Responsibilities of Each

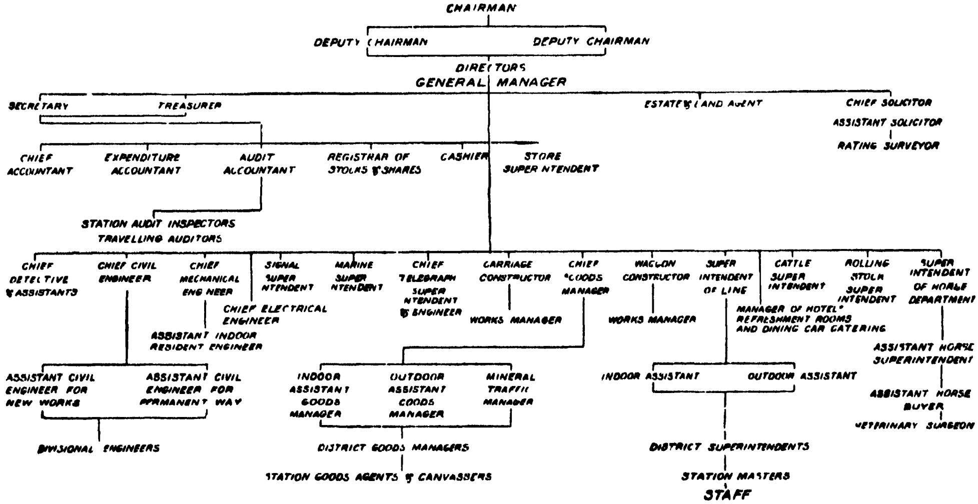
Continued from page 4189

By H. G. ARCHER

THE policy and administration of a British railway company is vested in a board of directors, presided over by a chairman and two or more deputy chairmen. The directors are elected by the shareholders. A certain number of directors retire annually or semi-annually, but are eligible for re-election. Any shareholder, provided that he possesses the qualification of holding a specified amount of ordinary stock, is eligible for a directorship. Besides electing their directors, shareholders also elect the auditors of the company. The full board of directors, as a general rule, meets once a month; but there is a number of directorial committees whose members confer together, and with the managerial chief or chiefs of the particular department which the latter represent, at more frequent intervals. For example. there is a finance committee, in close touch with the secretary, treasurer, and chief accountant; a traffic committee, who consult with the superintendent of the line and chief goods manager; and a locomotive committee, who associate themselves with the chief mechanical engineer, or locomotive superintendent; together with Parliamentary, Fares and Rates, Debts and Goods claims, Hotels, Docks and Steamboats committees, etc.

The General Manager. The responsible officer for the whole executive administration of a railway is the general manager. He acts as "chief of the Staff" to the entire undertaking, and although, of course, it is not practicable for him to supervise personally the actions of every employé, he is accounted the connecting link in the chain of responsibility between the board and the lately-joined lad porter. General managers have been known to rise to their pre-eminent position from very subordinate grades of the staff. No particular branch of the railway service can be earmarked as holding the ladder of success. True, the majority of general managers have mounted its rungs through the traffic department; but there are many instances of locomotive superintendents, engineers, and representatives of the Legal Department having attained the "blue ribbon" of the railway service.

Administrative Departments. The various administrative departments of a great railway company are best explained by diagram [1] The statutory officers are scheduled on the reader's left in the diagram. The existence of any or all other officers concerns the railway companies alone. Parliament in passing railway Bills realises the need of a secretary and treasurer only (although the posts may be combined by one individual), the former to keep the records and registers, and the latter to be responsible for the cash.



1. THE EXECUTIVE OFFICERS OF A GREAT BRITISH RAILWAY COMPANY

The general duties of these statutory officers are clearly defined. The secretary attends all board meetings, and makes record of the business done. He signs and issues stock certificates and transfers of every kind, executes mortgage bonds, agreements, and all manner of deeds, and his name *often* appears at the foot of the company's advertisements for tenders, notices of shareholders' meetings, and schedules of the bylaws exhibited for public information. The secretary, in short, is the legal representative of a railway company, while in most matters of policy, and in all those of finance, he is the adviser as well as recorder. Secretaries are the diplomatists of the railway service. In some instances, a secretary combines the duties of treasurer; but with the great companies the treasurer's is a separate department, which is subdivided, as shown in the diagram.

The Treasurer. The treasurer controls the management, collection, and expenditure of the company's revenue and is responsible for all the incoming and outgoing moneys to both the shareholders and the State; therefore, he must be supplied with the most detailed information regarding receipts and expenditure from every source, together with detailed statements of the company's liabilities. His right-hand men are a chief accountant, an expenditure accountant, an audit accountant, a registrar of stocks and shares, and a chief cashier.

Besides keeping and checking the accounts, the treasurer is charged with the preparation of all financial statistics required by the Board of Trade, statements furnished to the assessor of railways for valuation roll purposes, and those supplied to the Income Tax Commissioners—in short, all statements which in any way affect the financial concerns of the company. The departmental staff of the chief accountant of a great railway company, whose half-yearly balance-sheet runs into several millions of pounds, is a vast organisation of itself. It comprises scores of travelling auditors and bookkeepers, and a regular army of clerks engaged in recording and checking numberless financial transactions.

Railway Revenue. A railway company's revenue is derived from a variety of sources. The primary business of a railway is the transportation by rail (1) of passengers, (2) of goods. Under the receipts from passenger traffic are included not only the fares paid by ordinary passengers and season-ticket holders, but also the money paid for the conveyance of excess luggage, mails, parcels, carriages, horses, dogs, etc. Goods traffic receipts comprise the payments made for the transport of minerals, general merchandise, and livestock.

In addition to the above traffic receipts a railway company enjoys a large revenue from miscellaneous sources—such as steamboats, canals, docks, house rents, tolls, hotels, refreshment catering, etc. A remarkable feature of British railways is the large amount of capital sunk in steamboats, docks, hotels, etc., and the large amount of money spent on purposes entirely outside the working of trains. The companies which indulge most in these "side shows," as they are termed, are the Midland, the Great Central, and the London and South-Western. At present there is a strong predilection on the part of railway companies either to buy up existing docks, or to build new ones, and to establish fleets of cross-channel passenger and cargo steamers. The Great Northern furnishes the most striking instance of a railway company which has always steadily adhered to the principle of confining its business, as far as possible, to traffic by rail.

Stores Department. The stores department forms the commercial arm of the service. It is said of the chief storekeeper that he is the only railway officer whose principal qualification is that of a merchant; yet, while he needs no special railway service, he can be trained nowhere else. In the stores every conceivable requisite for railway working is found in stock, from the rails, sleepers, and chairs for the permanent way and the fuel and oil for the locomotive, down to the sponge cloths used in cleaning, the tools with which all repairs are executed, and the soap and towels which the passenger finds in a lavatory. All departments are dependent upon the storekeeper's vigilance and readiness. He has to be a specialist buyer of everything, at one moment bargaining with a steelmaster for rails, at another with a clothier for the supply of cloths for guards' and porters' uniforms. Then, he has closely to observe the daily prices of all commodities that fluctuate, so as to place contracts in the cheapest market. When he has completed his contracts he must see that the goods are supplied in the quantities ordered, and subject the latter to tests for quality. After this, he is responsible that they are distributed throughout the system where they are likely to be wanted, and can be got at without delay. But he not only buys and distributes, he also sells all old or worn-out materials—sleepers, telegraph posts and wires, rolling stock, fittings, etc.—again watching the market to judge of the best time for disposing.

The Legal Department. Every important railway company has its own legal department. The chief solicitor is the directors' principal legal adviser on matters of policy, and he or his qualified assistants are at all times accessible to the officers of every department. The legal department is, as a general rule, pretty sharply divided between a staff of assistant solicitors for Parliamentary work; another staff of assistants experienced in conveyancing, in respect of the company's landed interests; and another staff learned in Common Law, who deal with the constant crop of matters in connection with claims, outstanding accounts, demurrage, and prosecutions for breaches of bylaws, and frauds.

The Traffic Department. The normal organisation of a British railway company furnishes the general manager, as head of the traffic department, with two trusty lieutenants in the persons of a chief goods manager, and a superintendent of the line. The first-named has two assistants, one for outdoor working, and another for the indoor, including the making of rates, while occasionally a third assistant —a mineral traffic manager—is added. The superintendent of the line deals with the working of the trains, both goods and passenger, and controls every factor pertaining to the movement of the traffic, except the supply of the necessary locomotive power.

It is impossible to consider the working of the passenger traffic altogether apart from that of the goods, as every kind of train has to be accommodated to a great extent upon the same lines of rails.

Superintendent of the Line. Therefore, the superintendent of the line is the absolute head of everything connected with the movement and handling of the trains, both passenger and goods, and is in charge of all stations, except big goods yards. His operative duties are as follows: the control of every individual in the traffic department, including the shunting staff, responsibility for providing a sufficient service of passenger and goods trains, and for their economical working, for the safety of the working, and for the staffing of the trains. Then, the preparation of the time-tables, both public and working, and all matters concerned with the appointment, supervision, and promotion of the traffic staff are in his hands. Further, he travels with and takes charge of Royal and other extra-special trains. But his duties are not confined to the operative side of the traffic working. He is also responsible for the commercial side of the passenger traffic—that is, the securing and charging for ordinary passenger and excursion traffic, and all traffic carried by passenger trains, termed "coaching traffic."

How vast and far-reaching in its scope is the organisation of the superintendent of the line's department may be judged from the accompanying diagram [2]. For the commercial administration of the goods and mineral department, the entire railway system is divided into districts, under district goods managers, each of whom has a station agent (who is of equal rank with the stationmaster) and a town agent, together with a staff of canvassers, clerks, foremen, checkers, loaders, carmen, etc However, in less important districts, it may be possible to dispense with the services of a district goods manager, in which case the district superintendent becomes responsible for both passenger and goods working. Likewise, at small stations, the stationmaster acts as goods agent as well.

At stated intervals, "officers' conferences" are held at the company's general offices. These conferences are attended by the chief officers at headquarters, and by the whole body of district traffic superintendents and district goods managers. But the conferences are kept distinct—namely, traffic and goods, with the general manager presiding over each.

New System of Organisation. As already stated, the foregoing is the normal organisation; but certain companies have recently struck out a fresh line, which closely follows the American practice. With the old system of organisation, it is alleged that the

2 TYPICAL ARRANGEMENT OF STAFF AND DUTIES—OFFICE OF SUPERINTENDENT OF THE LINE

functions of the goods managers and district superintendents overlap one another at several points, and that the superintendent of the line's department is handicapped in the efficient plan-making and discharge of its technical duties for the economical handling of traffic by reason of its incorporating such essentially commercial features as parcels, advertising, canvassing, etc.? and being burdened throughout with an excess of office work. The new idea is to effect a complete severance of the commercial and operating branches throughout the traffic department. In the beginning of 1902, the North-Eastern Railway reorganised its traffic management on these lines, and the Great Northern Railway soon followed suit. The following is a *précis* of the new arrangement. There are three chief officers—*viz.* :

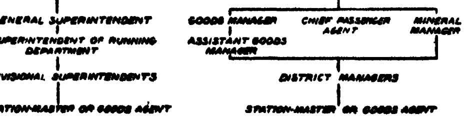
1. The *general superintendent*, who is charged with the movement and handling of traffic everywhere, and in every shape or form ; and supervising the use of the company's telegraphs and telephones.

2. The *chief goods manager*, who is charged with the administration of the department of the company's business connected with the securing and charging for merchandise, livestock, and mineral traffic

3. The *chief passenger agent*, who is charged with the administration of the department of the company's business connected with the securing and charging for all ordinary passenger and excursion traffic, and all traffic carried by passenger trains termed "coaching traffic"; preparing, printing, and issuing tickets ; advising the general superintendent as to the needs of the train service ; collecting and distributing information as to trade movements and developments ; supervising and controlling the booking and parcels office

Subordinate Officials. These three officers are responsible to a general traffic manager, and each has an organisation of subordinates, giving a carefully arranged system of devolution. Thus, with the North-Eastern Railway, the general superintendent has three divisional superintendents, below whom come nine district superintendents. The chief goods manager has six district goods managers, and to the chief passenger agent are allotted three district passenger agents.

With the Great Northern Railway, the arrangement is precisely the same, save that the general superintendent is assisted by a high official, known as the superintendent of the running department.



8. DIVISION OF OPERATING AND COMMERCIAL DEPARTMENTS IN THE TRAFFIC DEPARTMENT OF THE GREAT NORTHERN RAILWAY

Superintendent of Running Department. The duties in connection with the section under the immediate control of the superintendent of the running department are as follow :

1. Selects and controls yard and platform inspectors, foremen, guards, brakesmen, signalmen, and shunters, employed exclusively in the running or working of trains.

2. Arranges and controls the working of all passenger, goods, and mineral trains, and of all shunting in yards.

3. Arranges with rolling stock controller as to provision of carriages, waggons, and sheets required for working the traffic.

4. Arranges working of all dining cars.

5. Arranges with locomotive department regarding engines required for traffic purposes.

6. Arranges with signal inspector regarding ordinary matters of traffic working ; proposals for alterations of, and additions to, lines, stations, sidings, etc., and other special matters to be submitted through general superintendent.

7. Controls fog-signalling arrangements.

8. Reports upon all accidents, including cases of injury to passengers, employees, horses, cattle, and livestock.

9. Deals with cases of damage to rolling stock.

10. Supervises the cleaning of all rolling stock, also of cattle-pens.

11. Prepares and issues working and public time-tables and all notices with regard to the proper and safe working of the line.

12. Deals with correspondence from the public relating to the working of trains.

Clerical Staff. As a principle, the supervision and control of the clerical staff, together with the cartage arrangements in the provinces, fall to the commercial section, and that of the outdoor staff, including the staff employed in the goods sheds and warehouses, to the operating section. Exception is made, however, in the case of clerks whose duties are confined entirely to matter connected with the operating section and any members of the uniform staff specially employed in the commercial section.

Engineering Department. The chief (civil) engineer is at the head of two important branches—namely, one for maintenance of existing lines and works, and one for construction of new works. His assistant engineer, for maintenance of permanent way and existing works, has under him a quota of divisional engineers, and, if necessary, a canal engineer as well, while the subordinates of the former are the district engineers, draughtsmen, chief inspectors, sub-inspectors, foremen gangers, and platelayers, and relayers, artificers, carpenters, masons, etc., with their respective foremen. It may be added that when platelayers are engaged in fog-signalling, they pass under the jurisdiction of the traffic department, as represented by the superintendent of the line. His second assistant, the engineer for new lines and works, takes charge of operations once the plans have been prepared by the chief engineer, or, if the services of a consulting engineer should have been requisitioned, have been approved of by the latter. He has under him resident engineers, who, as the name implies, supervise operations on the spot, and are provided with assistants and draughtsmen. As a rule, the construction of a heavy length of line, harbour, or large station works, etc., is entrusted to a contractor, who carries out his task under the superintendence of the company's engineer for new works.

Locomotive Superintendents. We now pass on to the locomotive superintendent, whose duties embrace the designing and building of suitable locomotives for the various classes of traffic—for instance, express passenger, goods, suburban, "mixed," etc.—the maintenance and repair of engines, and the administration of the running department. In designing his engines, the locomotive superintendent, of course, takes his cue from the traffic department, which keeps him informed as to any projected increases of load and speed. His right-hand men are, first, an assistant locomotive superintendent, who is virtually in charge of the running department; secondly, a works manager, since most railway companies have their own engineering shops, where the locomotives are built. If a company go to private firms of locomotive builders for engines, the latter are still built strictly according to the specifications prepared by the locomotive superintendent. Below the assistant locomotive superintendent come the district locomotive superintendents, one or more locomotive accountants, and a staff of draughtsmen. This, in turn, brings us to the men who keep engines in repair at the running or steam sheds—foremen fitters, together with smiths of various descriptions; and the men and youths who prepare them for the road—coalmen, lighters-up, sand-driers, cleaners, washers-out, and bar-boys.

Chief Mechanical Engineer. As a general rule, the locomotive superintendent is no longer known by name as such, for he has blossomed forth into a far more important personage, with the title of chief mechanical engineer. In old days, the chief (civil) engineer was responsible for everything of a mechanical nature, and therefore had charge of the company's steamships, stationary engines, turntables, hydraulic installations, water-columns, etc.; whereas now it is the fashion to divide the department into two, respectively under a chief mechanical or dynamomical engineer, who deals with all moving machinery whatsoever, and a chief civil engineer, who may be said to be responsible for all machinery that does not move.

The smaller companies entrust the designing and building of carriages and waggons to their locomotive superintendent. More important companies have a distinct department for the purpose, under a carriage and waggon constructor; and the London and North-Western Railway finds it necessary to have both a carriage and waggon department, the works of the former being situated at Wolverton, and those of the latter at Earlestown, while the locomotive works are at Crewe. The carriage and waggon constructor has his own works manager, assistant superintendents, and draughtsmen, and his responsibility extends outside the works to the men who examine, repair and clean the vehicles all over the line.

Electrical Engineer. Modern conditions have added yet another highly-placed official to the engineering side of a railway in the person of a chief electrical engineer, who undertakes the maintenance of the power-houses and plant employed for traction on electrically operated sections of the line, and generating the current for lighting stations, goods yards, and offices. In addition, he advises or is intimately connected with the management of the signalling and telegraph department, as regards the rôle played by electricity in various kinds of signalling apparatus, and again, has charge of the arrangements for the lighting of passenger trains by electricity.

Signal and Telegraph Departments. The signalling and telegraph department proper is usually reckoned to fall within the scope of the chief civil engineer. Nevertheless, it possesses an organisation of its own, beginning with a signalling superintendent, and extending through a long chain of subordinates—namely, assistants, draughtsmen, signal inspectors, telegraph inspectors, fitters, signal linemen, and telegraph linemen.

Other Departments. The number of horses employed by the principal railway companies in "collection and delivery," and also (though in a steadily diminishing quantity) for shunting purposes, runs into many thousands. For example, the studs of the London and North-Western and Midland companies each include over 5,000 animals. This department is presided over by a horse superintendent, aided by an assistant superintendent, a horse buyer, and a staff of veterinary surgeons, together with inspectors of horses, provender, and stores.

The companies that own fleets of steamships and docks require the services of a marine superintendent, who exercises control over dock superintendents, ship captains, and officers, seamen, wharfingers, and dock labourers.

Now that so many companies possess hotels and also own the station refreshment-rooms, yet another department has been added to the headquarters administration—namely, that of the hotels and refreshments manager, with a staff of resident managers and cashiers.

Railway companies are empowered to let houses and lands of which they are the owners, and of which they may not require the use at the time. These circumstances call for the services of an estate and land agent, whose subordinates comprise surveyors, rating agents, assistant agents, and district agents. Lastly, for the better protection of their customers' interests and to conduce to the maintenance of good order within the precincts of stations, the companies have their own staff of police inspectors, detectives, and constables, commanded by a police superintendent or chief detective officer.

THE SUB-EDITOR

The Window-dresser of Journalism. Functions of the Sub-Editor. The Treatment of News. Headings. An Examination and Some Examples

By ARTHUR MEE

A GOOD sub-editor is worth his weight in gold, and he is as rare as he is precious. His position is second in importance only to that of his editor-in-chief. Upon him falls the responsibility of the final shaping of the paper as it goes to press. He is the window-dresser of journalism.

The Two Kinds of Papers. Most people, however little they know of journalism, know the difference between a bright paper and a dull paper. The dull paper is a sheet of solid type, in which one column looks as attractive, or as unattractive, as another; in which no effort is made to attract the eye at once to the most interesting news; in which most things are recorded faithfully and tediously as the "Annual Register" recorded them a hundred years ago. In the dull paper there is no change. It remains to-day as it was yesterday; it will be to-morrow as it is to-day Next Saturday's copy will look to the eye very much like last Saturday's, and the date at the top is the only way we can tell at a glance whether the paper is new or old. It is the solidest and most reliable thing in the world. It never disappoints us because it gives us no expectations. It never surprises us because we know exactly what it will tell us. That is the dull paper of the old days.

The bright paper looks as though it were alive. We feel as we open it that the world is a live place and not a museum. We feel, if we read it in the quiet countryside. that we are in a dream, with all the world outside us alive with energies, and wars, and crises, and that this busy world was never so busy as this morning. We open it and know at a glance what most people are talking about. We turn to a particular place, and if our eyes meet no sensation there we know that there is no sensation for them to meet. We feel that nothing in the world is unimportant. The headings are finger-posts pointing to a hundred avenues of human interest, whereon the busy man reads all he wants to know, from which the man of leisure discovers whether the matter will interest him or not. We know at once whether we must settle down quietly to read the paper or whether a glance as we wait for the train will do. It is the genius of the modern paper that it tells us as from the housetops the things that it contains. That is the bright paper of our own times.

The Sources of "Copy." The difference between the two is the sub-editor. It is fitting here, perhaps, to consider for a moment the economy of the newspaper office. At the head, of course, is the editor, whose word is law. Below him is his assistant. It is the editor's duty to direct the general policy of the paper, but the actual machinery by which news is collected from the ends of the town and the ends of the earth is under the immediate control of the news editor, who has authority over the sub-editors. Separate from these are the reporters, responsible in London to the news editor, and in the provinces to a chief reporter. In addition to these are special members of the staff whose functions are well defined on all leading papers, but whose duties are largely covered on small papers by the general staff. Among these are the leader writers, whose duty it is to write the editorial articles which set forth the views of the paper; the musical and dramatic critics, the sporting editor, the literary editor, the financial editor, the foreign editor, the magazine editor, the political editor—all these, individually or collectively according to the position of the paper.

From all these various departments comes the supply of copy, and not from these only, but from an innumerable host of correspondents in every town in the kingdom and in every country in the world. Through the Press Association and the Central News, or, in the case of the leading papers, through local correspondents of their own, the daily papers in every town have channels of communication with every other town. From early morning till after midnight, from early morning, indeed, till early morning comes again; to-day, to-morrow, and the day after; on, and on, and on without ceasing, the stream of copy comes. It comes in scattered fragments from the ends of the earth; it meets for the first time at the sub-editor's elbow—a battle story from Havana, a Parliamentary debate at the Cape, an excavator's discovery in Babylon, a wonderful wheat crop in California, a little child's death in London—all this panorama of the doings of a world comes together on the sub-editor's table.

The Sub-editor's Qualities. It is the business of the sub-editor to prepare copy for the printer, and, simple as it sounds, the work demands the exercise of many qualities which are all too rare. His post is more difficult to fill than any other post in journalism; it may be said that a good paper is always wanting a good sub-editor.

He will have prepared himself for the sub-editor's room, perhaps, along the lines we have considered. He should possess the general knowledge essential to every journalist in any capacity, and a year or two of reporting will do him a great deal of good. The qualities that will help him most, which his work will develop in him and he should never cease to cultivate, are a capacity for discovering the most interesting aspect of events; an ingenuity of expression; a real sense of the true proportion of things; the ability to condense a long report into a short one without sacrificing vital points; a genius for putting things in the most striking way; an excellent memory; a great contempt for verbosity or "wordiness;" and a hundred other things which only experience can reveal to him.

It is not easy to make up one's mind which of these qualities, if any, is the chief. The ideal sub-editor has all of them, and he could hardly point to any one of them and say, "I owe my success to this," "I owe my success to that." The man who will succeed as a sub-editor will do his utmost to train himself in all these varied ways. It can hardly be doubted, however, that journalism is developing along lines which make it more and more essential for sub-editors to be alert and keen not only for new facts about things, but for new aspects and new theories. It is interesting to know that a prisoner has escaped from prison, but it is much more interesting to know how he escaped. It is interesting to know that a great business has been ruined; it is much more interesting to know why.

How to Deal with News. If there has been a railway accident, it is more than likely that the most interesting thing in connection with it will be by no means the most obvious. The number of victims, though it adds to the sensation of the news, is not of any essential interest. It is terrible to know that fifty people lose their lives in a moment; it is a much more intense and dramatic thing if the accident was caused by an overworked signalman falling asleep after sitting up for a week at his little girl's deathbed. A terrible railway accident has just happened as this is being written, and one of the accounts brings out a striking picture of the train waking up the whole town as it dashed through the station and fell down an embankment. Nothing in this appalling story is more impressive to a journalist than the thought of this train waking the sleeping country town at midnight.

The sense of proportion is a vital possession. It is one of the faculties that no sub-editor can do without. He must, of course, learn to adjust it to his paper; he must, that is, realise that a proper proportion of news in one paper may be an absurd disproportion in another. Obviously, if he is on the DAILY NEWS the meetings of the Free Church Congress will be of much more importance to the readers of his paper than the meetings of the Primrose League, but the proportions would be quite reversed if he were on the MORNING POST. But he must learn a much more important thing than this. He must have the gift for discovering what is interesting to the public, and of putting these things, as a shopkeeper would say, in the front.

The Paper must Look Interesting. We come into touch here with the real genius of sub-editing. There are two supreme tests of a newspaper: Is it interesting? Does it *look* interesting? The first is the business of the editor; ultimately the responsibility for the interestingness of a paper lies with the man at the head. It is the editor-in-chief, with the news editor, who directs the supply of news which the sub-editor must deal with. Whether the matter is interesting or not is not a question for him. His concern is entirely with the treatment of it. He must, of course, decide upon the comparative interest of various items, and apportion them space accordingly, but his work lies with the matter supplied to him and not beyond it, so that in reality the question whether the paper is interesting or not depends upon the editor; he may have ideal sub-editors and his matter may still be dull.

But it is the sub-editor's own fault if his paper *looks* dull. How often are we attracted to a shop window by a bright display, only to find on a closer view that its contents do not interest us at all! The window-dresser has done his work well; he has been better than his master. The simile is so expressive that it seems hardly necessary to say any more. The sub-editor who remembers all the time that he is dressing a window will not go far astray. He must, of course, remember that even a window-dresser has responsibility. He must never deceive his readers by a heading which is misleading, any more than a draper must put superior articles in his window to advertise inferior articles inside. He must remember that in these days the busy man casts his eye rapidly over the paper, and often obtains his impression of the news of the day from the headings only.

News Without Views. More and more are headings becoming little summaries of what follows, and the sub-editor should be careful that his headings do not convey a false impression. A very striking case in point comes to mind. The proprietors of PUNCH appealed against a decision in a libel suit in which PUNCH was involved, and the appeal failed. The sub-editor was right in realising the interest of the case, but his strength was not in his discretion, and he headed the case PUNCH FAILS. It would not have been surprising to have heard a reader of that paper say to a friend at lunch that day, "I see that PUNCH is bankrupt," and one is glad, for the sake of the sub-editor and his paper, that Mr. Punch is such a merry man. The experienced sub-editor is keenly aware of the subtlety of temptation, and it is not the easiest thing in the world to write headings which shall go as far as they legitimately may go, and not a hair's breadth farther. It is not merely the risk of libel that must be guarded against, but the risk of conveying misstatements and false impressions.

Most of all the sub-editor, in writing headlines, should guard against the pernicious habit of importing opinions into headings of merely news events. It is quite legitimate for him, and may be his duty, to remember that his paper has certain views, but his first concern is not with these. In dealing with news the sub-editor should have no views; he should know no politics. He may believe that a certain man is a scoundrel, but if the man dies he must not head the news of his death DEATH OF A SCOUNDREL. Yet things are done by sub-editors quite as careless and quite as bad as that would be. Such things are not only bad journalism, but bad policy. A newspaper is first of all a conveyer of news. It should be possible for a man of any views to buy it, to be interested in it, and to obtain from it a fair impression of what is happening in the world. The sub-editor who forgets his duty by introducing bias into news is an enemy to his paper and his profession. He alienates the very important section of the readers of his paper who do not believe in the paper's politics but who buy the paper for its news, and he encourages a practice which would make journalism the tool of propagandists and parties instead of a living history of our times.

The Wrong Sort of Headings. The sub-editor will find it all too easy to blunder in headlines. He will find himself late at night with a heap of telegrams through which he must run quickly lest they be too late for press, and he will catch sight of some word or phrase which, in his haste, he will seize upon for a heading. The result will be what often happens, that we find ourselves reading a paragraph which has no real relation to the headline which attracted us. An actual example may be more helpful than any advice.

In a London paper the other day was a report from which it appeared that a pauper in London, who was charged with assault, had been in the workhouse since he was two years old, and that in 1883 he was sentenced to penal servitude for trying to set the workhouse on fire. This paragraph was coupled with another, not to be compared with it in interest and importance, from which it seemed that a violent pauper had spoken of a workhouse as "a British Bastille." A good journalist will find it difficult to believe that an important London daily paper headed these two paragraphs ALLEGED BRITISH BASTILLE.

A Sub-editor's Sin of Omission. Let us examine the heading. It was, in the first place, bad sub-editing to couple the paragraphs. The second paragraph was unimportant, and should not have been allowed to detract from the remarkable interest of the first. But, this mistake having been made, nothing could be more ridiculous than to select the heading from the second paragraph. The result of this was that (1) the first and most interesting paragraph was overlooked, and (2) the crazy nonsense of a crazy pauper was treated with all the respect and dignity due to an expression of opinion by, say, Lord Kelvin. It is ridiculous to suggest that there is anything like a British Bastille because a pauper says so.

But it is doubtful if the sub-editor's sin of commission, serious as it was, was half so great as his sin of omission. The first paragraph was intensely interesting, and the sub-editor failed entirely to see the point in it. It is true that the report was faulty, in that it did not give the age of the pauper, which was an important fact; and the sub-editor, if there had been time, should have discovered his age. That, however, may be left out of account, for the paragraph bore inherent evidence that the man had been in the workhouse since he was two, a total of at least forty years. He was, surely, the most interesting figure in that day's papers—a man who had lived forty years without a penny of his own, who had never done a stroke of work in his life except when he tried to set on fire the home with which a philanthropic nation provided him. That is the fundamental idea of the paragraph, a human document of the greatest interest, lost to the paper through bad sub-editing.

The Inaccurate Heading. It is not possible to discuss at equal length all the other points that come up in considering headings, but we may glance briefly at a number of headings taken at random from various papers. Here is one.

LIFE ON FOURPENCE A DAY.

PAUPERS WHOSE KEEP COSTS BUT ¼D. MORE.

Nothing could be more absurd than this. The paragraph explained how certain people lived on 4¼d. a day, and the sub-editor, straining for a heading, framed one containing a misstatement and demanding an explanation. It was as if, for the sake of round figures, he had headed a war telegram

A THOUSAND KILLED IN BATTLE.

AN ENGAGEMENT COSTING ONLY 43 LIVES LESS.

Headings should never need to be explained. If they are not clear at a glance they should not be used. It is easy for a sub-editor to become so engrossed in an article that one idea stands out prominently in his mind, and to "head" the article as though it consisted only of this idea; and the result in that case might be that the heading, though fitting a special interpretation of the article, was obscure to nine readers out of ten, and possibly to the author of the article himself.

The Dangerous Heading. Here is another example of a heading which no editor should allow.

GERMANY'S ISOLATION.

"INEVITABLE" WAR WITH ENGLAND

"A PIECE OF STUPIDITY."

It cannot be doubted that the effect of this heading is to create an impression that war between England and Germany is inevitable. But we know that the sub-editor meant nothing of the kind; he meant that it is a piece of stupidity to say that war with England is inevitable. And yet the vast difference between these two meanings is allowed to rest on the mere absence of a full stop at the end of the second heading. This is unpardonable. There was, in the first place, a rule between the lines, and a rule in the middle of a sentence is absurd; and, in the second place, the mere absence of a full stop is a slight method which might be due to an accident, and in any case is quite common in headlines, and should never be relied upon in circumstances such as these. This heading conveyed to thousands of readers an impression exactly opposite to that which the paper desired to convey.

The danger of conveying wrong impressions by carelessly written headings was illustrated in another paper reporting the death of a Belfast gentleman while exploring some famous cliffs. Seizing on the word "exploring," the sub-editor headed the report in big type EXPLORER KILLED, leading one to expect that some other Stanley or Livingstone had come to an untimely end. As a matter of fact, however, the gentleman was not an explorer at all, but a manufacturer, and all the exploring he had done was the sort of exploring we all do when we go to Hastings, or Brighton, or the Lakes, or anywhere else, for a holiday.

The Misleading Heading. An evening paper which does not often sin in this respect led its readers astray not long ago with a heading FREE POSTAGE FOR MEMBERS in its Parliamentary report. The impression conveyed—that members of Parliament were to have the privilege of free postage—was not confirmed by the subject matter; a question had merely been asked in the House. It is easier to defend this heading than some of the others we have considered, but there is a subtle error in it which sub-editors should always avoid—the error of leading people to imagine that a thing is a fact when it is merely a subject of discussion.

Another kind of heading to be watched is the joint heading which covers two things. One of the wittiest headings that has ever been written appeared in a London evening paper once when the House of Commons had an all-night sitting. It happened that at the same time the Great Wheel at Earl's Court stuck fast, its passengers being "held up" all night, and the STAR posted London that day with the words: THE HOUSE STILL SITTING; THE WHEEL STILL STICKING. There was an idea linking the two events which made excellent "copy" But the double heading is not always so happy; it was distinctly bad, for example, in a Parliamentary report concerning two separate subjects—cheaper postage for parcels and grants for necessitous schools. One question happened to follow the other in the House of Commons, and the sub-editor, coupling them, headed the report CHEAPER PARCELS AND NECESSITOUS SCHOOLS, leading the reader to wonder what subtle necessity could arise in poor schools for a specially cheap parcels post.

The Feeble Heading. The sub-editor must beware of giving undue importance to a trifling incident. The magnifying of trivial things, or the drawing of large deductions from slight incidents, is perilously near what is known in the newspaper office as "faking," an offence which puts the offender outside the pale of honourable journalism as a lie puts a man outside the pale of honourable society. "Faking" is the invention of news; a "fake" is a newspaper lie.

The sub-editor should beware, too, of such feebleness as that displayed in a paragraph quite unworthy of the paper in which it appeared not long ago. A fire, in which three persons lost their lives, occurred in London at Easter, and the inquest took place on Wednesday of Easter week. Following the report in a morning paper was a paragraph with a heading REMARKABLE COINCIDENCE; a paragraph with no other substance than the fact that on Wednesday of Easter week in the previous year also an inquiry was held in London into the deaths of three persons as the result of a fire. Nothing could well be feebler when we remember that lives are lost by fires in London almost every week; that Easter week could hardly ever pass without such an event; and to speak of such a commonplace as a remarkable coincidence is only to deprive oneself of the power of description when something really remarkable does happen.

The Legitimate Heading. But the candidate for sub-editing will study the papers for himself, will re-write headings as often as he can, and will learn the art of making them short, direct, and comprehensive. There is, of course, a display of headings that is perfectly legitimate, and, indeed, desirable. The days of the old journalism are dead, and the papers which cling to its traditions are dying. They are not, at any rate, the papers of the future. The interesting and enterprising papers of to-day are so familiar to us all that there is no need to single them out, and the journalist can study them as often and as much as he likes. He can compare the papers with old-fashioned headings, which still give a column of interesting matter under one uninteresting headline, with the papers which make their articles attractive; and he can choose which he likes best.

He has only one choice, however, if he is to make his way as a sub-editor. There was admirable wit and meaning in a conversation the writer overheard in a restaurant in London. Two men were discussing newspapers. One thought the TIMES uninteresting There were no headings to guide him, and so on. "The end of the world might come," he said, "and if you took in only the TIMES you would never know it." It is the business of the newspaper to *tell* its reader what has happened, not to compel him to search for the news with a microscope, and the newspaper which puts away the announcement of the end of the world in a corner will abundantly deserve its doom!

The American Heading. It is not, of course, desirable to follow the example of the American sub-editors, whose papers are made intolerable to English journalists by columns of headings which are a disgrace to the King's English. BRIDGE JAM WORST EVER was one of these; it was the sub-editor's way of saying "The Worst Bridge Accident on Record." But the line between the extremes is not difficult to draw, and the instinct of the true journalist will lead him aright.

We may sum up all that is to be said about headings, perhaps, in one or two words. If we have to choose as sub-editors between making a dull article look interesting, or making an interesting article look dull. we must make the dull article look interesting. The days when people read everything have gone, and every reader has become an editor. Every person who reads a paper edits it for himself. He will read only what appeals to him, and *only what appeals to him at once.* He will not sit down to make up his mind whether to read an article or not. He makes up his mind at once when he sees the heading, and the paper which is full of good matter with bad headings will not be read.

The Ideal Heading. The ideal heading is interpretative as well as descriptive. It is an idea rather than a phrase, or, better still, it is both. It strikes the mind at once. It does not call for any mental searching, or for dictionaries. It is plain to the man who runs. It is never misleading, but it need not be severely narrow. It need not be without imagination. It is suggestive, and may express with freedom not only the facts in the article but the thought behind it. It is written in the language of the people, and not in narrow terms of science, or theology, or great learning. It is wide, and free, and clear, yet definite and not vague, accurate and not ambiguous. It puts a thing in the way in which it will appeal to the largest number of people among those for whom it is written. The hope in the journalist's mind when he writes it is that it may impress itself so vividly upon the minds of those who read it that they will not casually pass it by. It takes the line, not of least resistance, but of widest acceptance.

The heading of articles does not, of course, by any means comprise the whole of the sub-editor's work, but it is probably the most important side of it. We have, moreover, devoted special consideration to the subject because a full understanding of it implies a general capacity for sub-editorial work, and in treating of headings we have been able to consider incidentally many aspects of sub-editing.

Kinds of Headings

The sub-editor should make himself familiar with all kinds and sizes of types, and with all forms of headings. There are many kinds of headings. The main title of an article is called the *heading;* the remaining titles are *sub*-headings. The heading of this paragraph is a *side*-head, standing above the matter either to the left or right of the column. The ordinary paragraph headings in the SELF-EDUCATOR are *run-on side*-heads, forming part of the first line of the paragraph. The heading of the next paragraph is a *cross*-head, standing above the matter in the centre. The other specimen shown is a *cut-in side*-head, let into the paragraph in a square space two or three lines deep. The general page headings to articles in the EDUCATOR are known as *box*-headings, a border being placed round the type.

THIS IS A CROSS-HEAD

Such headings have two objects; they may be either finger-posts to the article or simply means of display intended to relieve the solid appearance of the article. A simple way of relieving the heavy appearance of solid type, often adopted in speeches, or stories, or descriptive sketches, is to mark a number of pointed phrases at convenient distances for the printer to set as small cross-heads. This may be done quite easily in the manner indicated at the end of this paragraph, and if the last words of a paragraph are suitable for a heading it is much more convenient for the printers if these are selected. A smart sub-editor can very quickly give a solid column of matter an interesting appearance by making half a dozen [marks of this kind.]

This is a Cut-in Side-head Leaded type is type with blank spaces of varying thickness between the lines, thus making it more easy to read, and it is usual to "lead" articles of special importance in order to call attention to them. The leading articles in most newspapers are leaded. The size of type is governed by the relative importance of matter, and stock features occupying considerable space, such as commercial and sporting news, are usually set in smaller type than the rest of the paper. Small type is, as a rule, to be deprecated, and the type in which the EDUCATOR is set, known as bourgeois, is the usual size for magazine reading

Office Books. In dealing with the copy that comes before him the sub-editor should bear in mind all that has been said in this course and all that is to be said. Only experience can teach him the various ways of dealing with copy; the cutting down of an article five times as long as it should be; the elaborating of an expensive cable which has more points than words, or the dealing with a telegram which has, unfortunately, more words than points; the re-writing of an important piece of copy written without regard to order or grammar or proportion; the elucidating of obscure points; the introduction of explanatory notes and comments. He will know all the reference books which the journalist must have at his elbow; will know every page of WHITAKER and HAZEL: will be familiar with HAYDN'S DICTIONARY OF DATES, with the most up-to-date encyclopædia—at present the HARMSWORTH ENCYCLOPÆDIA; the index to the TIMES, and, of course, the inevitable and indispensable WHO'S WHO. Most of these and a score of other reference books are on the shelves of every well-equipped newspaper office. The sub-editor will have available, besides, the cabinet of information which every efficient newspaper maintains on lines we shall consider later.

He will find his work trying, involving an early beginning if on an evening paper, or working until the early hours of the morning for a daily paper; and unless he is strong and able to concentrate intensely for a long period he should not become a sub-editor. If all the conditions are favourable, however, he will find his work interesting, and if he does it well he may be certain of appreciation and advancement. A good sub-editor is assured of a comfortable living as long as papers last.

WORK IN THE BOOT FACTORY

Bootmaking Machinery and its Operation. Sewing, Eyeleting, Skiving, and Sole-cutting and Pressing Machines

BOOTS AND SHOES
continued from
page 4140

By W. S. MURPHY

FOR fifty years after machinery had been used for making boots the man who entered the trade had to count on meeting a hostile public opinion, in Great Britain especially. During that period it would have been as dangerous to offer an English gentleman a pair of machine-made boots as to suggest that he ought to wear a nose-ring. We say that the hostility was one of opinion, not prejudice, for it was founded on experience and fact. Machine-made boots were either very ugly or very unreliable, and sometimes they were both.

The First Machine-made Boots. The reasons or excuses for this state of matters may be put under two heads—namely, the low-class market catered for, and the crudities of the machinery The factory trade was always a shop trade, and well-to-do customers seldom patronised the shops, or, if they did, it was the bespoke department. Cut-throat competition had reduced profits on factory-made boots to almost nothing, and in the effort to cheapen production, manufacturers introduced machinery. To attempt the market in which the well-to-do purchased seemed hopeless ; the way to success was production of boots at popular prices in attractive styles. Cheapness, for the time, became the sole aim of the machine boot manufacturer, and when cheapness is the chief objective, quality suffers. During the seventies of the nineteenth century, the British boot markets were flooded with a class of boots unworthy of the bootmaking trade ; no worse were ever made since boots were worn ; but they were low in price People, however, soon found that the low-priced machine-made boots were not cheap, and a strong reaction set in. Everybody who could afford it went in for hand-made boots. A considerable section of the artisan class remained who were unable to buy hand-made boots, and for this market the boot factories competed. Prices were maintained, but quality was improved. To meet these circumstances, manufacturers demanded and got better and more reliable machines, or paid the high prices machine makers had required for the best machines.

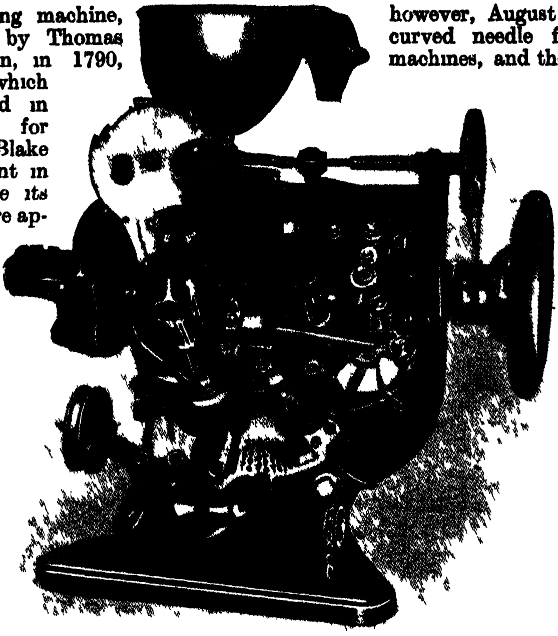
Bootmaking Machinery. According to American authorities, the idea of making boots by machinery originated from an invention by David Meade Randolph, in 1809. The boot in which the sole and uppers are united by pegging has always been made somewhere or other Randolph's machine was devised to insert the pegs and clinch them on an iron last. In 1810, M. I Brunel, improved on Randolph's idea, and patented a sole-riveting machine, which produced fairly good work of its kind

Sewing Machine. During the following 40 years the pegging-machines were improved, but the main direction of inventive effort was towards the making of a machine that would

35. SEWING ON THE SOLE BY A BLAKE OR MCKAY CHAIN-STITCH MACHINE

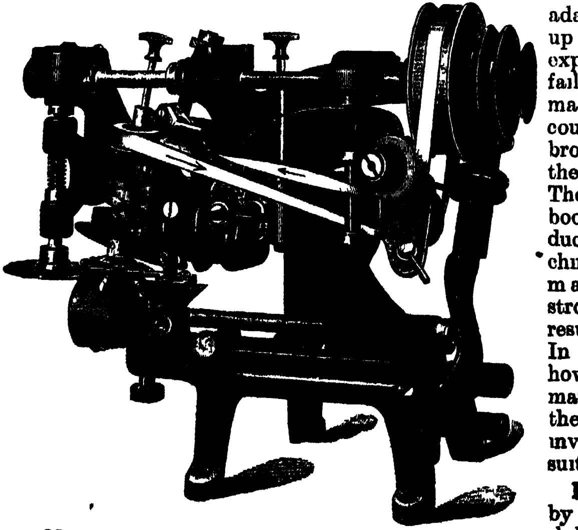
36. CUTTING THE PATTERN TO THE LAST

sew soles The sewing machine, originally invented by Thomas Saint, an Englishman, in 1790, gave the idea upon which Lyman Blake worked in devising a machine for stitching on soles Blake brought out his patent in 1858, and for a time its imperfections were more appreciated than its merits; but the Civil War gave Blake his opportunity Boots were needed in a hurry for the armies the Northern States were massing to fight the Confederates, and though not perfect, Blake's machine [85] could produce sewn boots with great rapidity The original machine is thus described 'This machine is a chain-stitch sewing machine The hooked needle works through a rest or supporting surface of the upper part of a long curved arm, which projects upwards from the table of the machine This arm should be of such a form as to carry the rest into the toe There is a looper in the rest, or horn, and this looper lies in the path of the needle with an eye The thread is led along the curved arm up through the looper and into the eye of the needle, tensions being on it"



37 DUPLEX EYELETER (B U Shoe Machine Co Leicester)

Though this first Blake machine professed to take the thread into the toe of the boot, it was not quite successful, and in 1860 an improvement was added which obviated that defect



38 FRICTION-FEED AMAZEEN SKIVING MACHINE
(B U Shoe Machine Co, Leicester)

Improved Sewing Machine. As the sewing machine then stood, it could not be accepted as a substitute for the hand sewer. It was rather a substitute for the pegging machine. In 1862, however, August Destory invented a curved needle for use in sewing machines, and the American partnership, Goodyear and McKay, successors to the Blake firm, took hold of the idea, and brought out a machine which could sew the boot on the last, and imitate hand sewing

British Machines. That is the story of bootmaking machinery on the other side of the Atlantic, but its history on the British side is somewhat different Long before machinery for bootmaking was thought of in America, a Leicester firm had devised machinery for the purpose, but the inventions were laid aside With plenty of skilled labour at hand, the need for machinery was not keen Besides, the boot required for the British climate did not lend itself readily to machine manufacture For the American climate, boots lightly pegged and slimly sewn were the very thing, and for this class of boot the machines were adapted and speeded up Here we have an explanation of the failure of bootmaking machinery in this country when it was brought over from the United States The American style of boot was not introduced, but the machines were used for making ordinary strong boots, and the results were pitiable In a very short time, however, the machine manufacturers rose to the occasion, and invented machines suited to British needs

Progress. Year by year mechanical skill has overcome more and more all

39. FITTING TOGETHER THE UPPER

the problems of bootmaking, till, at the present day, a well-equipped factory can produce boots that will stand comparison with the ordinary products of the craftsman. It is true, there will always remain a large field for the hand-made boot, and no one who loves his craft would wish it otherwise. No matter how excellent the machine, it can never equal the skilled hand in special lines; the highest class of boot is the special work of a special man. But for the great boot market of the world, the public willing to wear boots short of perfect, at a fair price, the boot factory is the great source of supply.

Number of Operations. As it stands at present, the boot factory is a fine example of the division-of-labour principle in practice. For every detail there is a machine. The making of a boot-top, for example, is a straightforward matter, but our machinist has broken up that process into no fewer than 16 different parts, each part with a machine specially designed to perform that one act alone. Let us take an instance. By smart work a bootmaker can eyelet a boot in about a minute, but here is a little machine that eyelets boots at the rate of 100 a minute [37]. The saving of time is simply enormous. All round the factory the same thing happens. By putting a machine, or set of machines, to carry through one simple detail, you increase production and lessen cost.

The Two Departments. The boot factory, like the bootmaking trade, is divided into two large divisions—the upper-making and the bottoming departments. There are even factories which do nothing except make tops; but, curiously enough, there are no factories employed exclusively in the soling and heeling business, and the question is, Where do all those boot-tops go? We fear that a good many bootmakers buy machine-made tops for hand-made boots. This is no trade secret, but a fact generally accepted, though it may not be widely known among the boot-buying public. Bootmaking by machinery is a succession of small details which may confuse unless we have a clear conception of the general plan of the factory. Before undertaking any piece of work, therefore, we will go round the factory, look into its arrangement, and view the process of manufacture as a whole.

The "Upper" Department. The first division of this department is the cutting or clicking room. The pattern is first cut in paper to the last [36]. Here boot-tops are being cut by the hundred. If the factory be of moderate size, one man is employed on each part of the top; in very big factories groups of men act in the same way, one group cutting out fronts, another group backs, another quarters, and so on. At the same time a smaller section of workers are busy cutting out linings, bindings, and such things. Observe the system. A well-organised boot factory is arranged in a series of circles. From the store-room counter at this side the leathers and cloths are given out, and the materials seem to circle round the cutting-room, and return in the shape of the various parts of boot-tops. Having been inspected, the materials are passed into the machine-room.

Machinery. The machine-room is a place of pretty machines, some of them small enough to go into a man's coat pocket. Here the circular motion is observed. First the parts of the uppers are skived—that is, reduced in substance at the edges. This may also be performed by machinery [38]. After this and other preparation

40. FITTING THE VAMP ON A BLOCK

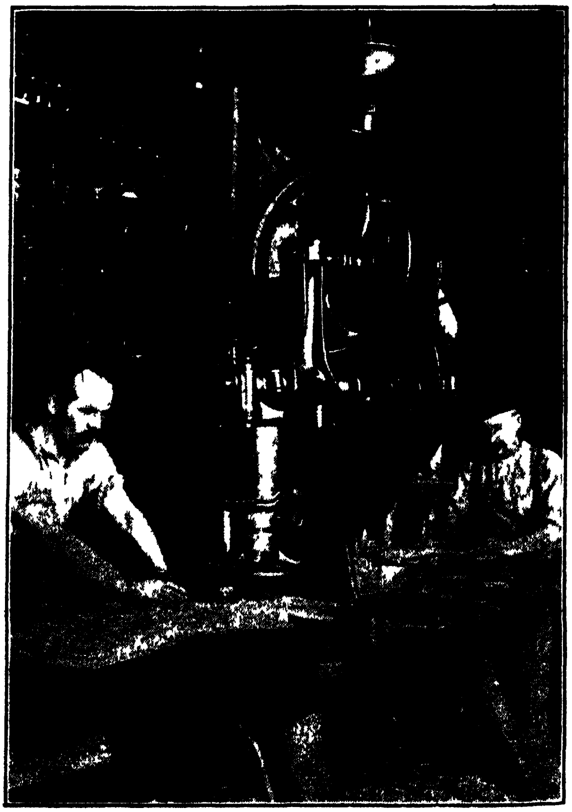
41. CLOSING UPPERS IN A FACTORY

the parts are fitted or pasted together [39] to keep them in position while machining. Sometimes this is done to a shape like a last [40] so as to give it a better shape and fit Linings and tops start on opposite sides of a row of machines, and move along from hand to hand, receiving additions and joinings at each machine, and then they meet, to be put together. In this shape the tops complete the circle [41], arriving at the other end as boot-tops ready for the bootmakers.

Inspection. Before the tops go down to the makers they are passed through the inspecting-room. This is a very important department in all machine factories. With a machine driven at 1,000 revolutions a minute the worker has not time to stop and repair slips; with the inexorable supply coming in on one side of her, and the continuous demand from the machinist on the other side, there is nothing for it but to go ahead. As a natural consequence, a small percentage of defective work is passed through, and must be checked.

The Bottoming Department. Heavy machines are used in this department, and it is therefore planted, where possible, on the ground floor. The machines are grouped together in two divisions, those used for preparing the bottoms, such as presses [42], which are used to press or cut out the sole leather into shapes corresponding with the shape of the bottom of the last; sole-rounding machines [43], each of which consists of a travelling knife made to travel round a wooden pattern the size and shape of the insole or outsole as the case may be. The heavy rollers are for compressing the leather, and take the place of the lapstone of the older craft. Guillotines for cutting the hides or butts into strips are also to be found in this department. Machines for levelling [46] the lumpy parts off the leather are also placed in here. Sole moulders [44] are used for blocking the bottom stuff to the curvature of the lasts, so that when they are sewn they shall be in their proper position. The counters or stiffeners are skived and moulded to shape by the counter moulders [45], while the insole machines feather or bevel the edges so that the substance of the leather shall not hurt the foot or cut into the upper.

The other range of machines last the uppers to the bottoms, tack the soles into position, lay the soles flatly to the shape of the



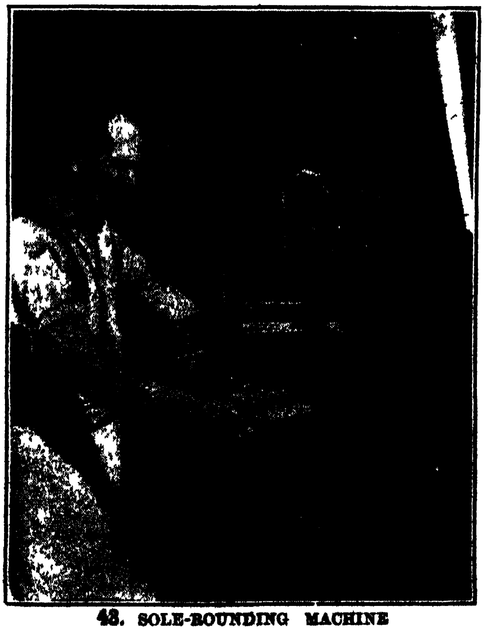
42. CUTTING SOLES UNDER A DOUBLE OPEN-ENDED PRESS

last, and sew the soles to the insoles, rub down the channels and relay the soles, build the heels, and perform many other similar processes. As we watch the process, we cannot help reflecting on the figure it presents of human social development, each generation taking the achievements of its predecessor, adding its quota, and passing the work forward. Beside each machine is a pile of stuff, and as the lasted tops come round another piece is added on, and sewn in place, and the boot is passed forward to another worker, who also adds something.

44. MOULDING THE SOLE TO THE SHAPE OF THE LAST

Finishing - room. From the making-up division the boots are taken into the finishing-room. Here there are machines that turn the heels into their required shape, revolving scouring-pads for giving them the requisite smoothness, and burnishers for imparting the high polish so much admired. The edges of the sole are trimmed to shape by the edge-trimmer, and set by an oscillating heated iron to prevent easy access of water or damp. The bottoms are scoured and stained and polished — all working swiftly on the boots and changing them from rather rough-looking things into finely-finished footwear.

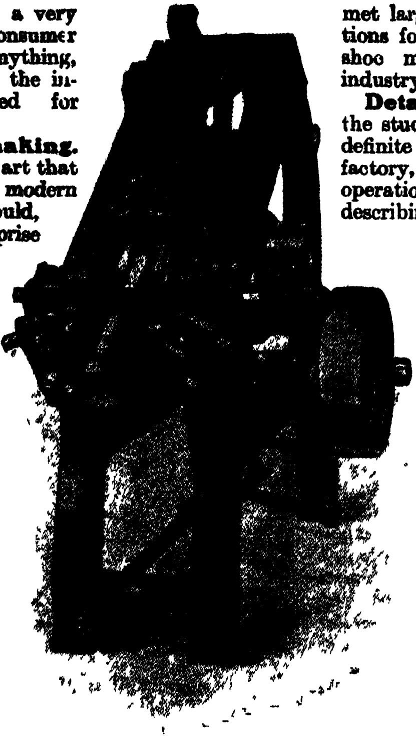
In following the boots we have unconsciously come out of the region of machinery into the quiet of officedom again, and here the inspectors are silently going over the boots before the packers take them away. A peg has sprung, a welt has broken, the channelling has frayed —any damage, small or great, is instantly detected, and the boot thrown out. As the boots are passed, the packers take them away, and they go to the market, wherever that may be.



43. SOLE-ROUNDING MACHINE

Various Factories. From this sketch a general notion of the boot factory may be gathered; but it hardly gives a full account of the trade. Some particulars must be added. Boot manufacture offers a wide and varied field to the industrious and persevering worker. Factories have been established for the making of one class of boots only. One factory that we know very well is employed in producing ladies' fine boots. and that variety alone; another makes children's and youths' chiefly; and there are other works in which only heavy boots are made. This specialisation, while it tends to restrict the worker's experience, affords opportunities to the young and enterprising man seeking to start in business. Matters have come to such a pass that the operative must surrender all hope of acquiring a knowledge of his whole trade in the factory. There is no injury, therefore, in the limit put upon his acquirement by the specialisation of the trade. It is to meet the need thus created that this work has been written. By technical study alone can the worker hope to rise above the position of a machine-minder, or detail labourer, and regain his status as a skilled craftsman on the higher plane offered by machine industry.

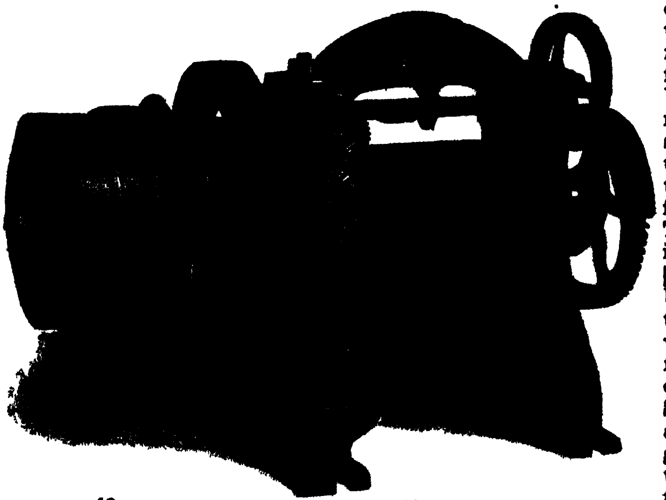
The modern development of the factory system has tended to cheapen and improve the footwear of the medium quality grade. The excellency of the machinery used has given for the same value expended in shoes a better built article, and although the price of the raw material has increased to a very large percentage, the consumer has had to pay little, if anything, extra for this owing to the increased facilities adopted for production.



45. STIFFENER MOULDING MACHINE
(B U. Shoe Machine Co , Leicester)

Science in Bootmaking. The amount of science and art that can be, and is, applied in modern shoe manufacturing would, upon investigation, surprise those who think there is nothing much in shoemaking but practical experience and skill. The lasts are copied from models by a scientifically-constructed lathe with a proportional attachment like a pentograph to regulate the lengths and widths; the patterns are cut and scaled into sets by geometrical means with mathematical accuracy; the variations caused by the various substances of leather are calculated and applied by scientific methods; the skins are laid out to get the best economical results combined with a correct disposition of the material so as to produce boots and shoes that will endure the strain brought to bear upon them during wear; and all through the various departments of the factory we find scientific methods in vogue in place of the empirical methods of the older craftsmen.

The finishes and colourings of the bottoms are art productions, and much thought and skill are brought into play in this section.



46. SOLE-EVENER (B. U. Shoe Machine Co., Leicester)

Treeing and dressing of the upper has become quite an important branch, and a vast amount of knowledge is displayed in selecting the materials and methods of dressing so as to avoid anything likely to ruin or spoil the durability of the leather. This demand upon the worker has been met largely by the technical institutions formed in all the centres where shoe manufacturing is the staple industry.

Detailed Study. In order that the student may possess a clear and definite knowledge of the whole boot factory, we purpose going into all the operations in detail, illustrating and describing the principal machines used. We shall stand by the side of the "clicker," and learn how to cut out the tops from the thousands of patterns kept in the factory. By a series of tables compiled from wide experience we exhibit the scientific methods of measurements by which the machine bootmaker has been able to meet the requirements of customers of all ages, classes, and tastes. Following the "stuff" of the boot-top, we examine the various sewing machines, and machines of various application, noting the special action and function of each, till the completed top has been realised.

Next comes the bottoming department. Here we begin with the cutting machines, striking out with dies soles and insoles, splitting welts, and shaping the various parts of the materials. Lasting is an important operation; and the appliances must be carefully gone over. Welting, cementing, and sole-laying are the next operations, and then follows sewing. The Blake sewing machine [85] has already been noted, but the practical working of it is further to be explained. Sole-pegging is another ingenious operation, and we find out the reasons why pegging has been restored to public favour after a long period of unpopularity. The heel then claims careful and detailed attention.

THE MYSTERY OF MAGNETISM

The Magnetic Needle. The Mariner's Compass. Magnetism of Metals. Magnetic Sounds. Magnetic Belts. The Error of the Compass

Continued from page 4094

By Dr. C. W. SALEEBY

WE must now turn to a systematic if brief discussion of a subject to which reference has frequently been made in preceding pages. We had no choice but to consider the relations of light, magnetism, and the electromagnetic theory of light before we had properly defined certain of the terms which we employed. But, at any rate, these references to the subject must have interested the reader in it. It is the old story: *electricity*—which derives its name merely from the Greek word for amber—was once a sort of freak phenomenon, but now its study dominates the whole of the natural sciences; and, similarly, *magnetism* is derived from the Greek name for a particular ore of iron, but is now recognised to be a phenomenon of the widest possible practical and theoretical interest.

The ancients knew that the *lodestone*, or *magnetic iron ore*—which, as the reader may remember, has the formula Fe_3O_4—is capable of attracting iron, in whatever form, and of endowing such iron with a measure of its own properties. They also knew that other metals do not share in this property, and that the intervention of other metals between the magnet and the iron does not interfere with the attraction. But to the few facts they knew they added a vast amount of pure fiction, which was accepted as fact for many centuries.

Invention of the Compass. According to Professor Chrystal, it was the invention of the compass that marked the first epoch in the science of magnetism. It is commonly believed that to the Chinese must be ascribed the first invention of this wonderful little instrument. It is stated by the Chinese historians that in the twenty-seventh century before Christ the compass was used in war. It is also a Chinese dictionary that first defines the lodestone. The Chinese appear to have long used the compass upon land before it was employed in navigation. It seems quite possible that the Chinese communicated their knowledge to the Arabs, and that the Arabs introduced it into Europe. At any rate, even in the twelfth century European sailors employed a primitive form of compass which "seems to have consisted simply of an iron needle which was touched with the lodestone and placed upon a pivot or floated on water, so that it could turn more or less freely. It was found that such a needle came to rest in a position pointing approximately north and south. . . . As these compasses were made of iron (steel was not used till much later), and were probably ill-pivoted, they must have been very inaccurate; and the difficulty of using them must have been much increased by the want of a card, which was a later addition, made apparently by the Dutch."

Discoverer of the Earth's Magnetism. The next stage in the history of our knowledge of magnetism is undoubtedly represented by the life-work of Dr. William Gilbert, of Colchester, who was physician to Queen Elizabeth, but who will be remembered not as a physician, but as "the Galileo of magnetism." It is true that he was President of the Royal College of Physicians and achieved great professional success, but he added nothing to medical science. On the other hand, he published, in the year 1600, the greatest work that has ever been written upon magnetism. He died three years later at the (probable) age of 63. Gilbert was the absolute pioneer in this subject. Not only did he make many experiments, but we owe also to him the capital discovery of the magnetism of the earth. Having found that the whole earth is none other than a great magnet, Gilbert was thereby enabled to explain not only the direction occupied by the compass needle, but also what is known as the *magnetic dip*. Says Fuller, in his "Worthies of England": "Mahomet's tomb at Mecca is said strangely to hang up attracted by some invisible lodestone; but the memory of this doctor will never fall to the ground, which his incomparable book, 'De Magnete,' will support to eternity."

Two or three years ago Professor Silvanus P. Thompson delivered at the Royal Institution some most interesting lectures upon the work of Gilbert, the tercentenary of whose death fell in 1903. Professor Thompson claimed for this remarkable man even more than is generally acceded to him, and supported the claim by many quotations. It amounts to this—that Gilbert must be regarded as a forerunner of Bacon himself in his exposition and demonstration of the true method of science—the method of induction—the interpretation rather than the anticipation of Nature. Certain it is that not only did Gilbert practise the scientific method, but he did so consciously, having a formal comprehension of its principles and of the need for it.

The Axis of a Magnet. We are apt to think of a magnet as a thing with two ends, but it is well to follow the example of Gilbert himself and take the case of a spherical magnet, which also has "poles." The phenomena of magnetism do not at all depend upon the form of the magnet. We shall afterwards see that they are not *molar*, but *molecular*. Such a spherical magnet, then, like any other, has an axis and poles. That end of the axis which always turns northwards we usually know as the north pole, and conversely. We shall soon see that it would be much more correct to describe the northward-turning pole of the magnet as its south pole and the southward-turning pole as its north pole. At any rate, when the magnet comes to rest, the vertical plane in which its axis lies is known as the *magnetic meridian*, indicating respectively the magnetic north and the magnetic south.

The Magnetic Needle. Having disposed of the notion that the molar form of a body has anything to do with its magnetism, we may now study the more common form of artificial magnet, usually called the *magnetic needle*. This will consist of a thin piece of hard-tempered steel which has been magnetised in one way or another. It may have been rubbed with a piece of lodestone or with an artificial magnet, or it may have been made magnetic by electrical means. A steel knitting-needle can easily be magnetised by the first process. First of all we must have some means of distinguishing one end from the other. Let us decide that the end we shall call A is to become the north pole of the magnet and the other end, B, the south pole. Let us then take a magnet, place its north pole on the point A of the knitting-needle, and draw it along the needle from A to B. Similarly, we may draw the south pole of the magnet along the needle from B to A. If this process be repeated often enough, we shall find that the knitting-needle has become magnetic. Such a magnetic needle may be made to float upon the surface of water, not because it is magnetic, but because of the surface tension of the water, as the reader will doubtless remember. And we find when we lower it very gently upon the surface of water that it will slowly turn until it comes to lie in the magnetic meridian. It is of the utmost value in many experiments to have a needle thus balanced so that it can move freely in a horizontal plane. A method employed by Gilbert, besides the method we have just described, was to suspend a very fine magnetic needle from a single fibre of silk, which scarcely interfered at all with its movements.

The Magnet and the Poles. What is known as the magnetic dip was independently discovered by several observers before the time of Gilbert. In 1544, a German vicar discovered that the magnetic needle, as he says, points downwards. "This may be proved as follows. I make a needle a finger long which stands horizontally on a pointed pivot so that it nowhere inclines towards the earth, but stands horizontal on both sides. But as soon as I stroke one of the ends with the lodestone, it matters not which end it be, then the needle no longer stands horizontal, but points downwards."

The magnetic dip varies in different places. It does not exist at all along a line which corresponds more or less with, but along a line which definitely differs from, the equator of the earth; this line is known as the *magnetic equator*. North of it the north end of the needle dips below the horizon; south of it the south end dips below the horizon. In each hemisphere, north and south, there is a point where one end or other of the needle dips vertically downwards. These points are known as the *north* and *south* magnetic poles of the earth respectively; but a further study of them belongs to the subject of terrestrial magnetism, and here we are dealing with the whole subject historically.

The magnetic dip having been discovered just before the time of Gilbert, it remained for him to explain it in terms of terrestrial magnetism. Before him there had been made, but not explicitly stated, the notable discovery of the mutual behaviour of the poles of magnets. This behaviour may be expressed by the very simple rule that *like magnetic poles repel, unlike magnetic poles attract each other*. The law of the intensity of this magnetic attraction and repulsion is the law with which we are already so familiar—it varies inversely as the square of the distance.

The Elements and Magnetism. As the name of the whole subject implies, there are inherent differences between the elements in respect of their magnetic properties, and this is a subject of which the chief student, beyond a question, is Michael Faraday. The pre-eminently magnetic substance is iron; with this, of course, we may include steel, since, as the reader remembers, iron is its chief constituent. Long after this element we must place nickel and cobalt, and also manganese and chromium Faraday studied an enormous number of bodies, and divided them into two great groups. Those which behave like iron, being attracted by magnets, he calls *para-magnetic*, while those which are repelled in greater or less degree by magnets he calls *dia-magnetic*. We need not give the list of substances which he tested: The interesting fact to notice is that almost every kind, if not absolutely every kind, of substance that can be experimented with is acted upon by a sufficiently powerful magnet in one way or another. We may select the following substances from Faraday's list of dia-magnetic bodies in order to show their heterogeneous character: Rock crystal, nitrate of lead, citric acid, water, alcohol, nitric acid, alkaline salts, glass, iodine, resin, sealing-wax, jet, sugar, wood, leather, beef, and blood.

The Magnetism of Metals. Of special interest is Faraday's study of the relative magnetic properties of the different metals. This must be of even greater interest to us than to him, for we are much nearer than he towards finding the clue to the facts. The following is Faraday's list of metals in order of descending susceptibility to magnetism reading down the columns. It requires a certain amount of revision, due, for instance, to the probability that iron is found as an impurity in several para-magnetic metals named:

PARA-MAGNETIC

Iron
Nickel
Cobalt
Manganese
Chromium
Cerium
Titanium
Palladium
Platinum
Osmium

DIA-MAGNETIC

Bismuth
Antimony
Zinc
Tin
Cadmium
Sodium
Mercury
Lead
Silver
Copper
Gold
Arsenic
Uranium
Rhodium
Iridium
Tungsten

The Range of Magnetism. But we must realise further that magnetic properties are by no means confined to solids. For Faraday found that gases have magnetic properties, though it is not necessary here to quote the table of his results. The most magnetic of all gases is apparently oxygen, though it may possibly be surpassed in this respect by its own modification, ozone.

Within the limits of magnetic action, the interposition of material bodies is of no more moment as such than it is in the case of gravitation, provided that the intervening bodies be themselves non-magnetic. It has already been noted that this important fact was recognised some centuries ago.

Though various forms of iron, for instance, are capable of magnetisation, they vary very much, and at present very mysteriously, in their behaviour when so magnetised. A piece of soft iron will become a magnet when it is touched by or placed sufficiently near to another magnet; but so soon as it is removed from this influence, its magnetic powers vanish. Steel, however, or a hard enough iron, when adequately magnetised, will retain the property indefinitely. We are as yet quite incapable of explaining these differences. No wonder, the thoughtful reader will say, when he remembers that we are hitherto incapable of reducing to their ultimate basis the properties of hardness and softness. This is certainly not a chemical question of the admixture of carbon or other elements with the iron, but somehow depends upon the physical constitution of the bodies in question.

How Physical Conditions Affect Magnetism. Certain illustrations of the effect of physical conditions upon magnetism may be quoted. Thus, in the case of soft annealed iron, under certain conditions a considerable percentage of induced magnetism can be retained. But the mere effect of a tap is sufficient to destroy this. This single instance is extremely suggestive.

Then, again, we may take the influence of temperature, which is found to be very decided. Up to a certain point a rise in temperature in the case of soft iron greatly increases its response to magnetism. Yet a point is reached beyond which the reverse action occurs, and the magnetism of the iron disappears. It is indeed true for all specimens and all varieties of iron or steel that there is a temperature—varying, of course, in different cases—which we may call the *critical* temperature, and beyond which the magnetism entirely disappears.

We commonly think of a magnetic needle as having two ends, which we distinguish as its north and south poles; but this is only a relation, and the remarkable fact which we discover when we break up such a needle is that this relation holds good of all its parts. Break the needle in two and each half becomes a magnet with its own north and south pole, their positions corresponding to those of the unbroken needle. Break up these halves again and the same result is found. Must we not then conclude that the ultimate molecular units—not, of course, the ultimate units—of such a magnet are themselves magnetised? In short, must we not form some *molecular theory of magnetism?*

A Limit to Magnetism. In the attempt to form such a theory we may note various facts, some of which have already been referred to. For instance, we may note the parallel statements of Wiedemann, which show us the apparent parallelism between magnetism and other physical conditions, for the explanation of which we must refer ourselves to the molecule. Thus:

1. Jarring a body under twisting stress causes increase of twist.	1. Jarring a bar under magnetising force causes increase of magnetisation.
2. Permanent twist in a wire is diminished by jarring.	2. Permanent magnetisation in a bar is diminished by jarring.
3. A wire permanently twisted and then partly untwisted loses or gains twist when jarred according as the untwisting is small or great.	3. A bar permanently magnetised and then partly demagnetised, loses or gains magnetisation according as the demagnetisation is small or great.

We owe to Weber the original form of the theory which attempts to explain such facts as the above in molecular terms. We may call it the theory of molecular magnets—the theory that the individual molecules of iron or steel are themselves magnets. Weber supposed that in unmagnetised iron the molecules are lying in all directions indifferently, and that they, therefore, neutralise each other's action, with the result that the mass as a whole has no magnetic action. Then, when the iron is magnetised we may suppose that the molecules have all been turned more or less in one direction, so that their action is summated instead of being mutually neutralised. Such a theory evidently leads to the conclusion, which is verified, that there is a definite limit to the possible magnetisation of any body.

In some form or other Weber's theory must probably stand. It has been somewhat modified by the suggestion that the molecules are not independent of each other but grouped in certain positions; and this supposition may serve to explain more of the facts.

Magnetic Sounds and Magnetic Belts. Under certain conditions sounds may be produced by the magnetisation and demagnetisation of iron and steel, the production of the aerial vibrations being due, doubtless, to mechanical changes in the metals. It was the great Joule, to whom we have often referred, who first clearly recognised that "the magnetic extension in the core of an electromagnet takes place so suddenly that the shock is sensible to the touch, and is accompanied by a musical note arising from vibration in the metal." The earliest telephone on record depended, according to Professor Chrystal, essentially on the magnetic sounds produced by a varying current in an iron core.

No doubt there may be magnetic belts on the market which do contain magnetised portions of steel or iron, though in many cases it is impossible to discover any activity in these articles. Statements designed to indicate the potency of the magnetism, and asserting that it will act through various non-magnetic obstacles, will be appraised at their due worth by the reader. The potencies and properties of magnetism and its relations to the living body are, of course, obscure, though certain definite facts are known, as we shall see. But it may be most positively stated that there is no evidence whatever to show that these magnetic belts have any appreciable action of any kind upon the body. That good results may sometimes follow their use proves nothing whatever as to their possession of any definite physical properties. For, as in a thousand other instances, the great majority of diseases are famously affected by anything in which the patient can be induced to believe. The interest of magnetic belts, therefore, is not really physical but psychological, and comes under the heading of the subject which the psychologist calls *suggestion*.

The Earth, the Sun, and the Magnetic Needle. In our brief introductory history of this subject we have already outlined one or two of the facts of terrestrial magnetism. We have seen that William Gilbert explained the behaviour of the magnetic needle by the extremely bold but justified speculation that the earth itself is a huge spherical magnet. It was this theory which led Gilbert to experiment with little spherical models of the earth which he called terrellæ, or *little earths*. We have also noticed the existence of the magnetic poles of the earth, and may briefly note that the term *isoclinic lines* describes lines drawn on charts of the earth so as to pass through places where the angle of dip is the same. At the magnetic poles the angle, of course, is 90 degrees. Again, though we speak of the needle pointing north and south we must remember that, except along two lines, there is a *declination*, or variation, at every point upon the earth's surface between the true meridian and the magnetic meridian. "Isogonic lines" indicate places where the declination is the same.

Poets are apt to use the magnetic needle as a symbol of constancy—"true as the needle to the Pole." But, as a matter of fact, there are incessant changes in the behaviour of the needle at any given place as regards both *variation* and *dip*. Some of these can scarcely be measured in less than centuries, others definitely correspond to the year, and others, again, may be measured from hour to hour. Lastly, we may note the amazing fact that the behaviour of magnetic needles on the earth is influenced by the state of the sun. It is definitely known that sun spots affect the magnetic needle.

The Error of the Compass. If the earth be a magnet, then it should have all the properties of a magnet. For instance, it should be capable of inducing magnetism in susceptible substances in its neighbourhood. It has this property, and it is found that steel masts and columns, pokers, hammers, and other objects of steel, are sufficiently magnetised to affect a compass appreciably. This is the result of induction by means of the magnet we call the earth.

This is a phrase used by Lord Kelvin in order to describe the influence upon a ship's compass of the ship's own magnetism. All the soft iron of a ship is magnetised by the earth's induction, though this magnetism is only temporary and not important. On the other hand, all the steel of the ship and its hard iron acquire a more or less permanent magnetism, the exact nature of which depends upon various factors, such as the position in which the ship lay while it was being built. This permanent magnetism of the ship is a very serious matter, and may mean the difference between life and death for the sailor.

The Greatest Inventor in History. It is not necessary here to describe the various kinds of error which the permanent magnetism of the ship may induce in the indications of the compass. But we must celebrate once more the great name of Lord Kelvin, that mighty genius whose practical inventions alone constitute him, perhaps, the greatest inventor in history, while his contributions to pure science would suffice to immortalise a dozen men.

The Thomson or Kelvin compass is now to be found on every ship that sails the seas, and no one can say how many lives it has saved or what worth of cargo. Among the distinguishing properties of the instrument we may briefly note the fact that the Kelvin compass contains six or eight magnetised needles instead of one, and that the various kinds of errors of the compass are corrected by means of appropriate apparatus, such as bar magnets, horizontal and vertical, the position of which can be altered, and balls of soft iron, which are fixed on to the binnacle at the level of the card of the compass, and which neutralise the magnetism induced by the earth in the soft iron of the ship.

The Field of a Magnet. We have already seen that in the neighbourhood of a magnet there is some essential difference from the conditions which prevail further away. The area over which the magnet exercises its influence we may describe as the *field* of the magnet. We have already noted facts from which we may properly infer that the earth itself, being a magnet, has a field in its immediate neighbourhood. And this is so. The existence and some of the characters of a magnetic field may be shown by spreading some iron filings evenly upon a sheet of paper underneath which lies a magnet. If we tap the paper we find that these filings arrange themselves along a series of curved lines passing between the two poles of the magnet. These curved lines are known as *lines of force*, and their study is extremely complicated and interesting. The appropriateness of the name will be seen if we make a further experiment, which consists in lowering a small magnetised needle over the paper and seeing what happens to it. Its point will be found to follow one of the lines of force already indicated by the position of the iron filings, and if the north pole of the needle be downwards it will be driven towards the south pole of the magnet.

CARPENTRY WORK IN ROOFS

Lean-to, Collar, King, and Queen Post, Compound, and other Forms of Roof. Arrangement and Dimensions of Timbers

CARPENTRY
continued from page 4116

By WILLIAM J. HORNER

THE carpentry work in roofs consists in the erection of the wood framework to which the slates, tiles, sheet metal, or other covering is attached. Roof work is not now so entirely the province of the carpenter as it formerly was. Very large roofs are built of iron or mild steel, with no woodwork about them. In timber roofs the ties, or members that are subjected to tensile stress, are often of iron. In no case is wood used as exclusively as formerly, when even the pins that united the timber joints were of wood.

No matter what the shape or size of a roof may be, the carpenter has to provide for and arrange a series of rafters 12 or 14 in. apart over the entire surface. If the length of these exceeds about 8 ft., intermediate support must be provided for them. Generally they run from the roof ridge or apex down to the eaves, but occasionally the horizontal position is adopted. For convenience in attaching the roof covering, it is generally necessary either to board the rafters entirely over or to nail on a series of strips transversely, the former method being best.

Different Classes of Roofs. When the span from wall to wall does not exceed 16 or 18 ft., the carpenter's work is of a much simpler character than in larger spans. This is because of the necessity of supporting long timbers at intervals, since it is more economical to provide intermediate supports for comparatively slender timbers than to render them independent of intermediate support by greatly increasing their section and weight.

Roofs, therefore, may first of all be divided into two classes—those in which rafters alone are used with suitable woodwork to which to attach their ends, and those in which an elaborate skeleton-work of wood must first be built up for the rafters to rest on. Those in the first class are suitable for sheds and very small buildings of various kinds, including small dwelling-houses. Those in the second may be divided into *king post* roofs, suitable for spans between 18 and 30 ft., *queen post* roofs for spans between 30 and 45 ft., and *compound* roofs for spans of more than 45 ft. There are also a few forms simpler than the king post which come between that and the simple rafter roof, and there are some other forms suitable for moderately large spans, which do not fall under either of these classes.

The Lean-to Roof. The single slope, or *lean-to* roof [**241**], for a span of not more than 10 ft., may be constructed only of rafters extending from one wall to the other at the necessary slope. In roofs so small that the distance from ridge to eaves is less than 6 or 7 ft., it is not necessary to use rafters at all, but simply to board the surface over, providing a suitable support at top and bottom for the ends of the boards to bear on. The boards in such a case should run with the slope. When laid on rafters in the ordinary way, they run transversely to the slope, which, as far as throwing off wet is concerned, is not so satisfactory a position. Sometimes in medium and large roofs boards are laid diagonally on the roof surface, the main idea in this being to make them act as diagonal bracings to the other parts of the roof framework. The advantage, however, is only slight, and there is considerable waste and extra work in fitting them in this way.

Wall Plates. In the lean-to roof, when rafters are used, a bar of wood, or *wall plate*, as it is called, is fixed along the top of the lower wall flush with the inside edge, and the lower ends of the rafters are fitted with a birdsmouth joint [**242**] and nailed on to it. At the upper ends attachment of the rafters to the wall is more troublesome, but it should be done securely to reduce outward thrust on the lower wall. A wall plate may be either built into or attached to the back wall at the desired height, and frequently bricks are removed or recesses chipped for the ends of the rafters to enter into, as in **243**. When this wall plate is not built into the wall, it may be bolted or nailed to it, or may rest on a projecting course of bricks built in for the purpose. Or another good method is to nail short lengths of hoop iron to the wood, leaving projecting ends of the iron, which can be built in between bricks as the wall is erected. With a wall plate securely attached the rafter ends are often not let into the wall, because it is always advisable to leave ends of timber exposed to the air as much as possible to preserve it from decay and dampness.

The section or scantling of the rafters will depend on their length, and ranges from 1¾ in. to 2½ in. wide, by 3 in. to 6 in. deep. On these the transverse strips or boards are nailed to take the roof covering.

A simple roof of this kind is limited to spans which do not exceed 9 ft. or 10 ft., but the same class of roof may be employed for considerably greater spans if suitably tied and braced.

Fig. **243** shows how a horizontal beam may be introduced at the base of the roof, and, if desired, a vertical post at the back, so making a rigid triangular frame which will exert no outward thrust on either wall. The dotted lines also show how a brace or strut might be introduced to afford support to the central part of the rafters, and if desirable a vertical tie might extend from there to the middle part of the horizontal beam. Generally, however, if the span be large enough to require this, the couple roof is adopted instead.

Function of Wall Plates. The purpose of wall plates is to distribute the weight of the roof uniformly on the wall instead of at intervals on the individual bricks upon which the rafters would otherwise have to bear. They are generally about 3 in. deep by 4½ in. wide, or in large roofs 6 in. by 9 in. They are generally spiked on the wall flush with the inner face, to avoid increasing the span. Sometimes two wall plates are used parallel with each other with a space between. When the lower ends of the rafters project over the wall it is sometimes necessary to have the wall plate flush with the front, as in **244**, and notch the rafters on to it. Another method is shown in **245**. Often in large roofs the wall plate is not continuous, but short plates, or *templets*, as they are called, are inserted for the roof trusses to rest on, the rafters themselves bearing on a pole plate, which will be described later. These templets are about 30 in. long and sometimes are of stone or metal instead of wood. The usual form of joint for wall plates, when it is necessary to join timbers end to end, is that shown in **246**.

The Couple Roof. The couple roof [**247**] reduces the length of the rafters by one half, and consequently increases their strength, thus enabling a larger span to be bridged without increasing the section of the rafters. The weak feature in such a roof is that its weight does not bear vertically on the walls but tends to thrust them apart; and as it is easy to modify its form so that all, or a great deal, of this outward thrust is prevented, the simple form in **247** is seldom employed for much larger spans than the lean-to roof, unless the walls are low or are thickened or buttressed to withstand it. As far as the strength of the rafters themselves is concerned, 12 ft. may be regarded as the maximum span for which this roof is suitable.

The Collar Roof. It may be strengthened and made suitable for larger spans by connecting the opposite rafters with a collar, as dotted in **247**, which acts either as a brace or a tie to the rafters according to whether their lower ends are rigidly fixed or free to spread. It is called a *collar* roof and would usually be adopted for spans between about 10 ft. and 14 ft. A short collar immediately under the ridge plate, as shown dotted in **250**, also adds to the strength of any roof of this kind.

In collar roofs the lower ends of the rafters are birdsmouthed on to a wall plate and the top ends bevelled to bear against the ridge plate, which is placed between [**248**]. The function of the latter is to provide a straight and continuous ridge along the top of the roof. Fig. **249** shows an alternative method. The rafters are nailed at their ends to the wall and ridge plates. The collar may be either nailed or held by a bolt to the rafters. Sometimes the joint is made more secure by halving the parts together, generally with a dovetail halving, but this is hardly advisable because it weakens the rafter at a point where it needs to be as strong as possible. In the ordinary collar roof the position of the collar is half way down the rafters. The lower the collar is placed, the less outward thrust the ends of the rafters can exert, and when placed absolutely at the base, as in **250**, it ties them completely.

The Couple Close Roof. The roof is not then called a collar roof, but a *couple close* roof, because it has two slopes closed by a tie at the base. In this form, unless a collar be added as well, the middle portion of the rafters loses the support which the collar would afford; but the main reason why a collar half-way up is used, if possible, in preference to a tie beam at the base is that the latter in a low building is often too much in the way or too unsightly. It also, of course, consumes more material and adds to the weight of the roof, for although the tie beam is in tension, it is necessary to make it of considerable depth to prevent sagging in the middle, and the greater its length the greater must its depth be.

In either of these roofs it is not essential that every pair of rafters should be tied. The connections may be only at alternate ones, or at longer intervals. In some cases the wall plates instead of the rafters may be tied. Fig. **251** shows wall plates tied by iron rods, and some intermediate rafters resting on purlins which are supported by collars at intervals. When the wood tie beam is employed it forms the base on which the lower ends of the rafters rest, and it extends several inches beyond the rafters at each end, so that a suitable joint can be made between them. The forms of joint generally employed were shown in **168** to **171** [page 4043], but the methods of holding it together vary with the size of the timbers. Further examples of these joints and fastenings are shown in **252** to **257**. Sometimes the parts are halved together, but a joint in which the rafters bear their entire section on top of the beam is best. When the rafter bears on the tie beam within the inner face of the wall, a stub tenon [**170**, page 4043], with its front at right angles to the body of the rafter, and tapering to nothing at the back, is generally most satisfactory because very little material is cut from the tie beam. If the rafter bears immediately over the wall, as it always should do if possible, a stronger joint can be made by cutting more from the beam, which is then better able to withstand the consequent weakening. A bridle joint [**167** and **256**] is sometimes preferred to a tenon, but it weakens the beam more than the latter and does not transfer the lost strength to any other part. Its only advantage is that there are no hidden parts which may not be in contact and taking their share of the stress.

The ends of the tie beam generally have a bearing of about 9 in. on each wall, and it is prevented from moving by being either spiked, cogged, or dowelled on to the wall plate. In small roofs it is customary only to nail or spike

A cogged joint was shown in **177** [page 4043]. The thickness of rafters and tie beam are usually the same, but the depth of the latter is generally greater because it is longer. If it acts as a joist for supporting a ceiling as well as being a tie beam for the rafters, then its depth must be increased accordingly. The rafters range from 3 in. to 6 in. in depth according to the size of the roof; 8 ft. is reckoned about the average length over which they can be allowed to extend without intermediate support, and their section then should be about 5 in. by 2 in. For a span of 12 ft. without intermediate support, which is the most that can be attempted with economy, their section should be about 7 in. by 2 in. or 6 in. by 3 in.

The King Bolt. In roofs of ordinary slope, which is about 30 deg. with the horizontal, the tie beam is the longest member and the first to need support at the centre. From 10 ft. to 12 ft. without support is generally considered as much as is advisable, but this is frequently exceeded in roofs where the total span is only a few feet more. When the span exceeds about 15 ft., the simple couple close type is abandoned and a vertical tie introduced connecting the ridge of the roof with the horizontal tie, as shown dotted in **250**. This prevents the horizontal from sagging in the middle, and leaves the weakest part of the frame then at the middle of each rafter. This is suitable for spans of as much as 18 ft., but beyond that the rafters need bracing and the king post truss is introduced.

The King Post Truss. For spans of more than about 18 ft., what is known as the *king post truss* [**258**] is employed, and this is so satisfactory an improvement on the preceding types that it is suitable for any spans up to 30 ft. In this the tie beam is supported in the middle by a vertical tie called the *king post*, and the rafters are supported in their middle by struts or braces from the base of the king post. It is obvious that this makes a very rigid frame, but the reason why that arrangement is best is not so apparent until the part which each member plays is considered. It would scarcely be supposed at first that the vertical member, or king post, was subjected only to tensional stress, yet it is a fact that it is entirely in tension. The diagonal struts, on the other hand, are entirely in compression. Of the outside frame members the horizontal beam is in tension and the rafters in compression, as in the previous forms described. The stress on the rafters, however, tends to bend and break them inwards, and consequently, as with the tie beam, their depth must be greater than their thickness. The struts, being subjected to compression with no definite transverse strain, will bend according to the direction of their least dimension, and consequently should be made as nearly as possible square in section, and not less either way than $\frac{1}{20}$th of their length. As straps are seldom employed on the struts, it is often best in large trusses to make them less in thickness than the posts and rafters, thus saving material and weight in the roof without loss of strength.

To demonstrate graphically how the middle of the beam and the middle of each rafter receives support from the internal members of the triangular frame, we will suppose, as in **259**, a chain substituted for the rigid king post, and the beam and struts separated from the rafters, the latter being prevented from spreading at their base, and acting as a tripod in supporting a weight. It is then apparent how the vertical tie supports the beam and the struts the rafters. In practice, of course, a chain is never used, but either a wood post or an iron rod.

All the parts of the king post truss, with the exception, sometimes, of the struts, are generally made of uniform thickness because flat iron straps can then be bolted on the surface to hold joints together. This thickness ranges from about 3 in. for a small span of 18 ft. or 20 ft., to 5 in. for a span of 30 ft. In their other dimensions the members vary.

Rafters. The rafters employed in the composition of the king post truss are of larger dimensions than the rafters previously alluded to, and of different character. In the smaller types of roof only one kind of rafter is required, but with the king post truss two kinds of rafters are introduced—the *principal rafters* and the *common rafters*. The common rafters are necessary in all roofs, and are of the dimensions already stated. The principal rafters support the common rafters in trussed roofs. The reason of this is that king post trusses cannot be formed under each pair of rafters without making the woodwork of the roof needlessly heavy and involving a lot of unnecessary work. King post trusses, therefore, are set on the walls at intervals of about 8 ft. or 10 ft apart, and are connected by transverse bars called *purlins*. At the apex they are connected by the ridge plate, which is let into the tops of the king posts, and at the base the tie beams are cogged on to the wall plates, and are also connected by a rail on top, of the same character as a purlin, but called a *pole plate*. This forms a framework [**260**] to which the common rafters can be attached, and which affords them ample support, so that they are not then required to carry a very great weight unaided. Sometimes trusses of different character alternate with each other, the heavier being used over buttressed portions of the walls, or to support heavier parts of the roof. The trusses are also known as the *principals* of the roof. The principal rafters are those which occur in the truss frames, and they have to be kept below the level of the common rafters because they carry the supports for the latter. They range in depth from about 4½ in. to 12 in., according to the size of the truss.

King Post, Tie Beam, and Purlins. Owing to the peculiar shape of the king post, it is necessary to reduce it from a piece of timber measuring about twice the width of the ultimate size of the central part. The exact size of the enlarged ends is got by marking the bevels of the rafter and strut joints, keeping them as nearly as possible at right angles to the inclination of those members. The arrangement of the king post joints is shown in detail in **261**. Iron straps are usually bolted across the joints to hold the

members together, and the stirrup which supports the tie beam is generally tightened by folding wedges through the post, as shown. Sometimes a bolt is inserted instead, as shown dotted in 258. In heavy timbers a cast-iron socket receives the base of the king post and the diagonal struts. The tie beam is given about ½ in. of camber to 10 ft. of length.

The purlins, or horizontal rails, on which the common rafters rest, are generally put immediately over the tops of the struts, as in 258, and as there are only two struts in a king post truss, the purlins are consequently two in number also, occurring on the middle part of the rafters. At the top the common rafters are fitted and nailed to the ridge plate, and at the bottom another rail called a *pole plate*, is nailed on top of the tie beams or on the lower extremities of the principal rafters [258 and 267]. On to this the lower ends of the common rafters are birdsmouthed and nailed. The purlins are notched or recessed ½ in. or so to fit over the principal rafters and nailed on, and further to prevent them from slipping or turning over under the downward pressure a block or cleat is fixed below for them to bear against [258]. Details of these joints are shown in 262. In ordinary work the cleats are usually merely nailed on the surface, without being fitted, as shown. Examples of end joints in purlins are shown in 263 to 265. The common rafters are notched to fit the purlins. The stirrup, tightened by folding wedges [261], is the best method of connecting the king post and tie beam. The bolt [258] is suitable only for small trusses. To insert it, a hole has to be bored up the centre of the post, and a slot cut in one side to insert the nut, after which the opening is plugged.

Heel straps [252 to 254], or a bolt [255 and 258] are employed to hold the principal rafters to the tie beam. Sometimes the strap is put on at right angles to the inclination of the rafter, and so holds the joint directly together, and sometimes the angle is increased, as in 252, so that it acts as a tie to the thrust of the rafter. At the head of the king post a bolt is sometimes used, as dotted in 267, but more generally straps [258], or sometimes plates. The truss should be put together with the king post slightly short and the struts full to length.

The Queen Post Truss. In spans of from 30 ft. to 45 ft., the beam and rafters are supported at two intermediate points in the length instead of at one only, and the arrangement of ties and braces for doing this is called a *queen post truss* [266]. The middle, or king post, is abandoned, and two shorter ones, called queen posts, are introduced, one on each side, at some distance from the roof centre, thus supporting the tie beam in two places. These two posts are connected at their tops by a horizontal member, called a *straining beam*, and the junction of these affords support at one point for the rafters. It will be seen in 266 that the principal rafters end at this point, and do not continue to the top of the roof as in the king post truss. A strut from the base of each queen post affords support to the middle of each principal rafter, and the purlin over this point occurs about a third of the distance up the common rafter, the next purlin at the top of the queen post beina another third. The queen post joints do not differ essentially from those of the king post, except so far as the difference in arrangement requires it. As in the king post truss, it is convenient to have the members of similar thickness so that flat straps or plates can be bolted across the joints. A useful rule by which suitable thicknesses for any given span may be obtained is given in G. P. Allen's "Practical Building Construction." For a king post truss divide the span by 5, and call the quotient inches, which will be the thickness of the truss. For a queen post truss, divide the span by 8, which will give the thickness in inches. Suitable dimensions, both thickness and depth, are given in the table on preceding page.

Compound Roof Trusses. For spans of more than 45 ft., compound trusses are employed, consisting of a combination of king and queen post trusses, and as many additional vertical ties with corresponding struts as may be required. There is no limit to the extent to which this may be carried, but in practice the horizontal tie beam is generally abandoned for other forms of truss, or the roof is broken up in a number of slopes, receiving support from below by pillars or walls when the area covered is very great. When the queen post alone is not

280. Arched roof 281 and 282. Timbers for arch 283. Hammer beam

sufficient, a king post is frequently inserted as well, either as in 267, or between the roof ridge and the straining beam, as dotted in 268, using a pair of struts from its base if desirable. The next step in a compound roof is to introduce another pair of posts outside the queen posts [267], also using struts from their base if required. Other posts or vertical ties may be employed.

Trussed Members. Purlins, ridges, or rafters may be trussed as an alternative to supporting them at frequent intervals, or to making them of sufficiently large section to extend long distances without intermediate support. The ordinary king or queen post trusses may then either be dispensed with entirely, or placed at great distances apart. Purlins are often trussed when the distance from wall to wall is hardly sufficient to justify the use of a transverse truss midway between. Rafters are not often trussed, because they are so numerous, and supports are more economical. Ridges require it only in exceptionally long spans.

Objections to the Tie Beam. The horizontal tie beam at the base of roof trusses is regarded more or less as a necessary evil. The one great point in its favour is that it ties the roof base and relieves the walls of lateral strain. The objections to it are that it obstructs a great deal of space in the interior of buildings, thus often making it necessary to build higher walls; while in very large spans it becomes economically, if not practically, impossible, because of the enormous weight of material necessary to form trusses of the required strength. The horizontal tie beam, therefore, which is the main element of the triangular-shaped truss, is often discarded, even in small spans, for ties which slope upward, 269 being a common example In some of the early wood roofs similar methods were adopted, but such ties are now usually of iron. Horizontal ties of iron are also often employed instead of the wood beam, but when ceiling joists have to be attached to the under surface, the wood beam is more convenient.

In 269 a collar is employed to impart rigidity to the rafters, and to its central part the tie rod is bolted In 270 a king bolt is employed to support the tie rod and two struts, thus making a stronger truss suitable for larger spans than 269. Figs. 271 and 272 show methods of employing iron king bolts instead of wood posts. Fig. 273 shows an arrangement for another kind of roof supported by posts instead of walls; 274 is an example of a sawtooth or weaving-shed roof. The last, however, are generally constructed entirely of iron. They are commonly employed for factories, and are arranged in a series instead of one span over the building. The long part of the slope is slated, and the short, steep part fitted with glass and facing the north so that the interior of the building gets a steady light without sunshine.

The Mansard or Curb Roof. The *mansard* or *curb roof* [275] is a peculiar form of roof often employed, especially for dwelling-houses. In this case the horizontal tie beam at the base is retained, but the space above it utilised. In ordinary direct sloped roofs the space above, although large, would not be of much value for rooms because of the sharp slope of the sides. In the mansard roof this is overcome by making the sides nearly vertical for some distance up, and then avoiding a very high and acute roof ridge by altering the angle to a very low one. In large spans the king post truss is employed for the upper part, with posts and struts at the ends between the upper and lower tie beams. Fig. 276 shows a method of joggling a strut to a beam, often adopted in the mansard roof. Fig. 277 shows another method of arranging the rafter and strut in a mansard, so that instead of the slates meeting where the angle changes, there is a drop from one slope to the other. In small spans there is no king truss in the upper part, but the rafters are tied by a collar.

Hipped Roofs. *Hipped roofs* [278] are very common, and considerably complicate the carpenter's work. Instead of having a vertical or gable end from which to begin the line of rafters, the roof is sloped at the ends as well as the sides of the building, and the rafters have to be arranged accordingly. This necessitates a stout diagonal rafter, called a *hip rafter*, from each corner of the walls to the end of the ridge plate, and the common rafters have to be cut to the correct length and angle to meet this, as shown in 278. A valley, also shown in 278, is the reverse of a hip, and is also frequently necessary. In small roofs what are known as a *dragon beam* and an *angle brace* are employed to prevent the outward thrust of the hip rafter from acting directly on the corner of the building. The arrangement is roughly shown in 278. The angle brace bridges across the corner at some distance back from where the walls meet, and is securely attached to the wall plates. The ends of the wall plates are half lapped, and the short dragon beam is notched over this and extends back, and is tusk tenoned into the middle of the angle brace. The base of the hip rafter is notched and stub tenoned into the dragon beam. In large roofs the hip rafter is trussed instead of a dragon beam being employed.

Trimming. Where chimneys, skylights, dormer windows, or other openings in a roof occur it is generally necessary to trim the rafters in order to leave sufficient open space. As it is very seldom that entire rafters can be omitted, it is necessary to provide support for the ends where a portion of their length has been removed. This is called *trimming*, and the transverse piece that supports the ends is called a *trimmer*. Occasionally the opening can be made immediately above or below a purlin, or between two purlins. But the usual method is shown in 279. The trimmers are tusk tenoned between two rafters, which are generally ½ in. thicker than the others, and are called *trimming rafters*. The ends of the intervening rafters that have been trimmed are tusk tenoned or notched into the trimmers, which are of the same section as the two trimming rafters. A frame of the desired size is thus provided in the roof surface without any rafters crossing it.

Other Varieties of Wood Roof. Among types of roof without horizontal tie beams there are several that have been popular when wood was the only material available, but in most of them either an enormous amount of work is involved or strength is sacrificed to appearance ; besides which, the walls often had to be made much thicker to sustain them than is the custom at present. It is obvious that an arched construction like 280 needs no tie at all to enable it to support itself and to exert no outward pressure at its base. As the only way of forming curves of great length in wood is to build them of a great number of pieces breaking joint with each other, that method has been adopted to form arched roofs of timber. The two most popular varieties of this kind have been built of timbers joined as in 281 and 282; but outside of these straight slopes have been required to stiffen the curved interior and to carry the roof covering. There are also numerous arrangements adopted in temporary centring for arches that are suitable for roofs.

Another variety of roof without a tie at the base is known as the hammer beam [283]. It is best suited for high-pitched roofs of not very great span. It throws considerable strain on the walls, which must be made thick enough to withstand it. Wood roofs without tie beams, however, are exceptional, because they can be better and more cheaply built of iron. In very large spans also wood cannot compete with iron. The principle on which such roofs are built is that of the arched girder strengthened by tie rods, and there is usually no carpentry about them.

Domical, conical, and polygonal roofs are occasionally required, and form very light and strong structures. Their rafters or ribs meet at a common centre at the apex, and radiate outwards and downwards to the wall plate, which extends entirely round the top of the wall. Shorter rafters may be employed between as the circumference increases, and transverse ribs or purlins where necessary. Interior ties and braces are often adopted, but in small roofs are not necessary. A domical roof requires curved or arched ribs, and when these are of wood they are made in the same way as 281, and the outer and inner edges cut to the sweep.

Drips, Falls, and Gutters. Some amount of woodwork is generally necessary on which to lay lead or attach gutters for carrying off water. For the details of this the carpenter is generally dependent on the plumber's instructions. In roofs with overhanging rafters, as in 258, 266, and 268, a fascia board is generally attached to carry a cast-iron gutter. In parapet and M-roofs, a flat or box gutter lined with lead is generally used, and to carry this, horizontal bearers are attached to the rafters or to the pole plate, as in 267, and boarded over to lay the lead on, a slight slope being given to the gutter lengthwise.

HOW TO DRESS & BE HEALTHY

Healthy Skin and Ideal Clothing. Cleansing of the Skin and Hair. Baths. Clothing Materials. The Best Dress for Men and Women

By Dr. A. T. SCHOFIELD

IT is unfortunately too generally true that cleanliness in clothes decreases as we near the skin. The collar and cuffs are frequently changed, the shirt not so often, the vest more seldom still, and the skin only thoroughly washed perhaps once a fortnight, and sometines not even then! The modern system of large baths in even small houses is an incalculable boon for the middle classes, while the public baths in most towns are so well appointed and managed as to bring cleanliness within the reach of all.

Impurities of the Skin. There are at least three impurities needing constant removal—the dried-up scarf skin of dead epidermal cells constantly being produced on the surface of the body, the continual secretion of oil and water from the glands and pores all over the surface, and the dirt which inevitably settles on the skin. Labouring men and porters, who stand much in need of baths and washing, have often more healthy skins than clerks and people in business. The reason of this is that they perspire frequently and excessively, and thus a good deal of the effete matter is washed away by a natural process. No cloth clothes or any garment that cannot be washed should ever be worn next the skin. They should be changed at least every week. The skin requires, however, often something more than merely to be kept clean. If it is at all delicate the face is apt at times to become hard and dry, wrinkled, spotted, or otherwise disfigured, often from preventable causes.

The best lotion or wash for a tender skin is pure *rain-water*, pure soft water, boiled water, distilled water, or artificial soft water, which can be made in any town where only hard water is laid on by putting at night in the ewer so much of Maignen's "Anti-Calcaire" as will lie on a halfpenny. In the morning, the water carefully poured off the sediment will be found beautifully soft and fit for the most delicate skin. For women no soap should be used for the face but pure curd soap, and, for delicate skins, prepared oatmeal, and, once a week, very hot water and a little curd soap. The worst thing for the face is hard water, and tar, carbolic, or strong yellow soap. Another way of making the skin of the face coarse and pimply is to use face powder.

The Turkish Bath. The Turkish bath, a great beautifier of the skin, is imported from the East, and in its English form is most safe and useful. Besides being by far the most effectual cleanser and pore opener that we have, it is a general restorative and tonic of the highest value. On brain-workers and residents in towns it confers the highest benefits. Taken weekly or fortnightly, it will be found beneficial in every way. There are some cases, however, in which it is dangerous, and medical advice should be first sought by anyone who intends to take it.

Cleanliness and Cheerfulness. Another result of the inaction of the skin which is very common is disease of the lungs, liver and kidneys. With a clean and healthy skin, the spirit is cheerful, the food is enjoyed and easily digested, exercise is a delight, the mind is calm, sleep quiet, and, in addition, there is a general moral elevation of the whole man. Drunkenness is rare amongst cleanly people.

How, then, is the skin best kept clean? First of all, by washing the body. This should be done every day with water, and once a week with soap. Sweeps, scavengers, sewer men, dustmen, many labourers, stokers, and blacksmiths get so dirty that it is necessary they should wash well all exposed parts at night with soap. In summer, water that has been standing in the room all night is quite warm enough to use.

Baldness is much more common amongst young men than women, and amongst the upper than the lower classes. This is partly due to the false idea that continual bathing of the head and brushing with hard brushes is good for the hair, and partly to the use of the tall silk hat, which is the worst enemy for the head ever devised. People are seldom bald excepting on that part which is above the level of the brim of the hat. It is not generally known that water does not promote the growth of the hair, but, on the contrary, injures it if too constantly applied Under ordinary circumstances a man's head should not be washed oftener than once a week, and a woman's once in three weeks.

The Effects of a Cold Bath. Cold baths have a temperature of from 60° to 65°. They first of all drive the blood to the heart, thus greatly stimulating it and quickening the circulation; then the blood rushes back to the skin, producing a violent reaction. A cold bath at first somewhat depresses and then stimulates the system. In slight congestion of the lungs, liver, and brain it is very good when the reaction is brisk—not otherwise. In chronic joint disease the cold douche is very valuable. In bathing it is bad to stand in cold water up to the middle only; this produces too much congestion of the upper half of the body. Usually a person should not dress until the warm glow comes.

A cool bath, from 70° to 75°, is a great luxury in hot weather. The body should be dry-rubbed all over with a towel before entering the water. There is a gradual loss of heat for a while, followed by a renewed sense of vigour. A tepid bath is another 10° hotter—80° to 85°—and, used in winter, is the same as a cool bath in summer.

A warm bath, from 90° to 95°, has a different effect altogether. It allays all pain and irritation, draws the blood towards the surface of the body, is a great sedative after fatigue, and a capital substitute for want of sleep. After travelling or exposure to the east wind it is very agreeable. It does good at the beginning of a cold, after illness, and after brain irritation. It is *the* bath for cleansing with soap and a flesh brush or flannel; it is good for aged people, and should be taken at any rate once a week, lasting from twenty minutes to half an hour, but not immediately after a meal.

The Ideal Bath. A hot bath, 100° to 105°, is a great stimulant of the system, but after a short time it rapidly exhausts the heart. It quickly relieves severe congestion of internal organs. After a hot bath, brisk exercise in the open air does not give cold. One of the most delicious combinations possible is to have a cold sponge after a hot bath.

If a bath at home is impracticable, there still remain the public baths. These are of three sorts—the plunge bath, the swimming bath, and the Turkish bath.

The plunge bath is for washing rather than for bathing, and, well filled with hot water, forms on the Saturday night an admirable conclusion to the week's toil. A cold shower bath is nearly always provided, and if taken at the end, and followed by a brisk rubbing with well-aired towels, is proof against catching cold on the way home. The swimming bath, regarded as still a luxury, will, we trust, soon be thought as much a necessity in every town and village as in the old Roman days. Of course, it may be abused. Boys or girls may remain in it too long, till they are blue and shivering; or silly and dangerous feats of strength and endurance may be attempted, resulting in some strain.

What to Wear. The purpose of clothes, from a sanitary point of view, is to cover the body so as to preserve it from feeling external changes of temperature, and to afford a general protection to the skin from wet and injury, as well as for adornment. In the present instance we are chiefly concerned with questions of warmth and protection.

Let us consider the essential qualities of a good clothing material, and then review those that are used and see which comes nearest to the standard with regard to warmth. A common idea is that clothes warm us. This they never do, of whatever material they may be made. It is we who warm them, just as we also warm our beds. The fact is, our bodies are exactly the right heat as they are, without any clothes, and if the temperature of the air were always about 90°, we should require no clothing for sanitary reasons; but as it is not, we want a material to isolate us from surrounding influences.

To be perfect, clothing material worn next to the skin should possess the following qualities: It should be *a bad conductor of heat*—that is to say, it should allow heat to pass very slowly through it in either direction. The effect of this is that in summer, when the sun is hot, it does not allow its heat to permeate through and warm our bodies too much; while in winter, when it is cold, it does not allow the heat of the body to escape and be lost. Such material we call cool in summer, and warm in winter.

The Qualities of Good Clothing. In the next place, such a material should be *porous;* it should absorb moisture, and at the same time allow the exhalation of the body freely to escape, be comfortable, and not too heavy or inflammable. We will, therefore, examine it as to eight main points.

1. CONDUCTION OF HEAT. What is wanted, seeing that our bodies themselves are kept the right heat by the blood, is isolation or non-conduction. When the external temperature is lower than blood heat (98½°) a non-conducting material keeps us warm. When it is above 98½°, which is rare, a conducting material is warmer. Wool is the worst conductor, then fur, feathers, silk, cotton and flax. Flax is twice as good a conductor as wool, and hence has half the warmth. That is why ice is kept in flannel, and wool is used for tea-cosies and kettle-holders. Colour affects warmth by conduction. Black absorbs twice as much heat rays as white, then dark blue, blue, red, green, yellow. Hence white flannels in summer and coloured in winter are worn for games.

2. ABSORPTION OF WATER, OR HYGROSCOPY. Wool here leads with 170 parts of water as maximum, and a minimum of 110; then come silk, cotton and flax, with a maximum of 75, and a minimum of 41. Wool being most hygroscopic, is badly adapted for outer garments exposed to the wet, as it gets intolerably heavy when soaked; thus, a waterproof is better than an ulster.

3. EVAPORATION OF WATER. This is a very dangerous process in clothing, as it lowers the temperature rapidly; hence materials such as cotton, from which water evaporates quickly, are cold. Wool, on the contrary, has slow evaporation.

4. POROSITY (to air). Wool comes first, with 10, cotton 6, linen 6, wash-leather 5, silk 4, waterproof 0.

5. IMPERMEABILITY (to wind and water). The order here is fur, wool, silk, cotton, flax.

6. INFLAMMABILITY. Wool leads, then follow silk, linen, cotton.

7. ABSORPTION OF ODOURS. Wool absorbs most.

8. ELECTRIC QUALITIES. Wool generates currents and allows body currents to pass; then come, in order of their electric qualities, silk, wool, flax, cotton.

The Best Clothing Material. The best clothing material, therefore, is that which is the worst conductor, hygroscopic, with slow evaporation, most porous, impermeable, least inflammable, and with electric qualities.

Only one material—as, indeed, is now becoming well known—fulfils these conditions, and that is the natural covering of the sheep—wool. When properly manufactured, woollen garments are the most comfortable to wear next the skin; hence wool is now used as the material in making an immense variety of clothes. One sort of vest suitable for summer is like a fishing net, with meshes ½ in. wide. Another is knitted like a stocking, of varying thickness and fineness; it shrinks little and wears well. Ordinary flannel is a third sort, and may be had of any thickness or fineness. An inner garment should always be rather loose in fit and in texture, thus ensuring warmth and sanitation. Again, wool is the lightest material for clothing in proportion to the warmth it gives when dry, and thus for every reason it is the best for underclothing.

The same amount of clothing in separate layers gives more warmth than in one—that is to say, two thin jerseys are warmer than two thick ones. This is in virtue of the air between the two.

At night, except for quite young children, linen or cotton forms a better dress and more soothing to the skin than wool, the bedclothes making a sufficient protection against cold.

Wool is rough, heavy, dirty, shrinks, absorbs odours, and is expensive. Now, roughness is a real advantage in all sedentary occupations when the skin is sluggish; on the other hand, woollen cloths are now woven almost as smooth as silk. It is not strictly correct to regard flannel as heavy, for wool is the lightest *for the same amount of warmth*. It does not show dirt readily, and is thus considered dirty. Shrinkage is the most serious drawback, but can be avoided by the use of distilled water and a purely neutral soap (with no free alkali whatever). Woollen articles can be boiled, and by this process alone disinfected, for 15 minutes without damage. In ordinary water and soap they are either utterly destroyed or made like a board. There can be no doubt that on the whole the advantages of wool far outweigh its disadvantages.

Various Clothing Materials. *Fur* forms an invaluable article of clothing, being absolutely impermeable and a bad conductor of heat. It is such an absolute protector that great care is required in its use. *Leather* is admirable for motoring and all rough, exposed work. *Feathers* form light and warm articles of clothing owing to the amount of air they retain.

Silk is three times as strong as flax, and forms a most delicate and useful material for underclothing as well as dresses. It ranks in most of its good qualities next to wool, and surpasses it in its smoothness and electric qualities, but is most expensive. China silk contains no silk, but is China grass.

Cotton is made into every conceivable article of clothing. Under the name of flannelette, a pure cotton cloth is made to resemble flannel by raising the surface, so that it can absorb more air and give a warm feeling. Cotton is most inflammable.

Flax can be spun into linen almost as fine as silk, and cloth of every sort of fabric can be made, from the most delicate muslin to ships' sails.

Cotton and linen are both good conductors of heat, though linen is the better. Comparative power in losing heat is seen in the fact that while woollen fabric heated to 150 deg. loses 10 deg. in 12½ minutes, cotton loses the same amount in 9½ minutes, and linen in 7¼ minutes. The advantages of linen and cotton are that they are easily washed, are soothing to the skin, and are white, which wool never is; but they do not absorb water. The result is that they are cold, even on hot days, as they leave the perspiration on the wet skin, instead of drawing it off into the cloth.

Paper may hardly be considered as a clothing material; but it is of great value to the poor as a covering for beds, etc., and worn under the clothes, being a great non-conductor of heat, and thus very warm. It is also inexpensive, though not nearly so much used as it might be. The wearing of paper spread over the chest and buttoned under the coat answers the purpose of an overcoat. It makes a capital extra lining for boots, waistcoats, etc.

Dress for Men. With men, clothing is fairly rational and sanitary, and even among women, as we shall see, such advances in a right direction have been made that the strong language used against their dress by health reformers some years ago is now quite out of place.

The head is the only part of the body naturally clothed, and save for cleanliness needs no other covering. Indeed, it is far better bare than crowned with the chimney-pot hat. A tight-fitting tall hat is often really dangerous owing to the compression of the temporal arteries. All head coverings should be light and well ventilated. The ordinary hat weighs more than twice as much as a proper head-covering need do, while the want of ventilation produces a great and undue susceptibility to cold. An ordinary cap, a soft felt hat, a fur cap in extreme cold are all sensible head coverings devoid of danger. In summer a straw hat is admirable, and is both extremely light and well-ventilated.

The neck should be but lightly covered, and left free of all constrictions, for mufflers and neck wraps are frequent causes of cold and bronchitis. A beard is, of course, a great protection, unless it happens to be frequently wet and imperfectly dried.

Men's Good Sense in Dress. With regard to the body, the ordinary dress worn by men fairly fulfils the requirements of health. It is not picturesque, as a rule, but it is suited to our climate. The knitted woollen vest with long sleeves is a capital garment, also a knitted belt round the body as a protection against liver chills; so is the outer jersey or guernsey of sailors and fishermen. The coat and waistcoat of civilised life is a sensible attire for a variable climate, for if very cold the coat can be buttoned up, if warmer it can be left open, if hot it can be discarded altogether. Braces should always be used in preference to tight belts. It may be taken for granted that any garment that compresses any part of the body is harmful. The habit that working men have of tightly buckling a belt round the waist when hard at work is most injurious, and may lead to serious strains. No garters should be worn on the legs. Men's boots are, as a rule, sensible; only, the boot of the countryman is generally as unyielding as if made of cast iron, rendering perfectly useless all the elaborate muscles of the foot. A proper boot should follow the natural shape of the foot, should be elastic in the waist and sole, and have broad, low heels.

Bright-coloured socks or stockings should always be avoided, as even now they too often contain poisonous dyes. Leather leggings and puttees are better than waterproof coverings.

How a Woman Should Dress. The chief errors which occur in women's clothes are the results of the vagaries of fashion. In one or two respects even ordinary clothing greatly errs, but it is undoubtedly in fashionable dress that the greatest danger lies. Garments cut on health lines *only* are confessedly absurd; for, after all, clothes have to fulfil many purposes, beauty being one of them. There are three great laws of health that must be obeyed in the dress of women, and they are: *No compression, no depression, no oppression.*

During the last twenty years there has taken place a revolution of the most beneficial character in the whole arrangement of a woman's underwear. The numerous petticoats and underskirts long considered so essential, which yet were so unhealthy and inconvenient, have well-nigh disappeared.

Since the hair of women is more plentiful than that of men, the need for head covering is less; hence, as a rule, their bonnets and hats are light, and less protective

With regard to the neck, a serious and common fault is to wear the collar of the dress far too tight. Another great fault is the very capricious way the neck is treated, at times thickly covered with fur boas and stoles, at others uncovered. When it is habitually left bare, the neck soon gets as hardy as the face.

Over the under-garment should be worn a well-fitting, but not tight, flexible corset. The corset, made of flexible material, is a useful support to the yielding form of women, though an unmitigated evil to growing girls in hindering the growth of the muscles of the back and producing weakness and curvature in that region. To adults its great evil is not so much in its use as in its abuse. Corsets can be worn without tight-lacing.

The Abuse of Corsets. Let a tape measure be passed round the narrowest part of the corset, and then round the narrowest part of the body when the corset has been removed. If the latter measure exceeds the first, the person undoubtedly laces tightly; for, to say nothing of the thickness of the corset, which should therefore measure quite an inch more instead of less than the waist, some allowance should, strictly speaking, be made for breathing.

Now, what are the real evils of compressing these lower ribs by corsets and thereby forming an artificially small waist? In the first place, the particular part of the body that has been selected for squeezing down to seventeen or eighteen inches is, unfortunately, the most important in the body. If the staylace wound about this part could be drawn tight enough to pass through the body, it would pass clean through the stomach, liver, and spleen; it would divide the bases of both lungs, and just miss the heart above and the kidneys below. It would divide the main blood-vessels and nerves of the body. It would also cut right across other organs, such as the pancreas and duodenum. Now, it is a literal fact that even a moderate amount of compression indents the liver with the shape of the ribs, produces shortness of breath, palpitation, and dyspepsia, while, if carried to excess, the ribs may be dislocated, the liver nearly cut in two, and the severest diseases set up.

The natural size of a woman's waist varies from 24 in. to 26 in., and all the generations of tight lacing have not been able to make it smaller.

Another evil is the use of heavy woollen skirts and underskirts tied round the waist, and hanging from it. The evil here is not compression, but depression of the internal organs. No strings should be fastened about the middle of the body, but a well-fitting bodice of some stout material should be worn over elastic corsets sufficiently supplied with buttons for the suspension of all the lower garments. Care should be taken to see that the clothing is not too tight under the armpits, across the chest, or on the arms.

Boots. As to boots, the modern French article is quite on a par with the Chinese boot. The only article worth calling a boot, and pretending to be a rational covering for the foot, is one in which the instep or tread is as broad as the tread of the foot, and where the toe follows to some extent the natural outline. The general fault about boots is that they appear to be made for the hand rather than for the foot, for the longest part is in the middle. This is so with gloves and the hand, but in the case of the boot the longest part is at the big toe, on the inner side, and only boots thus shaped are right. Most boots also are too small; yet it must be remembered that when the weight of the body is pressed on the foot as in walking, it increases one-twelfth in length and one-eighth in breadth. Some square-toed boots are, however, even greater delusions in their way than pointed toes, as the former may be very square at the end and yet too narrow higher up The great point is to see that the boot is as broad as the foot at the tread. The curve of the inner side should be very slight, and the heel of the boot must be low and broad to give comfort in walking. Attention to these matters, and the wearing of woollen stockings, will preserve the foot from chilblains, corns, and bunions. The waist of the boot, and the soles, as has been said before, should be perfectly flexible, any rigidity destroying the natural spring of the foot.

Dress and Good Taste. We urge our readers to choose their dress judiciously, and to be assured that it is far better taste and far more important to study quality than appearance. Let the hat be plain and serviceable enough to stand a shower. Let the dress be of good material and not too heavy or weighted down with useless flounces or trimmings. Let the underclothing especially be of wool, loose and warm. Let the boots be strong and well shaped. Let everything be good of its kind. It is a matter of regret that in this country so few dress plainly and according to their occupations.

TOOLS

continued from page 4151

By JOSEPH G. HORNER

BEFORE we proceed farther with tools which, though classed among cutting instruments, operate mostly by scraping, it will be desirable to consider the action of the scrape.

Action of Scrapes. The difference between a cutting and a scraping tool has been already explained thus—that the former has a very pronounced incisive or penetrating, wedge-like action, while the latter has not. If we look at a chisel [16], and then again at a common woodworker's scrape [17], the distinction is very apparent, the former cleaving the wood, getting well beneath the surface, the latter operating only to an infinitesimal degree below that surface. When the scrape is coerced, there is a very slight amount of penetrative action exerted, but it is so slight that any attempt to force the thick tool sensibly below the surface is in vain, and results only in the production of excessive friction and of heat.

Fig. 18 is typical of the mode of application of most scraping turning tools used for metal, top rake being entirely absent, and a clearance angle only being given to prevent undue friction and heating. Similar angles are employed in the scraping tools employed by wood-turners. An exception to this is the woodworker's scrape [17], in which there is actually a very slight amount of top rake imparted by the burnishing or sharpening of the tool, the edge being just slightly turned up by that act, and forming, while it lasts, a minute cutting edge. This is somewhat exaggerated in 17, but the penetrative power is not like that of the chisel, or plane iron

The Value of the Scrape The advantage of the use of the scrapes for wood [17] and for metal [18] is that they are capable of finishing surfaces very smoothly and very true. The first-named is used for smoothing simply, the second for both purposes. The wood scrape of the cabinet-maker effects a slight reduction in the surface of a cross-grained and curly piece of hard wood, veneer or otherwise, without tearing up the cross and curly grain as the plane would do. Having no penetrative power, it manifests no tendency to follow the grain and tear it out. Hence it can be used in all directions of the grain with equal effect. The metal scrape in like manner removes the marks of the cutting tools and of the files by which material has been removed in bulk, and also permits a localisation of effort when absolute accuracy of surface is desired. The point of a scrape can be made to operate over an exceedingly small area, whereas the action of a file or a cutting tool cannot be so concentrated. The most accurate results possible in hand work, therefore, are produced by scraping; all the metal slides and take-up strips in machine tools, engines and other mechanisms, and in surface plates and straightedges being so treated in the best work. Each of these tools, therefore, the wood scrape and the metal scrape, though so extremely simple in themselves, are as absolutely indispensable as the more pretentious cutting tools which we have already enumerated. They also figure largely in the kit of the ornamental turner working in hard wood, bone, and ivory.

Scrapes for Wood. Examples of wood scrapes are shown in 20, comprising the inclusion of straight lines and of curves. They may be purchased, but cabinet-makers often cut them from old saw-blades. A couple of metal scrapes are shown in 21, the first for flat surfaces, handled like a file; the second for concave bearing brasses, operating by the curved edges.

A group of scraping turning tools for wood, bone, and ivory is illustrated in 22. A is the round nose, B the diamond point, C and D the right and left hand side tools. The under side, or bevelled side, of each of these is seen, the tools being turned over for use. Succeeding tools are of smaller size, E, F, and G being of curved shapes for various curves, H and J cranked tools for internal straights and curves, while K is a parting tool. Several modifications of these types are used in ornamental turning for producing the more intricate forms.

Scraping Tools for Metal. Tools which operate simply by scraping are employed largely by the metal-turner and machine hand for broad finishing of surfaces; they obliterate the minute ridges left by the regular cutting tools. And they are also profiling tools, producing convex, concave, and other sections the exact counterparts of the tool shapes. Some common forms of these finishing tools are shown in 23. A is a plain, straight-nosed finishing tool; B and C, convex and concave tools, for finishing hollows and beads; D is a radius tool, for trimming the ends of work neatly to a curve. The circular tool, E. is used for large radii, the reduction of the shank permitting easy access to undercut curves; F is employed for inside work. The parting or cutting-off tool, G, is of narrow section. It is a type which tends to dig in, owing to the absence of side feed, and top rake is therefore not advisable. The spring tool H is not suitable for accurate work, but it produces a fine finish, and does not tend to dig in.

If the foregoing strict definition of scraping tools be adopted, they form an exceedingly numerous class. For to these belong not only the various scrapes pure and simple, but most of the milling cutters, the files, saws, and many of the cutters set in boring heads, some of the drills, the reamers, and rose bits—a very numerous family. But having stated these facts, we shall no longer follow a strict classification, but consider them all as belonging to the great group of cutters. This will be more convenient, being more in harmony with the variations that occur in tools of the same name and with the results which they produce.

Milling Cutters. The employment of single, narrow-edged tools of the chisel type, described in the preceding article, for operating on broad surfaces would appear rather incongruous even to an observer who knew nothing about workshop practice. And it has, in fact, always been considered most unsatisfactory by engineers that a powerful machine often costing hundreds of pounds should be used to operate one little tool taking off a slice, say ⅛ in. wide. Many attempts have been made to remedy so anomalous a condition of things. But experience has proved that it is difficult to multiply single cutting tools on a machine unless the work is of a very simple and repetitive character. Hence, improvement has come in another way. Instead of attempting to multiply these tools, the device is adopted of arranging a number of cutting edges in a circular form, and of operating them in rotation. Instead of taking off a narrow shaving of considerable depth, a broad but shallow cut is taken. These tools are termed *milling cutters*. The conditions of operation are different in the two systems, but the final results are similar. The milling cutter is more economical, and is much better adapted for some classes of work than single-edged tools are.

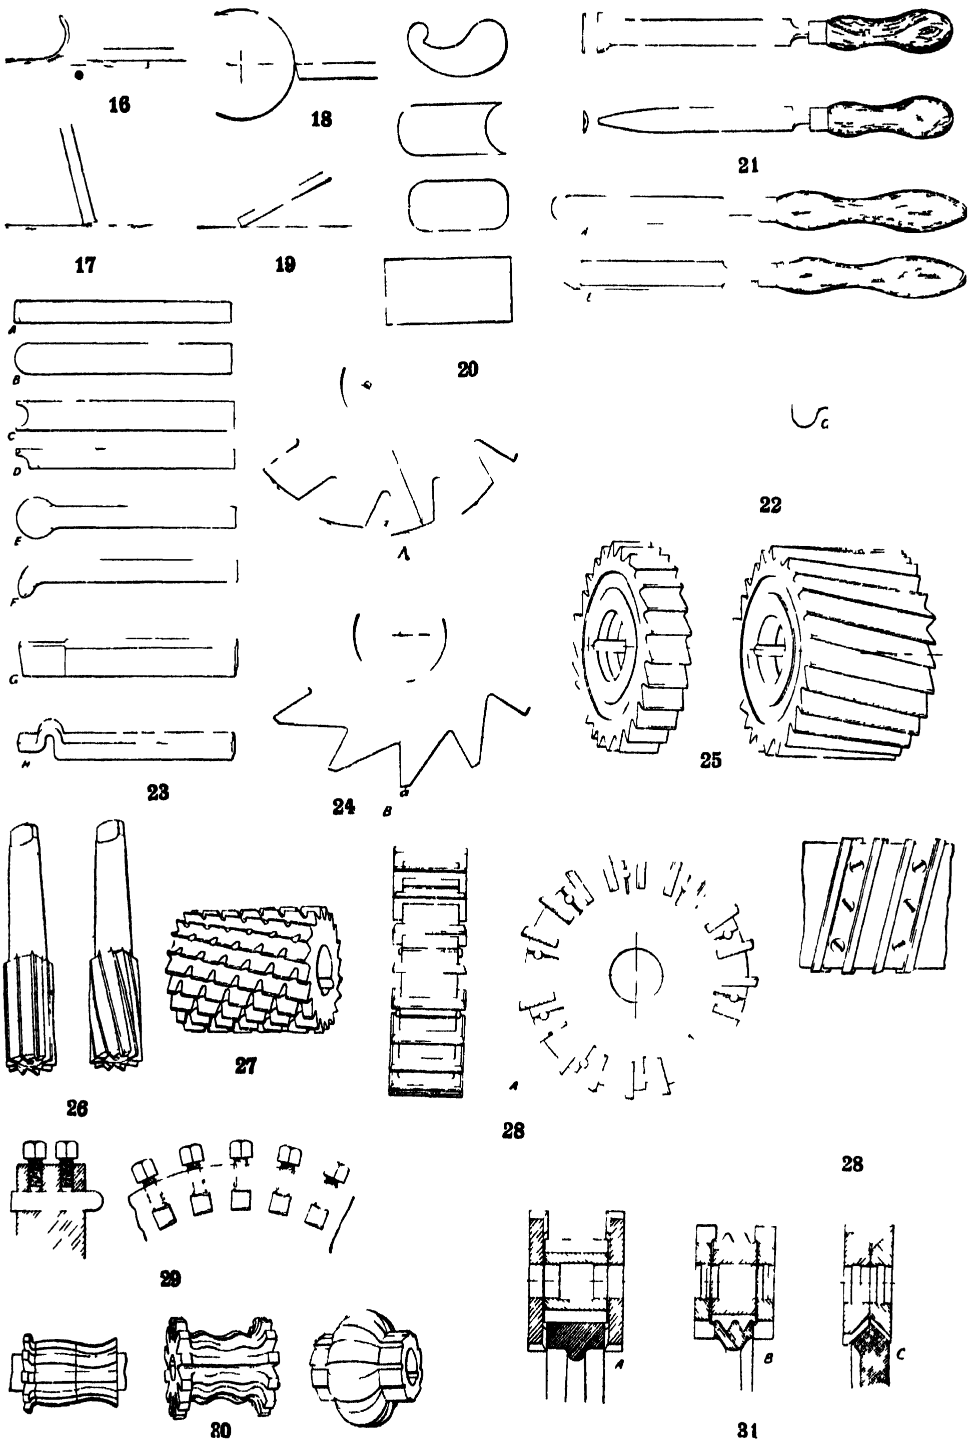
The milling cutters contain a large number of teeth arranged in circular form, each of which cuts in succession. The width may range from ⅛th in. to 24 in., or even more, so that surfaces of any reasonable breadth are finished without any movement or feed of the cutters transversely. But the teeth are not precisely like those of common tools. The front or top faces are nearly, or quite, normal to the surface of the work, so that the action is less that of true cutting than that of scraping. But what is lost in this way is more than gained by the multiplication of cutting edges and by the advantage of periods of rest intervening, due to each cutting edge revolving in air before taking a second cut, which gives it time to cool off.

Value of Milling Cutters. The cutting edges may be arranged round the periphery of a circle (*edge mills*), or on the face of a disc (*face mills*). They may occur in planes, or in any profiles, more or less irregular in contour. And one of the principal advantages derived from these cutters is due to the fact that they will produce irregular outlines, which cannot be nearly so well done by single-edged tools. They are immensely superior in this respect to any single tools, because the mill is made to the reverse form of the profile required, and thus finishes at once to shape. In form cutting also, outlines are produced which would be almost impossible of formation in any other machine. So immense is the development of milling practice that in many shops from 25 per cent. to 50 per cent. of the work formerly done on reciprocating machines of the planer, shaper, and slotter types is now executed by milling. In the cycle, sewing machine, and gun making industries, in which regular forms are so common, these cutters are used more extensively than in general engineering. The essential principle is the substitution of a multitude of cutting edges for one only. As the milling cutter revolves each edge operates in succession on the work which is passed under or alongside of it, with the result that a larger quantity is removed in a given time than would be possible with a single-edged tool, and generally the surface cut is much smoother. While, further, the width which can be covered by the edge of a single tool is always narrow, that which can be covered by a mill is almost unlimited. The only limit to width is the difficulty of the prevention of vibration in the mandrel or arbor which carries the milling cutter or cutters. A milling cutter can be driven twice or thrice as fast as a single cutting tool without getting hot.

The present growth of the milling cutters would never have been achieved but for the emery wheel. The early cutters had their temper drawn as often as the teeth became dull or damaged, to permit of refiling, after which rehardening followed. This, with its inevitable concomitant of distortion, rendered accurate results impossible. Actually, fine finishing was not attempted with the early cutters; they were used as roughing-out tools only or as preliminary to the subsequent corrections of the fitter or machinist. But when the emery wheel and its machines rendered the exact grinding of hardened cutters practicable, then the victory of the cutter became assured.

Relieving. Another event in the history of the cutter which contributed greatly to its success was the *backing-off* or *relieving* of the teeth in such a way that the sectional form of the teeth was not altered by any number of regrindings. The backed-off cutter has a centre eccentric in relation to the cutter centre from which the tooth curve is struck [**24**, A], so that whatever shape the tooth may present in profile is continued back over the width of the edge. Grinding, therefore, on the face, *a*, does not alter the form which will be milled, but only thins the tooth, and renders it weaker. The ordinary cutter [**24**, B] has no permanent profile, but is ground on the edge, *a*. This may be done to a definite outline, but is not nearly so simple a matter as the sharpening of the backed-off mill. Another advantage of the latter is that the teeth are much stronger, and able to take heavier cuts. Material help was afforded to the backed-off cutters by the invention of the relieving lathe, in which the tool slide of the rest receives a definite reciprocating motion for each tooth that is brought round and presented to it. All the teeth on a cutter are thus backed off alike, and rapidly, and so the labour of filing the clearance by hand is saved. Filing, moreover, would be a most difficult method of producing the profile.

Variations in Design. The milling cutter has also grown with the machine until it has become a protean tool. It is made very



WOOD AND METAL WORKING TOOLS

16. Action of chisel **17.** Action of scrape **18.** Action of turner's scrape **19.** Action of metal worker's scrape **20.** Scrapes for wood **21.** Scrapes for metal **22.** Scraping tools for turning wood, ivory, bone, etc **23.** Scraping tools for turning metal **24.** Backed-off and ordinary milling cutters **25.** Straight and spiral toothed mills **26.** Straight and spiral toothed end mills **27.** Staggered mill **28** Inserted tooth mills **29.** Inserted tooth face mill **30.** Form mills **31.** Built up mills for circular milling small and very large, with solid and with inserted teeth, suitable for finishing or for slogging. The staggered and the inserted teeth both have this end in view. On the other hand, the spiral arrangement of the teeth of mills has been a great factor in producing smoothness of cutting. There is no rule for this practice, which goes over a wide range, from a moderate twist to a very great amount, especially in some of the French mills. The shearing cut produced lessens chatter, and chatter has always been an evil to which milling cutters are peculiarly liable. Fig. 25 illustrates the difference between straight and spiral teeth, the one, a narrow cutter, being straight faced; the other, a wide one, having the teeth slanting. End mills [26] are also made straight and spiral. The staggered mills [27] are used chiefly for heavy roughing, the teeth being divided up into short sections by a spiral groove running around so that the chips break up into short pieces and so do not clog the action like long, stiff cuttings.

Inserted Teeth. The inserted-tooth cutters are made with the object of saving tool steel, and of giving facility for manufacture. One good method of fitting is that in 28 A, where the flat cutters are held in the cast-iron body by taper pins, which are driven in the sawn slots to open these out and jam the cutters on each side firmly. The cutters may be set straight faced, as shown at A, or on an angle, as at B, to give a shearing cut. Another device, also depending on wedge action, is that in 28 B. Here each pair of teeth is held by a strip wedge, jammed in with three or more set-screws. So long as the screws are tightened up, the cutters cannot move, They are frequently made with notches, so that a staggered effect is produced similarly to 27, the notches in one cutter coming alternately to those in the next cutter.

A simpler method is followed in the large face or ending mills, which are made up to several feet in diameter, set-screws, one or more to each tooth, being used for fastening, as in 29. Several dozen tool points may be held thus in a large disc.

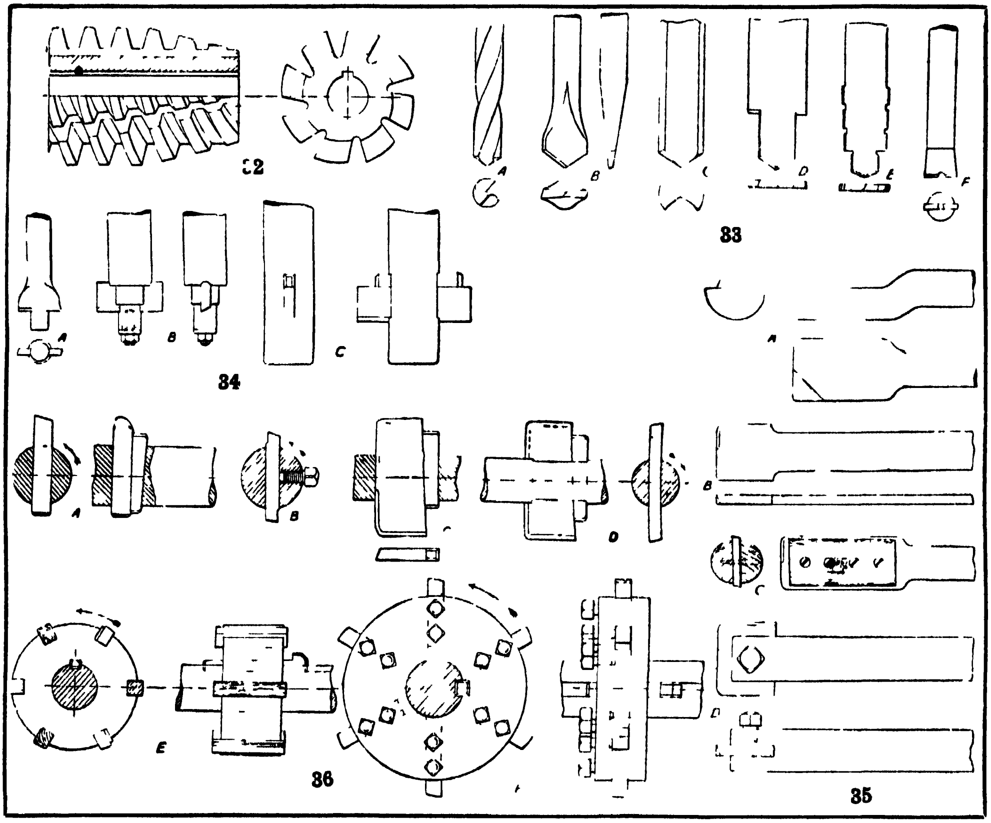
Form Mills. Form mills occur in innumerable shapes, including straight and curved portions, or in the latter alone. They are made in very intricate outlines, but as backing-off is done, the strength of teeth is ample, and the cutter remains in use for a long period. It is usually more convenient to build up difficult shapes from several separate cutters, stringing them together upon an arbor. A few examples of form mills are given in 30.

Built-up Mills. In 31, examples of built-up mills for circular milling are shown, the work revolving against the rotating cutter, which tools the edges and faces simultaneously in less time than they could be turned. A employs three cutters for milling a gear-wheel blank on the rim; B mills a rope-pulley with two grooves; while C shows two cutters tooling a bevel-wheel blank. There is hardly any limit to the profiles which can be thus treated, the number of cutters being increased if necessary. The wear of the side-cutters may be compensated for in A and B by placing washers between the three cutters and inserting fresh thinner ones when regrinding has reduced the height of teeth of the outer cutters.

A profile cutter of a different style is that shown in 32, a worm hob on the Reinecker system. It is turned up to the form of a triple threaded worm, grooved and backed off. The tapered form is produced in order to hob the wheel in successive stages to the full depth.

Drills and Allied Tools. In drills we see that precisely the same principles hold good among these as among other tools, and that they afford examples of tools some of which act by scraping only, others by true cutting. The best form of drill is the twist type [33, A]. Although a twist is imparted to the body of the drill in order to allow of the free passage of the chips upwards without choking, yet it also fulfils the very important function of imparting front rake to the cutting edge, an advantage which is absent from the common flat type [33, B]. Since the cutting edge is ground transversely to the face of the twist, the angle which the twist makes with the vertical equals the amount of front rake, and is constant. Also the bottom of the drill is ground slightly backward, and this gives the angle of relief, or clearance. Thus, the exact conditions of a true cutting tool are fulfilled here. In the flat drills, however, there can not only be no front rake, but the reverse very often, rake being negative, the cutting face actually leaning over from the perpendicular [B], which leaning over is necessary in order to keep the point or apex of the cutting edges as thin as possible. But the angle of relief is present, being imparted by the grinding backwards of the edges. In the lip drills, front top rake is imparted sometimes by turning up the lips, or by filling grooves in front of the cutting edges. These, however, have the disadvantage of not maintaining their edges so long as the flat drills; the grooves soon disappear by sharpening.

Efficiency of Drills. Badly formed though the flat drill is theoretically, yet as a drilling instrument it is very efficient. For it is a case of two equal and opposite forces—that is, of course, supposing that the drill is ground symmetrically—which balance each other, and maintain the tool in equilibrium. Moreover, the downward pressure of the tool in a conical-ended hole tends to preserve its concentricity, allows any force to be impressed upon it within the limits of the strength of the drill, and nullifies the very bad shape of the drill-point, which, passing straight across from face to face, can never actually cut, but only scrape and crush the metal. The slight amount of parallelism of the shank above the cutting edge also helps materially in the true guidance of the drill. But in the twist-drill we have almost absolute perfection—parallelism, front and back rake, and a clear passage for the chips, so that these drills must eventually drive all others out of the shops for general work. The outputs of twist-drills are greatly increased by an abundant supply of lubricant, which is conveyed to the point either through holes in the body of the drill, or through



METAL-WORKING TOOLS

32. Worm hob 33. Drills 34. Counterbores 35. Boring tools 36. Boring bars and heads

tubes lying in grooves along the body. A pump must be used to give sufficient pressure to force the lubricant in and wash out the chips.

The straight-fluted drill [33, C] does not possess top rake, and is therefore of more value for brass than for the fibrous metals. It has the advantage that on breaking through the metal at the end of the hole it does not tend to twist and run through, as twist-drills do. Two modifications of the flat drill are shown at D and E, used chiefly for brasswork, and generally in turret lathes. D drills a hole of two diameters, with a shoulder, being followed by a reamer when necessary, and E produces two diameters, the body being serrated to break up the chips. F is a slot drill, used for producing longitudinal slots, such as cottar ways and key ways, either the work or the tool travelling.

Counterbores. Counterbores resemble drills in their action, but are used for enlarging the end of a hole already drilled, to receive the head of a pin or bolt or screw. A plain forged form [34,A] has lips projecting from the shank, so that they cut an annulus of metal, the pin below keeping the tool central. The style at B permits of readily changing cutters and guides. The cutter is held by the central set-screw pressing with its point, while the guide below the cutter takes the form of a bush held on by the nut and washer. Different sized bushes may be substituted to suit the drilled holes to be counterbored. A simple type for large holes is that at C, the cutter being held in its bar by a wedge, so that it is readily removable.

Boring Tools. There is also a large group of tools used in boring. First, there is the D-bit, or half-round bit [35, A], which is capable of boring holes many feet deep, provided efficient lubrication be provided. It is used in the lathe and fed into its work by the loose poppet, or by the slide rest. It is a cutting tool, having slight top rake provided by the upstanding corner lip. Flat bits form a goodly proportion of the boring tools used in the lathe for the holes in pulleys, wheels, bearings, etc. No top rake is, of course, present. Fig. 35, B, is a style cutting on the front and along the edges ; it is fed up by the poppet, and steadied close to the work by a rest having a flat slot in it. A device often adopted is to screw blocks of hard wood to each side of the bit as at C, with the object of steadying it in the hole and preventing chatter. This is the chief trouble with these flat bits, want of guidance, so that unless care be taken they will follow the run of the cored hole, and result in untrue holes. In order to save tool steel, bits are frequently pinched in the end of a bar [35, D] with a set screw.

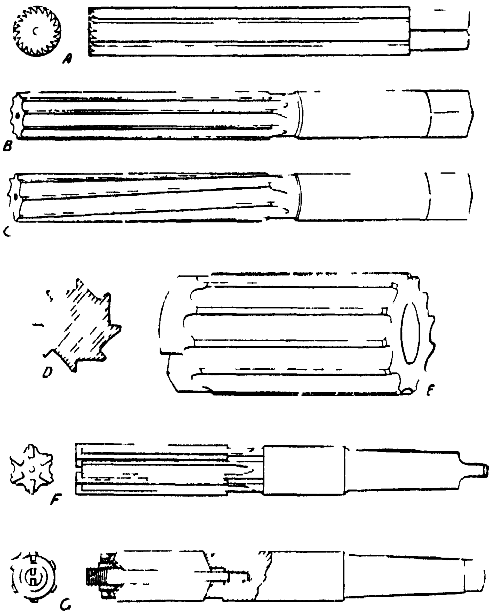
Boring Bars and Heads. Boring bars, which are revolved between the centres of a lathe, or in the boring machine, carry either a single cutter or a ring of cutters. For small holes the single cutter is very suitable; in fact, there is often no room to get more than one cutter to work. Fig. 36, A, is a square cutter held in the bar with a wedge. The cutter has no front rake; B is a double-ended cutter fastened with a set screw; C shows a double-ended flat cutter wedged in; it cuts on front edges, and along the sides also; D is a cutter secured centrally by cutting out a notch in the front, so that the two shoulders fit over the mouth of the slot in the bar, and prevent risk of lateral movement.

The boring head with cutters, used under so many modifications, consists usually of an assemblage of scraping tools, notwithstanding that true cutting tools are often employed in the same head. The advantage of the arrangement consists in this, that the cutting forces are balanced all around the bar, and the latter is therefore less liable to spring and is better able to bore a true hole; also, that in direct proportion to the number of cutters employed can the traverse feed be increased, because the duty is divided between all the cutters. Thus, a block with six cutters can be fed at six times the speed of a single tool. Fig. 36, E, shows a block with three cutters held in with wedges. There are also three hardwood strips driven into grooves alternating with the cutters, the object being to steady the head in the bore. Another style of head, shown at F, has six square cutters, each gripped with a couple of set screws. A good many heads of this style are built, with an increased number of cutters in the larger sizes.

Reamers. These are generally scraping tools, but some have a slight amount of front rake. A rose reamer (or broach) is seen in 37, A, and examples of fluted reamers at B, C, D, and E. These are of different design, but not different in their functions. They are used for enlarging holes to a finished dimension very slightly in excess of that left by a drill, and with a degree of accuracy usually unattainable with a drill. Also, even supposing the drill to be in good condition and the holes true individually, yet when two or more such holes have to come in juxtaposition to each other to take a single bolt or pin, there is often a want of strict alignment. Then the holes, being all reamered out at one operation, are true.

Fluted Reamers. The fluted reamers are either straight or spirally fluted, the two forms being shown at B and C. The latter has a smoother action. A device used in some cases is to form a fine thread for a short distance on the end of a reamer, so that it is drawn into the hole without excessive pushing effort on the part of the operator. The form of serrations usually made in reamers is shown in section at D, the front of the tooth pointing radially to the centre, while the back is cleared off in a slight curve. Alternatively a flat clearance may be formed. The edges of the teeth are either backed off with a flat, or with a curve, like relieved milling cutters, the latter form being rather stronger.

Shell Reamers. The hollow or shell reamers are made to fit on an arbor, a slot at the back of the reamer being driven by a cottar in the arbor. The flutes are either straight, as at E, or spiral. These shell reamers are of larger size than the solid types; by mounting one or more on a long arbor, holes in line may be reamered out in alignment. A device which is followed by some makers is to make an odd number of flutes, and sometimes to space them unequally, so that the teeth are less likely to follow the course of an irregular hole.



37. REAMERS

The disadvantage of the solid reamers is that they soon lose their original diameter by sharpening, and therefore cut under size. There are a large number of adjustable types constructed to increase the diameter from time to time. In 37, F, six blades of bevelled section are fitted into corresponding grooves in the body, these grooves tapering upwards towards the shank. As the diameter of the circle of blades becomes reduced, they are hammered farther into the grooves, thus increasing the diameter. When the limit of driving up is reached, a new set of blades is provided. Another method of fitting, shown in 37, G, involves the use of a central tapered plug, which, when screwed inwards, forces the blades out, the lock nut at the end being first slackened to permit of the adjustment being made. This principle of using a taper to expand the blades is followed in several other designs of adjustable reamers.

THE ROYAL NAVY

Conditions of Entrance and Service in the British Navy. Seamen and Artificers. Pay and Promotion. The Royal Marines

By C. DUNCAN CROSS

BY its glorious traditions and the opportunities it offers for seeing the world, the Royal Navy appeals alike to the patriotic and the adventurous instincts of a boy. The modern tendency towards comfort has shorn the Service of its hardship, and the opportunities for advancement make an appeal to a lad who loves the sea and is willing to work hard at an interesting career for a living wage and a comfortable pension. As the science of war advances so does the standard of intelligence, and to-day it is necessary for a Navy man not only to be strong, but also to have brains to direct his energy aright. For the past 50 years the class of sailor has been improving, till to-day he ranks high among the skilled workers.

So high is the standard of efficiency required of petty officers that the barrier between the officer and man is no longer insurmountable, and to-day a youth who enters the Navy at the age of 16 may well hope to reach a commission before he retires from the Service. Even should the hope fail to materialise, his training has been such that there is an excellent prospect of obtaining civil employment ashore.

How to Join the Navy. Application may be made to the station officer of any coastguard station; to the Royal Marine Recruiting staff officer at Belfast, Birmingham, Bristol, Exeter, Glasgow, Liverpool, London, Manchester, Nottingham, Southampton, or York; to the Commodore of the Royal Naval Barracks at Portsmouth, Devonport, Chatham, and Sheerness, and the Naval Recruiting officers attached to those ports; or at one of the outlying stations which are scattered through the large towns of the British Isles.

The standards vary from time to time, but it may generally be understood that a youth or man who possesses the qualifications set forth in the table may expect to be admitted as far as his physical requirements go. It should be observed with regard to chest measurement that the examining officer notes particularly the difference between the size of the expanded and contracted chest. This difference should not be less than two inches.

In reply to an application, a form is supplied to the candidate which he is required to fill up, and if his replies be satisfactory, he is provisionally examined. He is then sent to one of the depots for a final medical examination, the trade test (if the candidate desire to enter one of the trade openings), and a simple educational examination. If he fails to pass, his fare is paid home.

The physical standards required of candidates for the Royal Navy are as in the following table:

Age.	Height without Shoes.	Mean Chest Measurement.	
Boys:			
15¾ and under 16	5 ft. 2 in.	32½ in.	
16 ,, ,, 16¼	5 ,, 2½ ,,	33 ,,	
16½ ,, ,, 16¾	5 ,, 3 ,,	33½ ,,	
Youths:			
16¾ and under 17	5 ft. 2½ in.	33 in.	
17 ,, ,, 17½	5 ,, 3 ,,	33½ ,,	
17½ ,, ,, 18	5 ,, 3½ ,,	34 ,,	
Seamen, Special Service:			
18 and under 19	5 ft. 3 in.	34 in.	If 5 ft. 5 in., 34½ in.
19 ,, ,, 20	5 ,, 4 ,,	34½ ,,	Or over, 35 ,,
20 ,, ,, 21	5 ,, 5 ,,	35 ,,	If 5 ft. 7 in., 35½ ,,
*Over 21	5 ,, 5 ,,	35½ ,,	Or over, 36 ,,
Stokers, Continuous or Special Service:			
18 and under 19	5 ft. 3 in.	34½ in.	If 5 ft. 5 in., 35 in.
19 ,, ,, 20	5 ,, 3 ,,	35 ,,	Or over, 35½ ,,
20 ,, ,, 21	5 ,, 3 ,,	35½ ,,	If 5 ft. 7 in., 36 ,,
Over 21	5 ,, 3 ,,	36 ,,	Or over, 36½ in.
Domestics:			
16 and under 18	5 ft. 0 in.	32½ in.	
Over 18	5 ,, 3 ,,	33½ ,,	
Sick-berth Attendants:			
18 and under 19	5 ft. 4 in.	34 in.	If 5 ft. 6 in., 35 in.
19 ,, ,, 20	5 ,, 4 ,,	34½ ,,	Or over, 35 ,,
20 ,, ,, 22	5 ,, 4 ,,	35 ,,	,, ,, 35½ ,,
		Of any age between 5 ft. 5 in., and 5 ft. 6 in., 34½ in.	
Engine-room Artificers, Electricians, Armourers, Blacksmiths, Carpenters, Coopers, Plumbers, and Cooks' Mates:			
18 and under 20	5 ft. 3 in.	34 in.	
20 ,, ,, 22	5 ,, 4 ,,	34½ ,,	
22 ,, ,, 23	5 ,, 4 ,,	35 ,,	
Over 23	5 ,, 4 ,,	35½ ,,	
Ship's Stewards or Writers:	No fixed physical standard.		

* With Admiralty authority up to 25

NOTE. These standards are liable to alteration according to the supply of and demand for recruits.

Special Service. There are two varieties of service—continuous and special. A Special Service man enters between the ages of 18 and 25, agreeing to serve for the first five years with the Fleet, and for the remaining seven years in the Reserve. Providing he reaches the rating of able seaman, he may earn one good conduct badge at the end of his first three years' service. This bears 7d. a week extra pay. If the man enters the Navy from the Mercantile Marine, he may even earn this badge at the end of twelve months. An additional 7d. a week may be earned by those who qualify as *trained men.* On transfer to the Reserve, with a retainer of 6d. a day, the man is liable to one week's training every year, or a fortnight every other year. In case of national emergency he is, of course, obliged to join the Fleet. If, after his 12 years' service is complete, the reservist elects to continue to re-enrol for successive periods of five years, he will receive a gratuity of £50 when discharged on completing 20 years' combined service in Fleet and Reserve; but no man will receive the gratuity or be released from liability for active service until he reaches the age of 40 years. A special Service man has, be it observed, no chance of rising to warrant officer rank.

Stokers may enter the Navy in the Special Service class in much the same fashion as seamen. They must complete five years in active service and seven in the Reserve. Good conduct badges can be won in the same way as we have outlined above, and the gratuity on completing 20 years' combined service is the same. Special Service stokers do not, as a rule, rise above the rank of leading stoker, and it is hardly possible to rise even so far in the five years.

Generally, therefore, it may be said that in the Special Service there is no great prospect of a career. It is, however, an avenue for the men of the Mercantile Marine. They have five years' training, which is most valuable on returning to their civil occupation, and it secures them a retaining fee to add to their wages.

Continuous Service. Men of all ratings sign on for 12 years, at the end of which time they may re-engage for another 10 years to complete their service for a pension. At the end of 22 years' service they may retire with a pension, or they may be allowed in special cases, if their conduct has been all that could be desired, and if they have progressed satisfactorily, to serve until the age of 50, with an increase to their pension for every year's further service as tty officer. It is a condition with men and ys of the seaman or stoker class enlisted after March, 1901, that to qualify for the long-service pension they must belong to the Royal Fleet Reserve up to the age of 50.

Men disabled or invalided out of the Service are dealt with fairly generously on a sliding scale by pension or gratuity, according to the nature of their disablement and the circumstances in which they are placed. Men disabled in the execution of their duty are awarded life pensions, irrespective of the length of their services. Furthermore, a grant of £22,000 a year is made by Greenwich Hospital for the assistance of seamen or Marines who have no naval pension or whose pension is small. Pensions to widows, etc., are another feature of the benevolent side of the Service. Another most excellent institution is the Greenwich Hospital School, where 1,000 sons of seamen and Marines are educated and maintained free of cost. In addition, 100 boys and 150 girls are maintained at various homes.

All men, whether for continuous or special service, receive a grant towards the cost of their outfit and bedding. In addition to their pay they receive free rations on a scale greatly improved in recent years. Out of this, by careful management, it is possible to effect "savings," which are credited to the man, and go to buy luxuries.

Boys. A boy must be of good character, must produce a birth certificate, or a declaration made by his parents before a magistrate that he is of the proper age, and the written consent of parent or guardian to his entering the Navy and to his agreeing to serve until he has completed 12 years' continuous service from the age of 18. He must be able to read and write a passage from a Standard IV. reading-book, to write a similar passage from dictation, and to have a fair knowledge of the first four rules of arithmetic.

PAY OF WARRANT OFFICERS, PETTY OFFICERS, AND MEN.

On acceptance, the boy is sent to a harbour training ship, and is credited with £10, with which he must purchase the kit laid down in the regulations, the sum remaining over being placed to his credit for future expenses, for he will in future have to depend almost entirely on himself for new clothes.

After six or twelve months' training on board the harbour ship the boy is drafted to a seagoing training ship to gain a knowledge of seamanship and gunnery.

Youths. Youths entering between 16 and 17 years of age must have the consent of parent or guardian and join the training ship direct, without harbour service. They are rated as second-class boys for the first three months. Later, boys and youths are rated as first-class boys until they are 18 years of age. Before attaining this rating, be it observed, they must learn to swim.

The cruise ended, and the boys having reached the age of 18, they are sent to take their place in the ranks of the Navy as ordinary seamen. No examination is required for this rating, and it is only now that the ambitious young man has a chance of showing what he is worth. He goes to sea in one of his Majesty's warships, and he has the opportunity of learning from his officers and the instructors something practical of gunnery, seamanship, and sufficient engineering practice to pass his examination for able seaman.

Examination for Able Seaman. This examination is of the most practical nature imaginable, and consists of the following tests.

A fair knowledge of steering a ship, heaving the lead, rowing, knotting and splicing (hemp and wire rope), and general duties of seamanship; gunnery, torpedo, and field training, which he has learnt during his novitiate. He must be able to use simple engineers' tools and do ordinary stokehold work, such as sweeping tubes, cleaning boilers, etc. He must also have a knowledge of bunker work, firing, and watch keeping, all of which he will have learnt during his 30 days' course on board ship, during which time he is attached to the engine-room staff and is under the orders of the engineer. Furthermore, he must be able to make and read slowly a signal in semaphore, and understand the use of the flags used in flag signalling.

As able seaman he will turn his mind to gunnery, and will receive instruction in gunlaying, sight-setting, etc., from the gunnery lieutenant and the gunner, and in torpedo work, so as to gain the badges of seaman gun-layer, or seaman torpedo man, or turret gun-layer, etc., each distinction earning him a badge, and each badge carrying with it increase of pay, varying according to the qualification.

He will bear in mind also the good conduct badge which he will be permitted to wear after three years' service as seaman, with a "very good" character from his captain. These badges, awarded at the end of 3, 8, and 13 years' service, carry with them extra pay at the rate of 1d. per day each.

Leading Seaman. Leading seaman is the next step in the sailor's career, which means that he is a good helmsman and leadsman, able to assist in sailmaking and repairing ; a practical rigger. He must have a thorough knowledge of the practical side of gunnery ; he must be able to make and read semaphore signals, and he must know the use and colours of such flags and pennants as will enable him to look out a signal in the boat's signal book. His examination is carried out in a sea-going ship, and qualifies him for promotion to second-class petty officer.

Petty Officer. As petty officer the man must, to a certain extent, remodel his existence. He is now in authority ; he is directly responsible to his superiors that discipline is maintained, and that the men under his charge do their duty efficiently. By this time he will have made up his mind whether he prefers the duties of mere seamanship and the working of a ship, or whether the guns attract him more. In the first case his goal will be that of boatswain, and in the latter he will aspire to the position of gunner.

It is of the highest importance nowadays that men should take the earliest opportunity of qualifying in gunnery and torpedo work, for more and more attention is being paid to these branches of a seaman's education. and it may quite easily happen that his promotion will be very seriously retarded by the lack of a certificate.

From 2nd class petty officer the man is promoted to 1st class petty officer, and lastly he reaches the rating of chief petty officer or warrant rank (gunner or boatswain), when he drops the bluejacket's characteristic garb for the blue cloth coat and peaked cap.

Chief Petty Officer. Candidates for chief petty officer are not put on the roster until they have five years' service, with a very good character. Then their names are put down for promotion, and in due course they are selected by seniority, tempered by selection, on the reports of service and attainments. Since a warrant officer or a chief petty officer comes into close contact with the officers of the ship, it is most desirable that he should have taken every possible step to improve his education and his manners in the time of waiting by the assistance of the instructor and by private study.

Chief petty officer is the highest position reached by the majority of seamen. The man for whom this article is written, however, will aspire to climb yet one step higher to the commissioned rank of lieutenant. For this rank it is essential that his education should be excellent, for he may have to live in the ward-room with college-trained officers, and this point is taken into consideration in selecting men for commissions. It should be noted that commissions are given only to chief petty officers under 44 years of age, and that warrant officers must reach that rank before they are 35.

Promotion in the Navy. To give some idea of the rate of promotion in the Navy, it may be said that a smart young man with a fair education might hope, with luck and diligence, to reach the rank of second or first-class petty officer by the time he is 24, and to become chief petty officer at 28 or 30 years of age. Warrant rank would come in about the same time.

It should not be forgotten that for chief petty officers and warrant officers there are many good shore billets in the shape of instructorships at the colleges, at torpedo and gunnery schools, which not only carry with them a handsome increase of pay, but provide a most comfortable home for a man who has, perhaps, tired of the perpetual change of quarters which the exigencies of naval service involve. These go, of course, to men who are favourably reported to headquarters as being energetic, trustworthy, and who, by their application to the theoretical side of their work, have fitted themselves for the posts.

Engine-room Staff. Boys may be entered as boy artificers between the ages of 15 and 16 after passing the usual medical examination and an educational test of ability to read and write. They agree to serve for 12 years' continuous service from the age of 18.

On entry the boy artificer is placed on the ship's books for training at one of the home ports, and for the first four years is learning his trade as a workman under an instructor ; is instructed in steam and in general engineering subjects by an engineer instructor, and in general knowledge by a schoolmaster. His duty in life will be the care and repair of engines as compared with the stoker class, whose business is to drive them. After the four years' course, and a final examination in the subjects studied, he is classed as engine-room artificer 5th rate. He goes to sea for a year, and if he can pass the examination outlined below he is rated as acting engine-room artificer 4th class. It is possible for a practical engineer between 21 and 28 years of age to enter direct if he is able to pass the examination, which is as follows: A knowledge of the first four rules of arithmetic; ability to read and write well enough to record the working of engines and boilers; a general acquaintance with the names, uses of parts of marine engines; ability to run engines and to effect the ordinary repairs of an engine-room Candidates who hold a Board of Trade engineer's certificate, 1st or 2nd class, are excused this examination. After one year's service as acting engine-room artificer 4th class, the man, on obtaining a certificate from the captain that he is capable of taking charge of a watch in the stokehold, and that he is an efficient workman worthy of confirmation in his rank, becomes a 4th class artificer.

After three years' service above the rank of 5th class artificer, he passes to 3rd class artificer; in another seven years to 2nd class artificer, and, if he engages for another 10 years, to engine-room artificer 1st class. Above this lies chief engine-room artificer 2nd class, for which he must pass an examination in arithmetic up to vulgar and decimal fractions, and show his practical knowledge by being able, for example, to estimate bunker capacity or a cylindrical oil tank's contents. His knowledge of engineering must be wide and practical. He must know the best methods of prevention and cure of ordinary engine and boiler room casualties; must understand the management of boilers generally, and the running and use of valves; have a good knowledge of indicator diagrams and the calculation of horse-power; understand the adjustment of bearings and the fitting of brasses.

Six years in this rating qualifies him for chief engine-room artificer 1st class. Chief engine-room artificers of 29 years of age are eligible for advancement to warrant rank on passing the examination for artificer engineer and receive a gratuity of £25. These, again, may pass to chief artificer engineers, from whom, by selection, are chosen a few engineer lieutenants.

Stokers. The men who tend the boilers are in a far better position to-day than they were formerly. "Once a stoker always a stoker" used to be the saying; but now, by good conduct and willingness to work at the theoretical side of his trade, the stoker can rise to be chief petty officer, and even attain warrant rank, though few stokers expect the latter. An able-bodied man of good character and physical development, without previous experience, may enter as 2nd class stoker. After a period of instruction in his duties and in rifle, pistol, and cutlass drill (for a stoker must know how to fight nowadays), he is promoted to stoker on completing a year's service.

After four years' service comes a test examination based on the "Steam Manual" (Articles 351 and 509), and that being satisfactorily passed, he becomes leading stoker, and is rated as a 2nd class petty officer. After serving in this capacity he is eligible for advancement to acting stoker petty officer. It will now be necessary for him to work hard at his education if he wishes to rise further. He must attend a torpedo course to give him a knowledge of the engines and general working of these weapons, and after having served ten years in stoker ratings he may be promoted to chief stoker, which ranks as chief petty officer. The examination is the same as for leading stoker, but in addition he must have a general working knowledge of the parts and uses of engines and boilers. Provided they have at least five years to serve, chief and leading stokers who qualify are eligible to be rated as mechanicians, rising to warrant mechanician and chief warrant mechanician when they take charge of engines.

Signalmen. Signal boys are selected from the smartest of the 2nd class boys, or, if vacancies occur, from among the 1st class boys. Occasionally they are entered direct from Greenwich School. They are given an elementary signal course lasting some three months, and are taught the elements side by side with their instruction in seamanship. The work requires keen eyesight and a lively intelligence, for a signalman is one of the most responsible men in the ship.

The next step, that to signalman, is reached when the boy is over 18. The aspirant by that time must have gained a working knowledge of day and night signals. For this and the higher ratings men are not obliged to qualify in the same fashion as an A.B., but are exercised in gunnery and musketry. For the rating of qualified signalman is necessary a good working knowledge of day, night, fog, gun, and sound signals as applied to fleets, ships and boats, as is a proficiency in the use of the Morse code, semaphore, and flash signals.

After a sufficient experience as qualified signalman a man is advanced to leading signalman, when he must be able to undertake the duties of a signal petty officer, and must understand the regulations for prevention of collisions at sea. Every three years signalmen are obliged to go to one of the signal schools to requalify for their rating, so that they may not lag behind the times. Good men with sufficient experience are then promoted to second yeoman of signals. Yeoman of signals and chief yeoman are the next steps in the signalman's career, the appointments being made by seniority, tempered always by selection of the best workers and the steadiest men.

Naval Craftsmen. A few boys between 14 and 16 years of age are eligible for service as boy shipwrights, and a few boys between the ages of 15 and 16 may be entered as boy coopers. They have to pass the Civil Service examination laid down for dockyard apprentices, and agree to serve for 12 years after the apprenticeship, and are instructed in the yard until the age of 18, when they go to sea for training if they are found to be fit for the rating of cooper's crew or carpenter's crew.

Among the skilled tradesmen entered for service ashore and afloat are the electrician, the carpenter, and the shipwright, the armourer, blacksmith, and the cooper.

Young men of good character between the ages of 18 and 28 who are sufficiently good carpenters to do panelling, dovetailing, and sash-making, may join with the prospect of rising to leading carpenter's crew.

Coopers who can pass a trade examination in making a bucket, also armourers, plumbers, and cooks, with a knowledge of their respective trades, can all join the Navy with the prospect of rising to chief petty officer in due course.

Electricians. The electrician is another of the skilled tradesmen who are always welcome in the Navy. He must be between the ages of 21 and 28, and must have had three years' practical experience as fitter and turner. Men are preferred who have some knowledge of electricity or who have gained their experience in electrical shops. The candidate must pass an educational examination equivalent to school Standard VI., he must know arithmetic up to vulgar and decimal fractions, and be good at dictation and reading. The practical part of the examination consists in relining and readjusting metal bearings; metal turning and screw cutting on a lathe; and repairs to electrical apparatus and instruments.

As acting electrician, he enters the torpedo school and goes through a course of instruction, at the expiration of which he has to pass a further examination in repairing and fitting electric motors and all electrical instruments required in the Service. He must have gained a good knowledge of the construction and repair of Whitehead torpedoes, and he must understand the intricacies of electric lighting and wireless telegraphy. After his year's probation as acting electrician 4th class, he is advanced to 3rd class; in another six years to 2nd class, and in a further five years to 1st class electrician, provided he has re-engaged to complete his time for a pension. The rating of chief electrician, 1st and 2nd class, lies at the end of the service after a thorough examination in every branch of the art.

Sick-berth Staff. A limited number of young men between the ages of 18 and 22 may join the Service as sick-berth attendants if they can produce evidence of very good character, and have an elementary education. Selected candidates are accepted on probation, and go through a course of training at Haslar Hospital. They rise from sick-berth attendant through the grades of sick-berth steward, to chief sick-berth steward. There are a few shore berths open at Royal naval hospitals as ward masters, but promotion is not rapid, and unless the candidate has a special liking for the work, the position is rather trying.

The Royal Marines. The Royal Marines are soldiers with sea training and sailors capable of military duty; they are experts in artillery work, yet they can pull a boat as well as any seaman. Rather more than half are serving in detachments in sea-going ships, while the other half are at their various depots undergoing courses of infantry and artillery training. The advantages of the Service are change of scene and occupation, greater freedom of action than is enjoyed by soldiers, a wider field of training, and better pay. There are two branches—the Royal Marine Light Infantry (the Red Marines), and the Royal Marine Artillery (the Blue Marines).

Entrance Conditions. Growing lads from 17 years of age and men from 20 to 23 are eligible, provided they can pass the medical test and can read and write. On acceptance, they are forwarded to Eastney Barracks, Portsmouth, if for the Royal Marine Artillery, or the Depot, Deal, if for the Royal Marine Light Infantry. The Marine is obliged to engage for 12 years. Free kit and bedding are issued to every man.

The infantry recruit, after completing a course of infantry drill, swimming, gymnastics, and musketry, is drafted to one of the three great stations—Chatham, Portsmouth, or Plymouth—which becomes his home ashore, as is Eastney Barracks for the artilleryman.

Work of the Royal Marine. On completion of the above-mentioned instruction, the recruit undergoes a course of field training and heavy gun drill, and in about 15 months is considered a qualified man. He is then available for sea service, and, as soon as the exigencies of the Service allow, is drafted to one of his Majesty's ships. If his ship be serving in home waters, this period will be from one to two years, but if abroad, it will be [illegible] three years before he sees his "home" again, when he will take his leave on full pay and come back to requalify in shore work. Promotion to the superior ranks is not so rapid as in Line regiments of the Army, but he may expect to be promoted to corporal within five years, to sergeant in 10 years, and to colour-sergeant in 16 years. There are also 29 warrant officers' positions open by selection and seniority to senior non-commissioned officers and 17 commissioned posts as quartermasters. The educational standards required of the various ranks are the same as those of the Army for an infantryman, promotion coming by the passing of these examinations and the sea service completed.

Bandsmen. Marine bandsmen join the service between the ages of 15 and 23. They must be able to read and write, and have some musical knowledge. They are sent for training to the Royal Naval School of Music for instruction, and at the age of 18, or when fully trained, they become available for service on a battleship or a cruiser. The pay ranges from 4s. 8d. a week for boys to 38s. 9½d. for the highest ranks, with an allowance of 1s. 2d. per week for instruments, and good conduct pay up to 3s. 6d per week.

TOBACCO

Varieties of Tobacco. Climate, Soil, and Fertilisers Needed. Cultivation and Harvesting. Methods of Curing. Grading. English and Irish Tobacco

THE natural order *Solanaceæ*, which yields the wholesome potato and tomato, and the poisonous belladonna and stramonium, furnishes also the tobacco plant. The greater part of the tobacco of commerce is obtained from one species, *Nicotiana tabacum*. There are many distinct varieties of this one species yielding Virginia, Cuban, Havanna, and Latakia tobacco. East Indian or Turkish tobacco is the product of *N. rustica*, which is also cultivated in Germany, Hungary, Egypt, and West Africa. It is a hardier species, and requires less time for maturity than *N. tabacum*. Shiraz or Persian tobacco is the product of *N. Persica*, Yana tobacco is furnished by *N. repanda*, and a very strong tobacco used in Chili is prepared from *N. angustifolia*.

N. tabacum grows from 2 ft. to 9 ft. high, and the stem bears at its summit a panicle of tubular pink flowers [1]. The wide-spreading leaves are ovate, oblong, or lanceolate in shape, and are attached to the stalk in a spiral manner. The leaves are clothed with long soft hairs, and have lateral veins proceeding from a thick midrib in straight lines at angles of 40 deg. to 75 deg., gently curving upwards only near the edge. *N. rustica* has greenish yellow flowers, and the leaves have longer stalks. The smell of the fresh plant is narcotic, and the taste bitter and nauseous. The characteristic odour of dried tobacco is developed during the curing process.

Varieties of Tobacco. There are some 64 varieties of tobacco grown in the United States. Each of the varieties is accredited with certain characteristics of leaf; but as to which variety should be grown in any particular country it is not possible to give any exact information, as so much depends on the soil and climate. Bright-yellow tobacco, such as is grown south of the James River in Virginia and in the famous Granville section of North Carolina, will not succeed on dark, rich, loamy, alluvial soil. This particular kind fetches the highest price among American tobaccos. The rich dark variety exported to England is grown on alluvial soils containing some sand and with clay subsoil.

Tobacco-growing is best suited for regions having a mean temperature of not less than 40° F., and which are not subject to autumn frosts. The comparatively dry climate of tropical countries is one in which tobacco reaches the highest state of perfection as regards flavour. The liberal amount of heat and light, together with sufficient moisture, is found to produce the most luxuriant development of the plant, and to increase largely the percentage of nicotine.

The quality of the soil in which tobacco is sown exerts an important influence on the texture of the leaf, and on the colour and burning qualities. Tobacco grown on very rich dark soils burns badly, whereas that grown on sandy soil burns well. Chocolate and sandy soils are preferred on account of the better flavour and aroma of the crop both for cigar and pipe tobacco. Colonel Everard, in the Irish experimental tobacco growing, found that a rather heavy clay loam, with a clay subsoil in good manurial condition, produced the best results, the tobacco growing well, and curing out a good colour with plenty of body and elasticity. Tobacco will not thrive except on a well-drained soil; a retentive clay subsoil, therefore, is to be avoided. The soil should be well ploughed and harrowed until it is well pulverised before sowing.

The Necessary Fertilisers. Manures for tobacco crop must not contain chlorides, as chlorides in the tobacco leaf adversely affect the burning qualities. Sulphate of potash in excess has a similar injurious effect. Large quantities of phosphoric acid give a dark-coloured ash to the tobacco, and excess of nitrogen in the soil makes a coarse thick leaf, unsuited for wrapper types of tobacco but suitable for manufacturing and export kinds. To produce cigar wrapper leaf and bright yellow leaf only moderate quantities of stable manure may be used, or the leaf will be thick and coarse. Cotton-seed meal is a good source of nitrogen for the successful raising of tobacco when used with nitrate of soda or potash in a sufficient quantity to furnish a fourth of the nitrogen required by the crops. Cotton-seed hull ashes and high grade sulphate of potash are the most valuable sources of potash for tobaccos. Acid phosphate and phosphatic slag should be used in preference to animal phosphates. A standard fertiliser is one containing 3 per cent. of phosphate, 5 per cent. of nitrogen, and 15 per cent. of potash, but varying quantities are required according to the nature of the soil. Two hundred pounds to a ton of commercial fertiliser are applied per acre, but up to two tons are used where high-grade wrapper leaf or thin bright tobacco is desired.

1. THE TOBACCO PLANT

Tobacco Seeds. Tobacco seeds are very small, one ounce containing as many as 300,000 seeds. All the seeds are, however, not fertile, only about 75 per cent. germinating, so that allowing for imperfect conditions it may be reckoned that 35,000 seeds in an ounce will yield plants. It is usual to sow at least three times the amount of seeds, so as to get a sufficient number of plants all of one size.

The Seed Bed. The best site for a seed bed is one with southern exposure, south-east, south-west, and western being the next in order. The bed should be near water, because the temperature is likely to be more uniform, and a sufficiency of moisture will be obtainable without artificial watering. In Cuba open spaces in the woods are the favourite locations for the seed beds, on account of the protection from winds afforded by the trees.

The most experienced tobacco growers burn the seed bed as a preliminary, the object being to destroy grass and weeds and grubs and insects that may be in the soil. Wood is spread on the soil in a thin layer and burned, more fuel being added from time to time, the burning being continued long enough to thoroughly steam and bake the ground.

When the soil has cooled, break it up with a hoe to the depth of two inches, rake off roots, and leave the surface level, loose, and porous. It should not be worked deeply. Having made the soil fine by repeated working, apply fine pig or sheep manure, or some good fertiliser, as the soil cannot be made too rich, because the object of the seed bed is to force the growth of the plants. The manure is well chopped-in and raked level again.

After burning the seed bed and before sowing the seed, enclose the bed with a frame. This is made of 1 in. plank, 8 in. to 10 in. wide, placed on edge, and nailed at the corners with diagonal strips of 1 in. by 3 in. plank. If no planks be available poles may be used. The bed is best not over 3 ft. wide, so that it can be reached from either side. To prevent the ravages of insects, and to keep the young plants warm, a covering of muslin is arranged as a curtain, so that the cover can be withdrawn when desired to admit sunlight and air.

Sowing the Seed. To obviate the difficulty of the impervious coating of the tobacco seeds, which delays germination, it is sometimes the custom to scratch the surface of the seed by rubbing the seeds with fine emery paper and then to moisten them with water in a bowl for 48 hours. Mix the seed in the proportion of ¼ oz. of seed to 2 quarts of wood ashes, corn meal, or sand, and sow carefully and evenly over the bed. A light-coloured diluent is best for the seeds, as it is easier to see where the seeds have been sown. Sow the mixture by the thumb and fingers, and after sowing sweep the bed carefully over with a brush, simply disturbing the surface of the bed, taking care not to bury the seed too deep. Next sprinkle the earth with water, and make it firm by laying down planks and standing on them. Water the bed twice a week, or oftener in dry weather. The seeds come up two weeks after planting, and their growth should be stimulated by watering with weak liquid manure. In about six weeks to two months the plants will be ready for transplanting, but before this takes place the plants should have been hardened by removing the cover gradually and increasing the time of exposure to the air day by day.

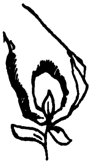
Transplanting.. The plants in the seed bed are planted out in the field when they have grown 4 in. to 6 in. high, although in Cuba the seedlings are allowed to become 8 in. to 10 in. high before this operation takes place.

Two or three weeks before planting, the tobacco field is harrowed and laid off in rows by means of a plough, the rows being 3 ft. to 3½ ft. apart. Open fields are usual, but in Florida a system of shading the fields with open lattice work is in vogue, which has the advantage of improving the leaf texture by moderating the sun's rays. It may be added that the distance apart of the rows varies in different parts of the world according to the kind of tobacco that is being grown, and whether hand cultivation or horse cultivators be employed.

The transplanting operation is best conducted in cloudy or damp weather. On the previous night the seed bed is well watered to loosen the soil, and the young plants are "drawn" early in the morning when still wet with dew, taking care not to injure the roots, and to keep as much soil adhering to the roots as possible. Take hold of each plant between the thumb and finger, and loosen the earth with a small garden fork. Put the plants gently into small boxes or baskets, cover with a damp cloth, and put in a shady place till the afternoon when the planting takes place There are two methods of planting —by hand or machine. In hand planting, the plants are dotted at regular intervals by a staff of labourers, usually boys or women, while others follow and make a hole with a dibble, into which the roots of the plant are inserted. The soil is then pressed round the root, and the loose earth brought up with the dibble, the surface being left as loose as possible. This process is sometimes varied by one man walking along and making the holes, another dropping the plant near by, and a third setting the plants. When the soil is damp, watering is not required, but if dry, water is poured into the holes before inserting the plant. If the weather continue dry watering will be needed until the seedling is firmly established. In Cuba a quicker process of planting in furrows is adopted.

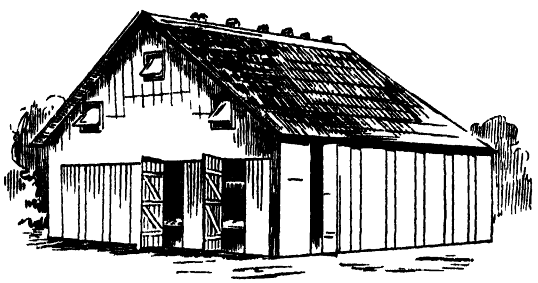
Machine Transplanting. Machine transplanting is practised in some districts. A planting machine, horse-drawn, carries the driver and two men or boys. The machine carries the water, which is run into each hole. It is stated that a man and two boys can plant two to six acres a day, about twice as much as can be accomplished by hand setting. In this stage care must be specially taken to have plenty of young plants ready, and only plant those of the same size in one field, so that all the tobacco will arrive at maturity together. Plant as early as possible after the time of frost has passed, and strive to have an early crop. In case of frost any young plants which show signs of having been affected should be replaced, and also any that have been bitten by insects within the first few days of transplanting.

Weeding and Earthing Up. The tobacco field requires very careful cultivation, and must be systematically weeded before the plants increase much in size. The first weeding, which is best done by hand labour, should be about a fortnight after transplanting, and in this, as in subsequent weeding, the greatest care must be taken not to injure the leaves, as their value would be thereby much diminished. If the soil become hard or baked, it should be broken up with a hoe used towards the plant, so as not to take soil away from the plant. The last weeding, in fact, should be done with the object of earthing up the soil round the base of each plant. This encourages root growth, and enables the plant to more easily withstand winds. Machine weeding is practised, but the loss through leaf damage is more than with careful handwork.



2. METHOD OF NIPPING OFF BUD

Topping and Priming. The operation of removing the top or main shoot of the plant is called topping. It is done with the object of preventing the transference of nourishment to the seeds and to promote the growth of the leaves. The lowest leaves are also generally removed, as they are rendered worthless if left on, owing to laceration through wind lashing, but in some districts the lowest leaves are retained as a protection for the roots. The time for removing the top shoot arrives when flower buds begin to form, but before the flowers appear [2]. It is usual to retain from 10 to 12 leaves on each plant, as that is considered to be the average number that can be brought to perfection ; but this is by no means a fixed rule, as from 15 to 20 may be left on in cases where the tobacco is intended mainly for cigar fillers or where the plant is very vigorous.



3. TOBACCO BARN

The topping of the plant causes it to send out buds or suckers at the junction of the leaves, and these suckers must also be removed, "suckering" being needed two or three times during the season. The side shoots or suckers are allowed to grow about 6 in., and are then pinched off to within 2 in. of the stem.

Insect Pests. The planter must closely attend to catching all grubs or caterpillars that infest the tobacco plants, as the quality of the leaves is soon injuriously affected.

Some insects attack the plants when still below the soil, but for this there is no practical remedy. Slugs are very fond of tobacco leaves, and as a preventive a little powdered quicklime is scattered or blown on the leaves, or one may use an arsenical spray. Many kinds of caterpillars also infest the plants, hand picking by children being the most effective method of dealing with this pest. Balls of poisoned meal are sometimes distributed about the fields to attract insect pests, and much success attends the planting of clumps of *datura stramonium* to act as insect traps.

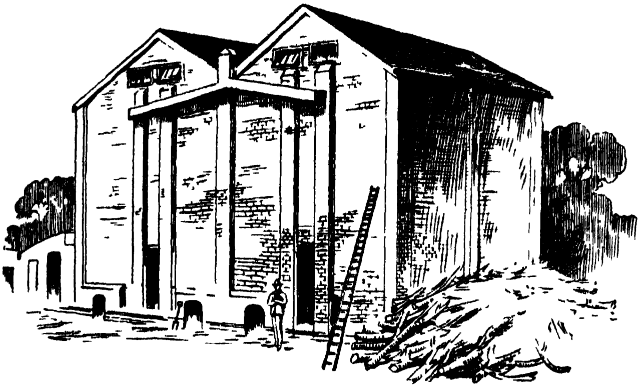
Leaf Diseases. Diseases which attack tobacco leaf often do considerable damage. One of these, known as mosaic disease, appears as light and green patches on the leaf, the cause not being well understood. The remedy is also obscure, although certain facts as to the cause are definitely known. As the disease is probably fungoid, well burned seed beds are desirable, and great care should be taken in planting so as not to injure the delicate roots.

Harvesting. In from four to six weeks after topping, the tobacco plant is ready for cutting down. The proper time for harvesting is a matter of considerable judgment and experience, as if the plant be cut before it be properly matured the leaves will cure dark, and, under some circumstances, will dry green, and never develop flavour. The following are the principle signs of maturity:

1. When a leaf is doubled up, and a nerve is pressed at the bend between the finger and thumb, it will break with a sharp crack if the leaf be ripe.
2. The leaf blade and leaf stalk bend towards the soil.
3. The leaf takes on a slightly yellow colour, and, on holding up a leaf, and looking through it more or less transparent spots like drops of oil are seen.
4. Walking through a tobacco field a characteristic smell of ripe tobacco is noticed.
5. On cutting across a branch a reddish ring will be seen if the plant be ripe.

The leaves ripen upwards, and, in bright tobacco districts, the bottom leaves are harvested first. In other districts the plant is cut when the middle leaves are nearly ripe. When the leaves are separately detached from the stem they are placed in baskets and taken to the drying-sheds strung on twine or wires back to back. A string of leaves is then attached to a 4-ft. lath, and the laths hung up in the barn. The principal method of harvesting, however, is that which involves the cutting of the whole plant. The plants are cut off near the ground with a sharp knife, and the stalk split from the top half-way to the bottom. The splitting is omitted in some countries, and the whole plant strung on a curing-stick. In both methods the plant is exposed to the sun till it is wilted, or made limp enough to handle without injury. It must then be conveyed to the curing-barn with as little delay as possible. Cutting is best done late in the afternoon, as the cut plants are easily injured by the hot sun pouring down on them. Harvesting must not be attempted in the morning when the plant is wet with dew. After rain it is wise to allow at least one fine day to intervene before harvesting.

Stacking in the Field. Instead of conveying the wilted whole plant direct to the barn, it is stacked on scaffolds on the field if the weather be fine and mild. From 8 to 14 plants are placed on a stick, and removed to the scaffold previously built in the neighbourhood. The sun begins the curing process by yellowing the plants and reducing the amount of moisture they contain. Both on the scaffold and in the curing-barn [8] spaces of from 8 in. to 12 in. are left between the sticks for the circulation of air. It should be added that, owing to the liability of the leaves to damage from exposure to the sun and weather, it is now considered wiser to get the crop safely in the barn at once without running any risk from climatic conditions. Special frame waggons are used for transporting the tobacco to the curing-barn, the object being to carry the plants so that they do not touch the sides or the bottom of the waggon. Otherwise the sticks of tobacco are piled on an ordinary waggon in layers with the butts and tops alternately on the outside. The leaves that are separately harvested are strung on twine in small shelters built outside the curing-barns.



4. RHODESIAN TOBACCO BARN

Curing the Plant. The next process to which the tobacco is subjected is known as *curing*, and, as the quality of the product depends to a considerable degree on the care which is exercised at this stage, it will readily be seen that curing is one of the most important, as it is the most difficult of the processes. This should not be understood to mean that an inferior leaf can be made into first-class tobacco by suitable curing, but rather that the good leaf can be spoiled in the process through want of skill.

There are several methods of curing in vogue, which we will now consider separately.

Fire Curing. The method of curing by means of *open fire heat* is used for export tobaccos as such tobaccos stand transportation better than others. The burning charcoal or wood imparts a distinct flavour somewhat like creosote to the product. The following is a description of the process as usually followed: The curing-house is arranged with ventilation windows, and on the second day after cutting, the sticks upon which the tobacco was placed when cut are arranged in the barn. On the third day artificial heat is applied in the form of charcoal or wood—preferably the former, as there is less risk of burning down the shed. The heat is raised to, and kept at, between 70° F. and 80° F., the fires being kept up day and night until the lower part of the leaf shows signs of drying. This happens after about 24 hours, when the temperature is raised to 90° F., increasing by 10 degrees every 24 hours till 150° F. is reached. When all the moisture has evaporated from the leaf and the stem of the leaf the fires are discontinued, but resumed for a few hours if rainy or foggy weather come on or the leaf show signs of softening. When all the moisture has been driven out the tobacco is taken down, stripped from the stalk, and graded for the market.

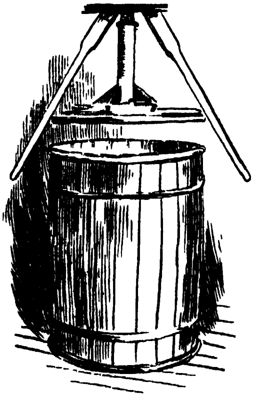
5. PLAN OF FLUES

Flue Curing. In the process of *flue curing* the heat from an outside furnace is conveyed through the curing-house [4 and 5] by means of large iron flues or pipes. This method is used for curing bright yellow tobacco, the stages being:

1. The yellowing process, when a temperature of 90° is kept up for from 20 to 30 hours.
2. Fixing the colour, the temperature being raised to 100° for four hours, and increased 2½ degrees every two hours, until 120° is reached.
3. The curing process proper, at a temperature of from 120° to 125° F., for from six to eight hours.
4. Stalk curing, at 125° to 150° F., the heat being raised to the latter temperature by five degrees an hour, and the heat continued till the stalk is thoroughly dried, which will be in from 12 to 15 hours.

A simplified process of flue drying is as follows: After the tobacco is cut it is placed in the curing-house, and the air warmed to 90° F. for two or three hours. The heat is then increased rapidly to 125°, or even higher, if the leaf will stand it, and, after letting the heat stop at this degree for a few minutes, the fires are damped, and the heat gradually reduced to 90° F. The finishing part of the curing process is the same as we have explained in the previous process.

Sun Curing. The method of *sun curing* is practised in a part of Virginia, but as it involves many handlings of the tobacco, the expense for labour becomes a serious item. The process is, however, much valued by the manufacturers of plug tobacco, as the product is very sweet, and specially suited for chewing. Scaffolds are erected near the curing-house, and upon them is placed the tobacco as soon as it is cut. On the approach of a storm, the tobacco must be carried into the barn, as the colour and taste would be impaired if rain were allowed to fall on the leaves. The tobacco is exposed to the sun in this way for some weeks, until all moisture is dispelled. The storing and handling of sun-cured tobacco needs much more care than in the case of *fire* or *flue dried* leaf.



6. SCREW PRESS

Air Curing. Cigar leaf, and other tobaccos of thin delicate texture, and smaller leaf and stem, are cured by *air*, in well-constructed curing-houses, in which wooden windows are arranged for ventilation purposes. The process lasts six to eight weeks, and during this time the temperature and moisture are regulated by opening or shutting the ventilators. Air-cured tobacco is of better flavour than that cured by other methods, being free from smoky taste, and, being more absorbent, it is largely used by manufacturers of chewing tobacco. White Burley tobacco cured in this way has a cherry-red to a red-brown colour.

Fermentation. The *fermentation* or *sweating* process, which follows, is undertaken for the purpose of developing the aroma of the tobacco. The process is one often entrusted by the grower to the experts who specialise in this department. The method employed is known as *bulk fermentation*. The tobacco is sorted out into three grades according to the texture of the leaf, each grade being separately bulked or stacked in rooms heated by steam. The moisture of the air is also capable of being regulated. The size of the heaps varies according to the grade; for instance, if light shade leaves be required, 3,000 lb. to 5,000 lb. of leaves are placed in the bulk, while in the case of ordinary fillers, 10,000 lb. to 20,000 lb. are the average bulks. The leaves are piled up to a solid stack 5 ft. or 6 ft. high, and in definite order. The bulk is then covered up with canvas, and after a short time fermentation, as evidenced by a rise in temperature, takes place. The temperature must not be allowed to go beyond 130° F., to prevent which the heap is from time to time taken down and rebuilt. Some three to five weeks is occupied by the process. Steam is injected into the room when the leaf is in a very dry condition, but some leaf handlers prefer a spray of water. It is during the fermentation process that the lower grade tobaccos are *petuned*—that is, treated with flavouring ingredients to improve the aroma.

The temperature of the heap of tobacco is judged by putting the hand inside, or by using a thermometer, an automatic electric instrument being in use in up-to-date establishments.

Grading. The fermented tobacco is next graded and packed. In the case of Cuban tobacco, the leaves are made into *hands* of about 40 leaves each, the outside being bound round with bast into a *carotte*. Eighty carottes are made into a *bale*. Loose tobacco is packed or prized into *hogsheads*, averaging 56 in. high and 42 in. diameter at the head. Pressure is applied as the leaves or hands are being packed, the screw press used with hogsheads being shown in the illustration [6]. Care must be taken not to mix various kinds of tobacco in one package, as the market value of the tobacco is thereby diminished. Before being brought into use, tobaccos are kept in stock for from two to four years to age, the tobacco in this way becoming softer and mellower in flavour. The weight of tobacco in a hogshead varies according to the kind, from 600 lb. to 1,000 lb. of lighter tobaccos, up to 1,600 lb. to 2,000 lb. of dark leaf being averages. Half hogsheads are used for exporting to certain markets.

English Tobacco. By an Act passed in the reign of Charles II., the growing of tobacco is illegal in England and Ireland, an exception being made in regard to physic gardens, which were allowed to grow half a pole for medicinal purposes. The Act as regards England and Ireland has been relaxed in so far as experimental culture was allowed in 1886, at a time when, owing to agricultural depression, it was thought that the cultivation of tobacco might profitably be carried on at home. Experimental cultures were made by Lord Harris at Faversham, Mr. De Laune at Sittingbourne, and Mr. Wigan at East Malling. The experiment was deemed a success from some points of view, but it was hardly to be expected that tobacco of first rate quality could be grown without considerable experience as to the best seeds and most suitable soils for the crop.

Irish Tobacco. For some years, experimental tobacco growing has been carried on in Ireland. The Department of Agriculture has had charge of the arrangements. Colonel N. T. Everard has published an interesting account of his work in the "Journal of the Department of Agriculture." To encourage the experiments, a rebate of one-third of the duty has been granted for a period of five years, from 1904. Professor Keller, a tobacco expert, is studying the kinds of tobacco best suited for the various soils in Ireland, and this is held to be the crux of the question.

THE CAMPAIGN OF MAN

Sociology is the Study of Ourselves. The Science of Saving Society from Its Own Mistakes. The True Ethical Ideal must be Sociologically Possible

Continued from page 4124

By Dr. C. W. SALEEBY

THE present writer's estimate of the importance of sociology grows yearly—in this respect he questions not, resembling the estimate of all who are capable of learning. In so far as it is possible to speak of the root of any such matter as we have instanced, sociology "gets there," and time and again one finds that questions which appear at first sight to belong to subordinate sciences, and which the subordinate sciences can solve upon paper, just as the present writer can say upon paper, "Let every mother nurse her baby and you will have no infant mortality worth mentioning," can be solved in practice by the sociologist alone. He it is who deals with underlying principles. He it is who, in conspicuous contrast, for instance, to the unthinking kind of socialist, takes into account that supreme factor which we call human nature.

The Place of Ethics. And now a word as to the relations of sociology to the transcendent science of morality. Accepting as, at any rate, partially true that conception of morality which confines its gaze to human life as we know it on this earth, we see at once that, in one of its aspects, at any rate, sociology is inextricably interwoven with morality. The idea of justice, for instance, is, of course, a sociological idea as well as a moral idea, and even if abstract morals insist upon the truth that justice is justice, whatever the practice of men may be, yet the moment the practical moralist begins to ask himself how justice may be furthered, maintained and effected, whether by stern laws or by providing all citizens with good mothers, or by some other means, at that very moment the question of practical morals is seen to be a question of practical sociology.

There are a great many thinkers, chief among whom, perhaps, is Professor Lester Ward, the most distinguished of living American sociologists, who, having a too narrow conception of ethics, declare that it is not a science, still less a separate science, at all, but is merely a part of sociology. For Ward's discussion of this view, see his "Pure Sociology" (Macmillan, 1903). This, as it might be shown, is surely an exaggeration; but, at any rate, the fact which we are trying to emphasise remains—that while, on the one hand, sociology has the most complex and indissoluble relations with the sciences that are beneath it, on the other hand, it can never be dissociated from the one science which is above and beyond it.

Sociology a Science—and More. And this leads us on to another consideration which sociologists would do well to make more explicit, and the neglect of which has led to much misunderstanding. Just because sociology is intermixed with ethics, it has the peculiar character of that science. A pure science, whatever its subject matter, is properly concerned solely, exclusively, and cold-bloodedly with *what is*. Pure science has nothing whatever to do with *what ought to be*. The student of society, being a man as well as a scientist, cannot fail to have his own opinions as to what ought to be. He cannot fail, in his heart of hearts, to feel emotions of disgust or pleasure at the facts which he discovers. His case is thus totally distinct from that of the chemist, let us say. The student of atomic weights discovers that the mass-ratio of oxygen to hydrogen is 16. He is concerned merely to know that this is so. The fact will give him greater or less pleasure, certainly, according as it fits in with and confirms, or is incompatible with and throws discredit upon, other facts or supposed facts; but he passes no moral judgment upon the result he has obtained, and, whatever the result is, no question arises of any attempt to alter the facts. The efforts of all the chemists in the world could not change the atomic weight of oxygen, and there is no reason why they should.

The Search for Social Facts. Vastly different is the case of the moralist and the sociologist. If these students are to be worth anything at all in any permanent sense, they must, in the first place, treat their subject as a pure science. They must divest themselves of all interests in it save the interest which truth has for them as such. Science is concerned with what is and has been. The sociologist, if he is to call his study a science at all, must find out what is and has been. "His not to make reply"; his not to say, "I approve or disapprove"; but precisely as the chemist is concerned to discover chemical facts, so the sociologist is concerned to discover social facts. Indeed, if one were asked to describe in a phrase the distinction between the modern conception of sociology and the standpoint of nearly all those who in the past have thought and taught and written about social matters, the reply would probably be that sociology as we conceive it now, is at any rate, whatever more it may or may not be, a deliberately cold-blooded, detached, impartial study of things as they are and as they have been, the past, of course, being the interpreter of the present. The sociologist in making this study is, one may suggest, to resemble as nearly as possible the gods as Plato imagined them. In opposition to the popular nonsense which believed that male and female deities, morally inferior to the average man and woman, constantly interfered with human affairs, it was taught that such gods there were—taught for prudence sake, though it did not save Socrates—but that they did not interfere with human affairs. They sat upon Olympus "in god-like detachment," contemplating all things, understanding all the motives of men, seeing all the fashions in which they lived together, and the various consequences of all those practices, but never raising a finger on one side or another, and never caring a straw.

This exactly would be the attitude of the pure sociologist as such. It would be the ideal of sociology as a pure science—to make the science an omniscience of social facts, present and past, to record, classify, and generalise them, and put them into a perfect textbook.

The Sociologist Must Have Ideals. Now, it is quite certain that unless we recognise this conception of our business, unless we admit its validity, as far as it goes, unless we attain this impartial and, so to speak, careless point of view whilst we are ascertaining our facts, we shall, in the first place, forfeit the title to call ourselves scientific, and shall, in the second place, either mistake for facts what are not facts, or else shall make an artificial selection from the facts, choosing, perhaps, the few and insignificant which suit our prepossessions—as, for instance, in favour of authority or in favour of liberty—and omitting the many and weighty ones which prove that our prepossessions are false. Precisely the same necessity arises in the case of the moralist.

But there never yet was sociologist or moralist of any moment whatever who was not more than a pure scientist The driving power, even in the case of such a costly and prolonged, despised and dreary enterprise as Spencer's "Descriptive Sociology," has always been the passion for what Carlyle called "that divine word reform"; and sooner or later every sociologist has renounced the purely scientific purpose and surpassed it. He has left the question of what is and has gone on to the question of what ought to be and how it *shall be.* The present writer certainly does not dare to question the value of pursuing truth for its own sake, and he is among the first to admit that the purely scientific conception of sociology is invaluable; but it is fortunately in the nature of the case impossible that anyone can set his mind to the study of social facts without being irresistibly compelled to ask himself how they can be modified. The student who did not ask himself this question would be as impossible a monster as the student of disease who studied it for its own sake and did not care two straws to ask whether the disease might have been prevented or might be cured.

Sociology a Campaign of Man. There are many splendid signs of the times which show clearly enough that the double conception of sociology—(1) as a pure science and (2) as a *Campaign of Man*—is making its way into the modern mind. Two distinct parties of people are approaching sociology. On the one hand there are the scientists whose own work lies in various departments of the science of life and living things. Every biologist, and every physician worthy of the name, for instance, is rapidly journeying to-day towards sociology. The greatest of national problems, the making of a vigorous and worthy people, is uniting medical men and sociologists, and with them also the students of heredity. These men of science are coming to discover that sociology provides them with an almost unsuspected storehouse of facts, and it is facts with which science is concerned.

The New Reformer. And from the other side sociology is being approached by the humanitarians, lovers of children, lovers of justice, lovers of liberty, lovers of the poor, social reformers of all kinds. Let us try to realise the significance, which has never yet been adequately recognised, of the change which the scientific idea is working in these times. Take, for instance, the great sociological questions of crime and punishment—criminology and penology. It is not so very long ago since a John Howard or an Elizabeth Fry set to work to do something for the wretched state of our prisons. They gave the miserable inmates, forsaken by man, their own personal service and sympathy, with all that this implied of moral regeneration. They immortalised their names amongst a "Christian" people because they did not content themselves with reading the 25th chapter of St. Matthew, but acted upon it. "I was in prison, and ye came unto me." It would be better never to write another word than to detract in any way from the splendour of their service and achievement.

But consider what the scientific idea is now beginning to accomplish in such cases as these. The deathless pioneers have done their pioneer work of awakening our consciences, but their successors do not follow the old plan. How all but hopeless was it to visit the prisons when the treatment of children, especially of naughty children, when the whole conception of crime, the whole social system that produced crime, the whole of the methods for repressing crime, were false and rotten, and when crime, and yet more crime, was the product of their putrefaction! Nowadays we do differently. The great scientific truth that causation is universal, and that all facts, being part of truth, are sacred and worthy of recognition—these are entering into the modern mind.

Reform on Wrong Methods. Nowadays, then, we have devoted students who study the facts of crime as the chemist studies the facts of calcium, and the day is dawning when, by a sane treatment of children,' by the institution of methods of education which reckon with human nature and are based upon the facts of physiology, we shall abolish crime by preventing the formation of the criminal. This is obviously a more excellent way even than the visiting of the prisons—prisons which not one prisoner in ten thousand, brought up in a social environment adapted to his needs, would ever have entered. This particular illustration might be indefinitely multiplied, and it is impossible to exaggerate the practical importance of the change.

Hitherto, the social reformer has usually had more heart than head. The history of "charity" is the history of the consequences. Thoughtless charity has caused immeasurably more misery and wretchedness and sin and evil than it has ever relieved. Social reformers without number, and social efforts without number, have not only done more harm than good, but have actually brought our great ideal of reform into discredit—a pitiable end.

Heads and Hearts. But we are just now at the birth of the time when Science is to exert her beneficent sway—irksome though it may not infrequently appear—over the full heart of the social worker and the social reformer. The observer will find that bad schemes, promising an apparent immediate benefit, but threatening a lasting injury, have now to face the criticism not of one isolated philosopher here and another there, but of a whole host of thoughtful and well-informed people. In short, we are beginning to abandon the old method of trial and error. Sociology is teaching us that the past has made enough experiments if we would only look at them. Sociology is establishing generalisations which, like other generalisations or products of induction [see LOGIC], are capable of being used for purposes of deduction.

The reformer, the enthusiast, comes forward with a new plan, and sociology is able to say beforehand, in some cases at any rate, "No, this will not work," just as the student of Energetics [see PHYSICS] is able to say to the perpetual motion schemer, "No, this will not work." Furthermore, many social workers, whose good hearts are known to all, are having the possession of good heads as well revealed under the influence of the scientific atmosphere which is beginning to invest this subject. Hence they are being set to work to collect the generalised facts just as if they were one of the impartial deities to whom we have referred. Many of them are rapidly acquiring the temper which seeks to follow truth wherever she leads. In consequence, there are being rapidly produced books which contain matter of fact, and are as properly scientific in method, aim, and execution as the driest treatise on hydrodynamics. Conspicuous instances are furnished by Messrs. Rowntree and Sherwell's really epoch-making books upon the alcohol question, and any number more might be cited.

Discovering Ourselves. Throughout our course, then, we must endeavour to preserve the very difficult ideal, the two parts of which so many in the past have found incompatible, of (1) studying our facts as facts, and (2) studying our facts as means which will enable us *to effect further facts*. For sociology is unique among the sciences in that man makes the facts. We are far from saying, of course, that man in so doing is not determined by his nature and his education, by custom, tradition, mental inertia, and so on. But, nevertheless, the truth remains that the sociologist is in a unique position. It is as if an atom of carbon in the benzene ring [see CHEMISTRY] had set before itself the problem of discovering the constitution and potentialities of that ring. Itself is part, and a necessary part, of the facts which it is about to study, and (this, we think, being the most valuable part of our analogy) its comprehension of the facts will be determined by its position in the ring. If it be a short-sighted atom, it will know no more than that it is united by two hands to an atom of carbon on one side, by one hand to an atom of hydrogen, and by the other to a second atom of carbon. It will never occur to the short-sighted atom, perhaps, that its neighbour atoms are in exactly the same case as itself, just as it might have never occurred to an atom in another kind of molecule that its neighbours' circumstances are *not* the same as its own. But in any case the judgments of the atom are coloured and in part determined by its own circumstances and point of view.

The Intellectual Difficulty. The sociologist is in the same case. He is himself a part of the organism which he is studying, and unless he be far-sighted his comprehension of it will be no greater than the comprehension which the atom will have of a molecule, or which one of the white cells in your blood will have of *you*. Such a white cell would form one opinion of you ; a nerve cell would form a very different one ; and a muscle cell yet another. Similarly, the soldier turning to sociology will form one idea of society which can scarcely fail to differ profoundly from the idea formed by the workman sociologist or from that formed by the aristocrat sociologist. The problem is, being part of the organism oneself, to see it steadily and see it whole. There is the intellectual difficulty.

And then there is the difficulty that not only is every student of society himself a constituent of society, but also, unlike the atom or the cell, he has *will*. He is not only a fact, but the potential source of new facts, and these may be good or bad according as he is good or bad. The reader is asked to keep in mind this last sentence, because we are about to return to the idea which it contains—an idea which we believe to be the central truth of all sociology.

Truth is Never Impossible. Before we consider it, we must complete our study of the relation between the study of society and the study of morals by emphasising the most important proposition which has lately been laid down by one of the most distinguished living students of both these subjects, Professor Harald Höffding, of Copenhagen. This is the profoundly important proposition that morals and the moralist must recognise the existence of sociological truths. "The ethically right" (says Höffding) "must be sociologically possible." This statement may have no particularly attractive appearance, but it throws a most searching light upon the history of religious and moral systems. It condemns all ethical systems which are impracticable. This, of course, is not to say that it condemns ethical ideals as ideals, or that it demands the subordination of morality to the ugly facts of society and human nature. It means, as the present writer has tried to show elsewhere, "that the moralist, in seeking to establish the true ideal, must be certain that his ideal is possible. It means that no ethical ideal can be true which—so to speak—would become impracticable directly it was realised. For instance, asceticism cannot be the ethical ideal, since a society of consistent ascetics would soon cease to exist."

"Untrue" Ideals. Asceticism can have value only as a temporary protest against sensuality. Abolish sensuality, and asceticism would be merely silly. Similarly, the doctrine that "life is for others," the doctrine that the ideal is complete self-sacrifice, cannot be regarded as ethically right, for it is sociologically impossible. It may serve a useful temporary function, but that it is essentially absurd must become apparent so soon as we try to conceive the social state in which everyone has reached the ideal. Self-sacrifice becomes impossible so soon as there remains no one who is willing to benefit by it. One man can be self-sacrificing, as a rule, only on condition that another is not. When all are equally and completely self-sacrificing, none can be so. Again, if every one is to live entirely for others, the result will not be the greatest happiness, but the greatest inconvenience and lack of economy. If I am to spend all my time in the pursuit of your happiness, and you all your time in the pursuit of mine, neither of us will be as happy as we might otherwise have been; and thus the purpose of our efforts will have been frustrated. Thus, unqualified altruism cannot be the ethical ideal, since it is sociologically impossible. Plainly, unqualified egoism is immoral: hence the ideal is neither "live for self" nor "live for others," but "live for self and others." This may claim to be ethically right, since it fulfils the first condition that it is sociologically possible.

The Great Central Truth. There are certain kinds of figures which one can build with cubical bricks and others which one cannot, this being an instance of the proposition that the nature of any whole depends upon the nature of its constituent parts. The central truth of sociology is precisely this, that the structure of societies depends upon the characters of its constituent individuals, can only be explained by reference to its units, and will be good or bad less on account of the fashion in which the units are related to one another than on account of the characters of the units themselves.

Now, let us take an illustration from chemistry. The characters of a compound may be said to be determined by two factors: (1) the number and nature of the atoms that go to compose each molecule of the compound, and (2) the manner in which those atoms are combined with one another. Similarly, the characters of a society are determined (1) by the nature and numbers of its constituent units, and (2) by the relations of those units to one another—the manner in which they are combined. One would not expect to go far in an understanding of the chemical compounds until one knew something of the characters of the elementary atoms. Similarly, one cannot go far in the study of a society unless one takes into account the characters of the individual man and woman.

Societies and Molecules. *But* there is a point at which our analogy breaks down, and much is always to be learnt at the point at which any analogy breaks down. As a matter of fact, if we consider the organic compounds we discover that the character of the individual atoms seems to go for very little. We may find two compounds of markedly different nature, which are yet isomeric, each containing the same number of the same kinds of atoms. In such cases it is the relation of the atoms rather than their nature that is all important. Now, the case of the supreme organic compound which we call a society differs immeasurably from that of the organic molecule, just because the units of the one are *mechanical*, whereas those of the other are *spiritual.* In the case of a chemical compound, even though we admit that the nature of the component atoms must be reckoned with, we constantly find cases in which it seems to be of trivial importance. The all-important thing seems to be the manner in which the atoms are bound together.

The Test of All Societies. Now, it is true that societies differ profoundly—as, for instance, a military and an industrial society—in consequence of the different manner in which their units are related, but this difference is itself only a sign of the differing characters possessed by the units. Yet again, there is a reaction between the spirit of man and its surroundings, so that, as never in the case of the chemical compound, the character of the society modifies and may most profoundly change the character of its units. Now, as we shall shortly see, a society is not an end in itself. The only reason for its existence is that it provides conditions for the production of worthy and happy life in individuals. *Therefore, the one sole criterion by which all societies are to be judged is their effect upon human nature and the conditions of life for the individual.*

Here, then, are our propositions dogmatically stated; they are among those truths which have only to be stated to find immediate acceptance. *The key to sociology is human nature. Every kind of society* that was, is, or will be, whether large or small, ancient or modern, barbaric or civilised, military or industrial, autocratic or democratic, dominant or servile, progressive, stable, or retrogressive, *depends for its characters, one and all, upon human nature, upon the individual, subjective, personal, spiritual, moral and intellectual characters of the individuals who compose it.*

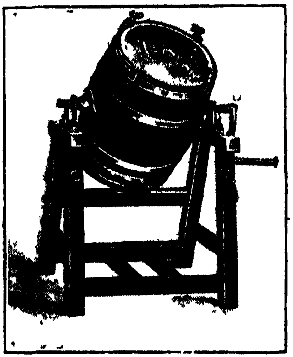
By Professor JAMES LONG

Forms of Churning. There are on the European market nearly 150 varieties of churns, of which many are modifications of well-known types, a few comparatively new in some feature, and the majority but reproductions, more skilfully finished and equipped, of churns which were used from half a century to a century ago. A good churn should contain as few angles as possible. If *beaters* be used, although they are quite unnecessary, giving additional trouble and sometimes preventing perfect cleansing of the interior, they should not be fixed. The opening of the mouth should be large, to facilitate the cleaning or removal of the butter; the lid should be simply and skilfully constructed that it may be fixed easily, quickly, and prevent the escape of cream; there should be a ventilator, and a tiny window of glass, while the size of the churn should be specially adapted to the work it is intended to perform.



25. END-OVER-END CHURN
(R. A. Lister & Co., Dursley)

Churns are made in various forms. Some are barrel-shaped, others square, rectangular, cradle, or millstone shaped; indeed there is scarcely any limit to the form which they now assume in the hands of manufacturers [27]. The barrel-shaped churn is perhaps the most popular—we refer to that which revolves end-over-end—for the reason that it contains no beaters, and that the lid is large and the opening correspondingly so [25]. The best utensils are made of oak, polished outside, and skilfully finished. The chief systems adopted by churn makers are: (1) churns fixed with movable beaters or dashers within, a type common in Denmark, Sweden, and Germany, and represented by the Holstein churn, which permits of the easy removal of the butter; (2) revolving churns with fixed beaters, some of which are removable through the mouth; (3) revolving churns without beaters or dashers; and (4) the fixed churn, within which a disc revolves with great rapidity.

Although the end-over-end barrel churn is popular for the reasons already given, there is probably no churn in the market which does better work than the Holstein. In good hands, however, good butter can be produced and a minimum quantity of butter fat left in the buttermilk in any well-made churn.

26. DELAITEUSE, OR BUTTER DRYER
(Dairy Supply Co., Ltd.)

What the Churn Does. The object of churning is to extract the fat from the cream in the form of fine granules [28], which, by washing, can be made up into sweet, well-keeping butter. Where butter is over-churned [29], or churned into a lump, it is practically spoiled, for the buttermilk, which contains impurities, cannot be extracted. If churning, however, cease when the butter has *broken*, as it is termed, into granules about the size of grains of rice, the washing which follows removes the buttermilk, and consequently the casein and sugar that it contains. If the temperature of the cream be too high, these granules are soft, and adhere to each other, and thus prevent perfect washing. If the granules are too small, like grains of mustard seed, for example, washing is still difficult; hence the preference of skilled makers for the size which has been mentioned. There must be no greasiness; on the contrary, by skilful manipulation and the aid of very cold water, the rice-like grains may be rendered firm and crisp, and perfect washing facilitated. No process of churning or washing, however, will enable the most skilled of makers to produce good butter from imperfect milk or cream.

How to Use the Churn. The churn should never be filled too full of cream; not, indeed, more than one half. The larger the quantity of cream placed in the churn, the longer the time occupied in bringing the butter, while the smaller the quantity, the shorter the time occupied. For instance, in a churn intended to deal with 60 lb. of cream, 16 lb. pro-

27. DIAPHRAGM CHURN
(Pond & Son, Ltd., Blandford)

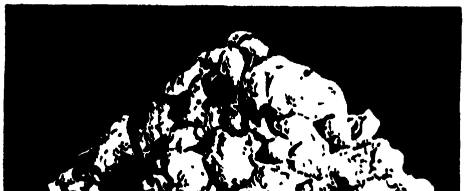
duced butter in 28 minutes; when double the quantity of cream was churned, 39 minutes were occupied; and when four times the quantity of cream were used, 85 minutes were occupied—the percentage of butter produced being slightly smaller with the increase in the quantity of cream. Cream, however, like milk, does not all churn alike; something depends upon the individuality of the cow, and something upon the food consumed. Speed, too, exerts some influence, and, as we have seen, the quality of cream employed.

28. WELL-CHURNED BUTTER

Influence of Cows' Food on Cream. We have much yet to learn as to why the cream of one cow is more churnable than that of another, and also why cream produced from some classes of food is more churnable than that produced from others. It is, however, well known that where cows are fed upon grass in summer, the percentage of fat obtained in churning is greater than when the same animals are fed upon hay and certain other dry foods in winter. The speed adopted in churning varies with the churn and its size; the number of revolutions per minute should be noted, together with the results which follow, and the careful operator will quickly learn what speed to adopt. With the disc churn, butter may be produced in five minutes; indeed, with almost any class of churn rapidity is followed by the production of the butter in a shorter time, but sometimes at the expense of either quality or quantity. With the average churn, butter is produced in from 30 to 40 minutes, the number of revolutions varying from 45 to 55 per minute.

Modifying the Temperature. We have already referred to the influence of temperature, but, whatever figure be adopted, it cannot be more than approximate, for the reason that the fats of which butter is composed are not all constant in quantity; the solid fats, for example, vary as between winter and summer, and these fats possess different melting points. The influence of temperature is also modified by the material of which the churn is made, the consistence or richness of the cream, and the temperature of the dairy in which the work is performed. A high temperature must always be avoided, if it be sufficient to produce an approximate oiliness in the cream. If churning be protracted and the cream swell in volume, or froths, and become bitter and "sleepy," churning should be stopped, and half the cream removed before beginning again; when both lots have been converted into butter, the butter should be washed with sweet milk, and salted with half an ounce of salt to the pound.

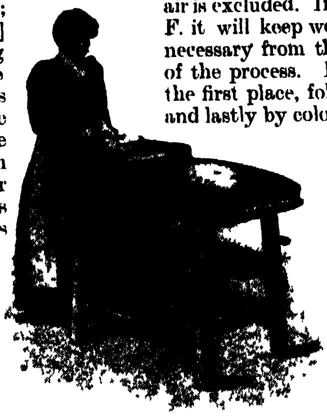
What Occurs inside the Churn. Before beginning to churn, the vessel should be scalded and brought as near as possible to the temperature of the cream. If the temperature be, however, too high, it may be reduced with cold water; or, if too low, by scalding again. Neither soap nor soda should ever be used to clean a churn. After starting to churn, the gas within (carbonic acid) should be allowed to escape by pressing the ventilator. Steady work should be continued until the butter breaks. This may be noticed by watching the glass of the window, or by listening to the splashing of the cream, which changes from a dull thud to something like the splashing sound of water; while the glass, hitherto covered with a film of cream, becomes almost clear, and tiny grains of butter may be noticed adhering to it. At this point the butter should be examined, and, unless the grains be quite distinct and crisp, a little cold water, as near 40° F. as possible, may be added. The churn may then be turned gently for a few revolutions, in order to increase the size of the grains to that of rice or small wheat [28]. When this point is reached the buttermilk may be drawn off through a strainer, and more cold water added for the first washing. If the temperature has reached 58° F. to 60° F. the colder the water the better. The churn may then be rocked and the water drawn off through the sieve. Two or three similar washings may follow, rocking each time, until the water comes away quite clear. The work in the churn may then be completed by washing with brine made by adding one pound of dry salt to 1½ gallons of water. After drawing off the brine, the grains of butter may be removed from the churn with the butter-scoop, either on to a wooden trough which some persons use for draining purposes, or to the butter-worker, where it may remain in a pile in the grain until it has drained sufficiently to be ready for working. Some makers, however, remove the granules of butter into a *Delaiteuse* [26], a hand machine



29. OVER-CHURNED BUTTER

which, revolving at high speed, removes the water by centrifugal force.

The Butter-worker. The butter-worker is made in two forms—circular [31] and rectangular, its floor being either high or low in the centre in the case of a circular machine, or sloping from the centre to the ends in the rectangular machine to help drainage; but in either case a fluted roller [30] passes over the butter, squeezing out the moisture, and at the same time making the mass of grains homogeneous. Care must be taken not to smear the butter or to cause friction, which results in spoiling the grain, nor must butter be worked when it is too soft, or upon a table which has not been prepared by scalding, salting, and finishing with cold water.



30. MAKING UP BUTTER
See roller placed away beneath
(T. Bradford & Co., London)

In making fine, fresh, mild butter, brining alone is sufficient. For mild salting, ¼ oz. to 1 lb. is added by the aid of a dredger when the butter is on the worker. Slightly heavier salting is the result of ½ oz. to 1 lb., while for preserving purposes ¾ oz. may be employed. The salt used should be of the purest obtainable, ground almost as fine as flour, and well dried in an oven. Salt attracts moisture, and where excessive moisture is present in butter coarse salting is followed by a mottled appearance, which renders butter almost unsaleable. Butter should never be artificially coloured. If it be pale it may be improved by the addition of Jersey or Guernsey cattle to the herd.

31. CREAMERY, SHOWING REFRIGERATOR, CYLINDRICAL COOLER FOR RIPENED CREAM, BUTTER-WORKER AND PORTION OF CHURN
(By Permission of W. Douglas & Sons, Putney)

Handling to be Avoided. In *making up butter* [30], prints and moulds are no longer used in this country in the ordinary way, although quite common on the Continent, where butter is moulded by implements or machines, which at the same time cut it into various weights. English butter is usually made in pound or half-pound rolls, although occasionally these are stamped. Butter should never be touched by the hand. It is a well-known fact that the pores of the skin are the media through which perspiration passes, this being secreted by glands, and containing not only carbonic acid, but small quantities of urea. In potting or preserving butter, well-made tubs or boxes, which should be lined with greaseproof paper, or glazed earthenware vessels should be used. Butter for preserving should be churned at 56° F., well drained, dried, salted with three-quarters or one ounce of salt to the pound, and packed carefully so that air is excluded. If it be kept at from 35° F. to 37° F. it will keep well and long, but great care is necessary from the beginning to the completion of the process. In judging butter, flavour takes the first place, followed by grain and toughness, and lastly by colour and firmness. Where points are adopted, half are given for flavour and a quarter for grain.

Prices. The value of milk for butter production depends upon its richness in fat. The practice of paying the farmer upon the basis of quality is not only a just one but it offers him an inducement to improve the quality and character of his herd. The milk as it arrives at the dairy or factory should be sampled and tested either daily or weekly, in the latter case through the medium of a composite sample by the Gerber or Babcock machine, and the farmer credited with the percentage of fat which his milk contains, and he should be paid accordingly. Let us suppose that three farmers, A, B, and C, supply milk in similar quantities for a similar period, containing respectively 3, 3½, and 4 per cent. of fat. Instead of each man receiving a similar cheque, B would receive one-sixth more than A, and C one-third more. Thus, if 5d. per gallon were paid for milk containing 3 per cent., 6d. for milk containing 3½ per cent., and 7d. for that containing 4 per cent. of fat, each man sending 30 gallons per day, or, say, 10,000 gallons per annum, B would obtain £41 more than A, and C £83 more. The system of paying on the basis of fat percentage, however, may be varied, so that each farmer may receive payment for each pound of fat which he supplies in his milk, the quantity being calculated on the basis of the fat percentage. Reform in this direction is much needed.

RESOURCES OF SOUTH AMERICA

Mountains, Forests and Grasslands. The Great Rivers. Resources and Occupations of the Various Republics

By Dr. A. J. HERBERTSON, M.A., and F. D. HERBERTSON, B.A.

SOUTH AMERICA (7,000,000 sq. miles) extends from the Isthmus of Panama to the southern extremity of the New World. It is longer than North America (4,600 miles between Capes Gallinas and Froward), but not so broad (3,200 miles between Capes Parina and Branco).

Coast Line. The Pacific States are Colombia, Ecuador, Peru, and Chile. The Caribbean States are Colombia and Venezuela, and farther east are the British, Dutch, and French Colonies of Guiana The eastern or Atlantic States are Brazil, Uruguay, and Argentina. The inland States are Bolivia and Paraguay. All are republics except the British and Dutch Guianas.

Gulfs and Islands. The compact form and short coastline contrast strongly with the indented shape and extensive coastline of North America. Notice the absence of inland seas, gulfs, peninsulas and islands. The southern coast of Chile is fringed with islands and indented with fiords recalling the very similar coast of Norway. The island of Tierra del Fuego is separated from the southern mainland by Magellan Strait, a stormy channel leading from the Pacific to the Atlantic. Farther out in the Atlantic are the Falkland and South Georgia Islands.

Mountains and Rivers. There is a marked similarity in the disposition of the mountains, and plains of North and South America. South America, like North America, is bordered along the whole length of the Pacific coast by a high, broad mountain system consisting of many parallel chains. These are the Andes, or South American Cordillera, corresponding with the North American Cordillera. From their eastern base stretch vast plains, covered with forest or grass, corresponding with the central lowlands of North America. East of those great lowlands rise the Atlantic Highlands, also corresponding with those of North America. The Amazon, which corresponds in position with the St. Lawrence, separates the Guiana Highlands, comparable with the Labrador Highlands, from the Brazilian Highlands, comparable with the Appalachians of the United States. The different shape of South America prevents the formation of a south-flowing river on the scale of the Mississippi, with which the Paraguay-Parana corresponds. The Orinoco, both in position and direction, suggests a comparison with the Saskatchewan-Nelson. Interesting as these resemblances are, they are more superficial than real, and must not be pushed too far. The fact that the southern continent is broadest in the latitude of the equator while the northern continent is broadest in the latitude of London sufficiently indicates how widely the two continents must differ.

The Andes. The structure of the South American Cordillera, or Andes, is not yet thoroughly known. Fitzgerald, Whymper, and Conway have climbed the loftiest peaks, but, brilliant as such feats are, they teach the geographer less than does the careful survey of a region area by area. The nature of the Andean region makes this process a slow one, and it will probably be long before we know the South American Cordillera as we know that of North America.

The Coastal Ranges. The coastal ranges of South America are not continuous. In Colombia they form a densely-forested and little-known region, which is separated from the Cordillera proper by a depression in which the Atrato flows north and the San Juan south. Further south in Ecuador this depression is represented by the valleys of Western Ecuador. From Guayaquil to Arica the coastal range is absent, but south of Arica it reappears, the Atacama Desert occupying the depression between it and the Cordillera South of Aconcagua it can be traced in the mountains which form the western boundary of the narrow valley of Chile. South of 42° the coastal range is represented by the islands of Chiloe, Chonos, and Queen Adelaide, and the depression by the channel which separates them from the deeply fiorded coast of Southern Chile.

The Andes of Colombia. In Colombia the Cordilleran system consists of three chains, separated by long, narrow, parallel river valleys. These chains diverge to the north, but converge in the south to the node or knot of Pasto. Between the Western and Central Cordilleras is the valley of the Cauca, an affluent of the Magdalena, which flows parallel to it between the Central and Eastern Cordilleras. The highest part of the Central Cordillera is in the south where the great volcanoes of Tolima and San Ruiz rise to 18,000 ft. The Eastern or Bogota Cordillera, which is not volcanic, forks, the western fork running due north to the Sierra de Santa Marta of the Goajira Peninsula, while the eastern fork is succeeded by the Sierra de Merida (15,500 ft.) and the northern coastal range of Venezuela.

Many fine views are obtained from summits in the Colombian Andes. From the mountains above Bogota a magnificent view is had of Tolima and San Ruiz, nearly 100 miles to the west, their great frozen sides glittering under the tropical sun.

The Andes of Ecuador. In Ecuador two main chains can be traced, both containing many lofty volcanic peaks. In the western chain are Chimborazo (20,500 ft.), Illiniza (17,500 ft.), and many others over 15,500 ft.

The eastern peaks include Cotopaxi (19,600 ft.), Antisana (19,300 ft.), Cayambe (19,200 ft.), Sangai (17,500 ft.), and others almost as high.

Volcanoes. Sangai and Cotopaxi are seldom at rest. All this region, as well as Colombia, is often visited by disastrous earthquakes.

The snows of the Eastern Cordilleras of Colombia feed the many streams which rush down precipitous and densely-forested gorges to form the tributaries of the Orinoco. Only the extreme south of the Colombian Cordillera sends its waters to the Amazon, to which also flow the waters of the Eastern Cordilleras of Ecuador, through scenery equalling the finest parts of the Himalayas.

The Andes of Peru and Chile. The Andes in Peru form three chains, which increase in height from north to south. These are separated by narrow river valleys recalling those of Colombia. Between the Western and Central Andes is the valley of the Marañon, the principal head stream of the Amazon. The Central Andes are separated from the Eastern Andes of Peru by the valley of the Huallaga, which flows parallel to the Marañon, and like it goes to form the Amazon. Both turn east and break through the eastern chain in magnificent gorges. The three ranges converge towards Pasco, near the source of the Huallaga, south of which the height of the peaks increases. The Ucayali, a tributary of the Amazon, gathers up the many streams which flow from the Eastern Andes through densely forested and little-known country. The eastern or Cordillera Real now begins to diverge from the western, and between the two lies the lofty plateau of Bolivia, the Tibet of the Andes. Both chains contain lofty peaks. El Misti and others in the western chain are not far short of 20,000 ft., while Illimani and Sorata in the Cordillera Real are over 22,000 ft.

The Andes of Chile and the Argentine. In the north of Chile and the Argentine, the Andes form three ranges. The eastern chain is divided from the Central Andes by a plateau over 4,000 ft. above the sea. These three chains are replaced by the western coastal and main or eastern chain further south. This main chain contains the highest peaks, including Aconcagua (23,000 ft.), the culminating point of the New World. Though Aconcagua can be clearly seen from the Pacific coast, its snows feed streams which flow to the Atlantic, 700 miles away.

After every kind of hardship, the summit of Aconcagua was reached in 1897, and the continent lay spread out below. "The line of the Pacific stood high on the horizon, stretching away for 150 miles. Range after range of mountains could be clearly seen between Aconcagua and the ocean. We seemed to look right down into the valleys between these ranges. Fifty miles away stood the great snow mass of Mercedario, one of the highest mountains in the Andes, towering above all the surrounding ranges. Of the pampas, or plains, of the Argentine we could not see anything: there were too many high ranges between. To the south the clouds were not high enough to cut off the magnificent view of Tupungato (22,000 ft.) and the great range to the north, including the beautiful peaks of Pollera (19,000 ft.), Navarro (19,500 ft.), and Juncal (20,500 ft.), which so distinctly mark the boundary line between the two republics." To the north the Cordilleras widen out, until at lat. 32° 50′ they rise up from Mendoza and continue almost to the sea coast, a distance of 150 miles.

The Cumbre Pass. At the base of Aconcagua is the Cumbre or Uspallata Pass, 12,800 ft., leading from Chile to the Argentine. There is no pass so low as this for many hundreds of miles to the north. It is the route followed by the transcontinental line from Buenos Aires. A tunnel below the summit of the pass is in course of construction.

The Andes South of Aconcagua. South of the Cumbre Pass the Andes are narrower, but still very lofty. The great plain in which Santiago is situated is not more than 45 miles to the west from Tupungato. These 45 miles are filled with range after range of high mountains. From the top of Tupungato eastwards, a man can look down almost into the great plain of the pampas.

Southwards the range sinks as well as narrows, to disappear at last beneath the waters of the ocean. The mountains rise steeply from the Pacific, and the sea has penetrated far up the valleys, forming fiords like those of British Columbia. Beyond lies a fringe of islands, representing the almost submerged coast range. At the eastern side are many picturesque lakes which recall those of Switzerland or of Scotland.

Central Lowlands and the Orinoco. The Central Lowlands may be grouped as the Orinoco Lowland, the Amazon Lowland, the Plate or Paraguay-Parana Lowland, and the Patagonian plateau. Between the Orinoco and Amazon Lowlands rise the Guiana Highlands in the east, while the Brazilian Highlands separate the Amazon and Plate Lowlands. The Orinoco rises in the Sierra Parime, the south-west part of the Guiana Highlands, round the western and northern base of which it flows in a semicircular course of 1,500 miles, the direct distance between its source and mouth being only 500 miles.

The traveller approaching the coast of Venezuela notices far out to sea the milky waters of a great river, sharply contrasting with the blue salt water. This great outflow of fresh water convinced Columbus of the neighbourhood of a continent, for no West Indian island could feed so great a river. Six or seven of the 70 channels which cross its delta are navigable. A waste of mangroves fringes the coast, succeeded inland by a labyrinth of vegetation, through whose innumerable creeks dart the canoes of half-naked Indians. Beyond the swamp-forest of the delta the country opens out on the west bank to the grassy llanos, which stretch to the horizon, apparently level, but really rising imperceptibly to the forests, or selvas, at the eastern base of the Andes.

The grass is very luxuriant in the wet season, but withers in the dry season, when the vast herds of cattle, horses, and mules, suffer terribly from hunger and thirst.

The tributaries of the Lower Orinoco are the Caroni and the Caura, swift streams rushing down from the densely-forested wilds of the little-known Guiana Highlands. Between their confluences the Orinoco narrows, and there, at the head of tidal navigation, is built Ciudad Bolivar. The Lower Orinoco becomes enormously swollen in the rainy summer months, and floods the lowlands for many miles.

Quite different in character are the left bank tributaries—the Meta, Guaviare and others, which come from the Eastern Andes across the llanos. These are navigable for hundreds of miles, though in the dry season sandbanks may interrupt the channel. The Orinoco itself is navigable as far as the Atures and Maipures rapids, above the confluence of the Meta, where the river descends from the highlands to the lowlands. These rapids are a step-like series of cascades where the river, measuring some miles from bank to bank, is broken into innumerable narrow channels by rocks and islands all densely clothed with palms and other tropical trees.

The course of the Upper Orinoco is through the forests of the Guiana Highlands. At no great distance below its source the river forks. The Cassiquiari, the western branch, never rejoins the main stream, but connects with the Negro tributary of the Amazon.

The Amazon. The Amazon, the largest river in the world, rises about 60 miles from the Pacific, and after a course of nearly 4,000 miles, pours its waters into the Atlantic. Its longest head-stream is the Ucayali, but the Marañon is generally regarded as the source. Both the Marañon and the Huallaga rise in the Peruvian Andes, near Cerro de Pasco, one of the highest towns and richest silver mines in the world. Both flow north, descending from their lofty sources in a series of cataracts and rapids. Both at last turn east and break through the outer or eastern Andes to the lowlands, forming magnificent gorges, through which the river roars in cataracts of terrible beauty. Soon after entering the lowland the rivers unite, and, after receiving the Ucayali, are known as the Amazon.

The Amazon Forest Lowland. Nearly all the Amazon Lowland—an area three-quarters that of Europe—is covered with dense forest, or *selva*. No traveller can describe its wonders, the luxuriance of its vegetation, and the profusion of its species. In it one may journey for weeks in any direction without ever passing out of the world of trees. The eye itself cannot take in the vision. "The whole glory of these forests," says the great naturalist Wallace, "could only be seen by sailing in a balloon above the undulating, flowery surface. It is, indeed, a magnificent sight to behold a great tree covered with one mass of flowers, and to hear the deep hum of millions of insects gathered to enjoy the honeyed feast, but all this is out of reach of the admiring naturalist. It is only by the river banks that we can see all the beauty of the tropical vegetation. There we find a mass of bushes, shrubs, and trees of every height, rising over one another, all exposed to the bright light and fresh air, and putting forth within reach their flowers and fruits which in the depth of the forest only grow far up on the topmost branches. The huge buttress trees, the fissured trunks, the extraordinary air roots, the twisted and wrinkled creepers, the elegant palms, are what strike the attention and fill the mind with admiration."

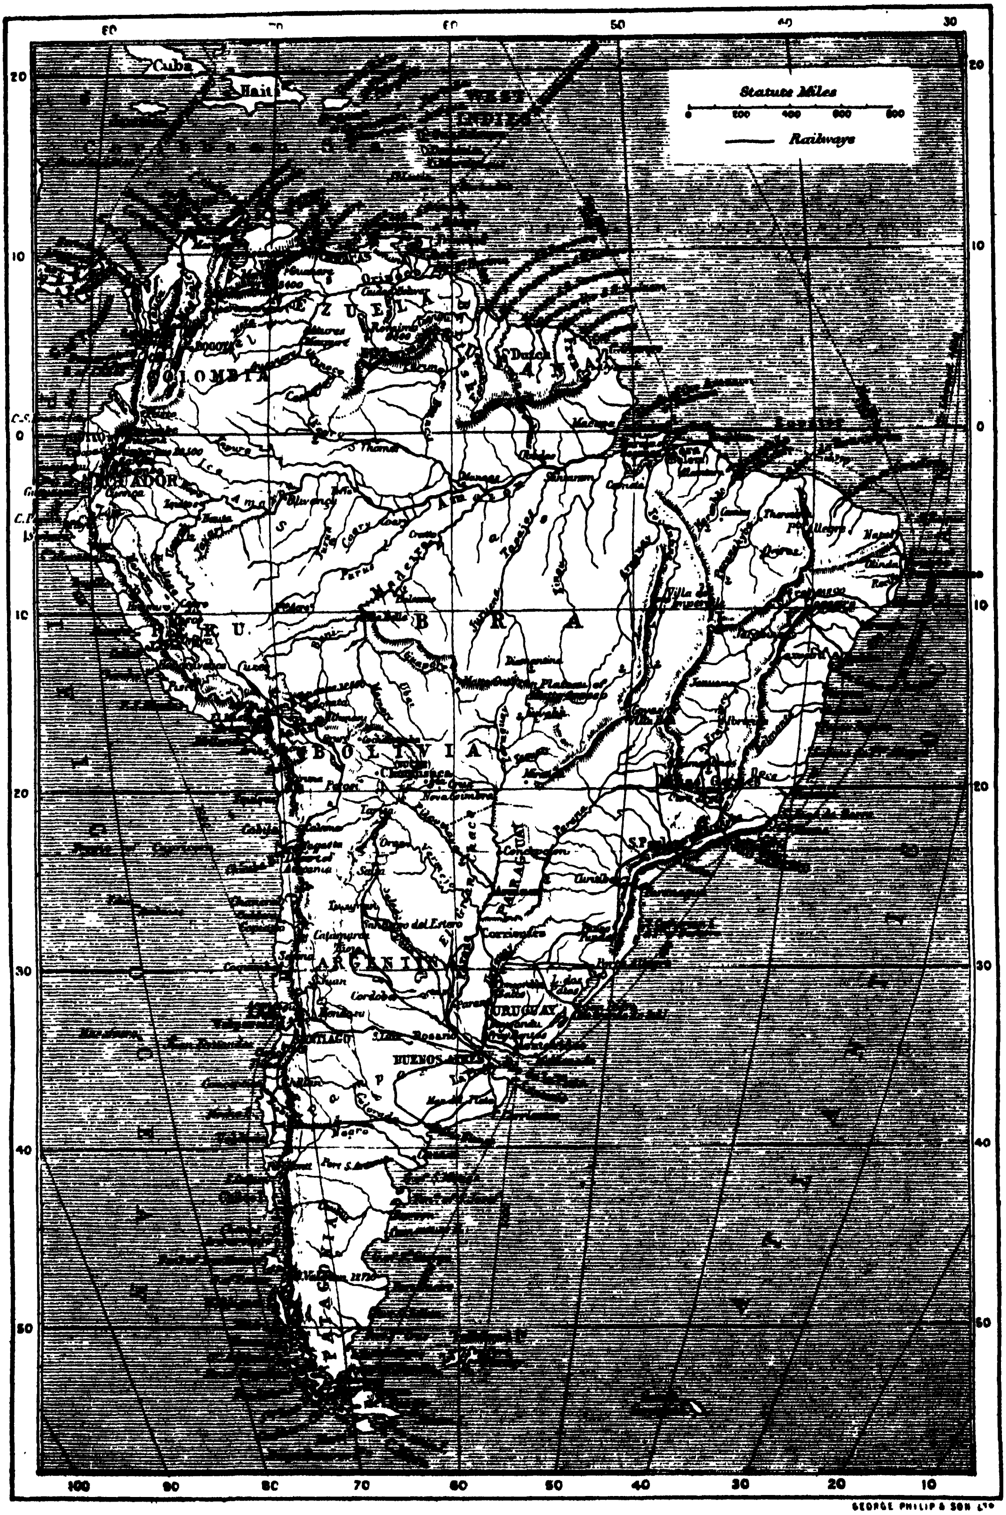
The Middle and Lower Amazon. Through this vast forest, the greatest in the world, flows the Amazon and its mighty tributaries. Of those from the north the Rio Negro is the largest. Purus, the long Madeira, Tapajos, and Tocantins all come from the south, so that the stream of the Amazon is fullest during the southern rainy seasons. The main stream is often miles in width, bearing many verdurous islands on its broad bosom. It breaks up into many parallel streams or side channels, along which one might travel through the dark recesses of the forest for many hundreds of miles without ever returning to the main stream. Along these, Indian tribes who make the forest their home push their way in their rude canoes. On the main stream there is regular steamer navigation. The main stream is navigable to where the Marañon issues from the eastern wall of the Andes, and most of its tributaries almost to their sources. The Madeira, the most important, is navigable to the base of the Bolivian Andes with a break where there is a succession of rapids.

The Amazon does not form a delta, but a great estuary, which for the last 250 miles is 50 miles wide, and at its mouth as much as 500 miles. Up this funnel the Atlantic tides rush for 500 miles, often with great violence, forming formidable waves. The influence of the river freshens the sea water for 150 miles out to sea. Steamers enter the Amazon by the Para River, south of the island of Marajo, through narrow and intricate winding channels.

Resources of the Amazon Basin. The products of the forest are too numerous to be mentioned. The most important is rubber. The timber would be of enormous value if it could be conveyed to the markets of Europe and Asia. The region will develop either by the slow growth of small plantations, carved out of the forest by the natives with infinite labour and patience, or by trading syndicates which will utilise the timber in the course of clearing the forest, and employ native labour for all work involving exposure to heat and rain.

The important towns of the Amazon are all at the confluence of important tributaries—Nauta, where the Ucayali joins the Marañon; Manaos, at the confluence of the Rio Negro, commanding many routes; Obidos, at that of the Trombetas; Santarem, at that of the Tapajos; and Para, at that of the Tocantins.

The Plate Lowlands. If the Amazon Lowland be a typical forest land, the Plate Lowland is a typical savana land. The Paraguay, the main stream of the rivers flowing to the Plate estuary, rises in the plateau of Matto Grosso, in the



GEORGE PHILIP & SON Ltd

145. SOUTH AMERICA

Brazilian Highlands, and flows due south, receiving the Pilcomayo and other tributaries from the Andes. These cross the Gran Chaco, with its forests and plains of grass dotted with innumerable fan-palms, and then emerges into the treeless pampas. They pass thus through country similar to that crossed by the Meta and other Andean tributaries of the Orinoco. This region, like the llanos of South America, the prairies of North America, the steppes of Europe and Asia, and parts of the veldt of South Africa, is a great pastoral land, broken up for cultivation in the moister richer parts. Mounted horsemen, the gauchos, generally with Indian blood in their veins, follow up vast herds of cattle and horses which roam over the infinite reaches of the pampas.

The Patagonian plateau lies east of the Andes, descending by low terraces to the narrow coastal plain. It is a pastoral land, too dry for much agriculture.

The Eastern Highlands. As in North America, the Eastern Highlands are the worn-down remains of a very ancient region, far older than the higher Western Highlands. They are tablelands of the African type, and are divided by the Amazon Valley into the Guiana Highlands to the north, and the Brazilian Highlands to the south of that river. Both are only very partially explored.

The Guiana Highlands. The Guiana Highlands are, in a sense, an island, enclosed between the Atlantic Ocean, and the Orinoco and Amazon rivers, which are connected by the Cassiquiari. The whole region is rugged and difficult to penetrate, covered either with dense forest, or with savanas of giant grass. The rivers are wild torrents, forming innumerable falls and rapids, and of little use as routes. The interior of this region is practically uninhabited. As recently as 1900 an exploring party suffered intense hardships on the Caroni, and the majority perished of the exhaustion caused by the difficulty of clearing a track and of obtaining food.

The highest part of the Guiana Highlands is round Icutu (11,000 ft.) and Roraima (8,500 ft.). The latter, a magnificent table mountain, rising above a sea of forests, sends its waters to the Caroni tributary of the Orinoco, to the Essequibo River of British Guiana, and to the Rio Branca tributary of the Rio Negro, whose valley drives a wedge of lowland far into the highlands. The Sierra Parime, rising steeply above the Amazon Lowland, is the source of the Orinoco.

The Brazilian Highlands. The Brazilian Highlands are enclosed between the Atlantic Ocean and the Amazon and Paraguay-Parana rivers which, in the rainy season, are connected by the Guapore branch of the Madeira. From Cape Frio, north of Rio Janeiro, a line of high ground, forming the Minas Geraes, Goyaz, and Matto Grosso plateaux, separates the rivers flowing north to the Amazon from those running south to the Paraguay-Parana, or east to the São Francisco. The highest summit is Itatiaya (9,000 ft.). Much of this region is densely forested, and difficult to penetrate. Elsewhere it is a savana land, well wooded in the Matto Grosso and other regions.

Climate. Most of South America lies between the tropics, and has a tropical climate. The continent is broadest in the equatorial region, and the climate of much of the interior is always hot. Contrast this with North America, where the continent is broadest in temperate latitudes and the interior has a very extreme climate. The hottest region in summer (January) lies between the mouths of the Amazon and Plate. The hottest region in July is the northern seaboard. Elevation must, of course, be taken into account. In the Andes we have the same succession of zones (*tierra caliente, tierra templada*, and *tierra fria*) as in Mexico and Central America. South of the Plate Estuary the summers are those of Southern Europe, and the winters those of the British Isles. In the extreme south, both summers and winters are those of our own country.

The rainfall of the Amazon basin is heavy at all seasons, but especially at the equinoxes. The Guiana coast, also, has heavy rains at all seasons. Dry areas are found on the west coast in Peru and Chile, in the trade wind area, and in the lee of the Eastern Andes, in the west wind belt. The rest of the continent has a rainfall of from 40 in. to 60 in., with dry winters. There is a relatively dry area in Brazil, round the middle of São Francisco, where the Brazilian Highlands are high enough to intercept the Atlantic winds. The valley of Central Chile has winter rains, and may be compared with the valley of California.

Vegetation. We have already seen how dense is the vegetation of most of tropical America. The Amazon forest is the greatest in the world. All tropical species are represented, but rubber is the most important commercially. On the slopes of the Andes, the cinchona-tree, furnishing quinine, is extremely abundant.

These selvas of the Amazon Lowlands pass into the llanos of Venezuela in the north and the pampas of the Argentine in the south. There are open or parklike woodlands or campos in many parts of the Brazilian Highlands. Patagonia is poor steppe land, with the characteristic thorny vegetation of a dry climate. The Pacific slopes of Southern Chile have coniferous forests like those of British Columbia.

The cultivated plants are mainly those of the tropics. Cacao is an important product of the cultivated slopes of the Andes, sugar of the Guiana Lowlands, and coffee of the cultivated Atlantic slopes of the Brazilian Highlands. Outside the tropics in the Plate Lowlands wheat is a crop of ever increasing importance.

Population and Occupation. No continent presents greater contrasts than South America. Round the coast we have a few great cities which will bear comparison with any in the Old or New World. In the heart of the continent we have tribes of wandering Indians, ignorant of all arts except hunting, the manufacture of the needful weapons, and the building of rude canoes. Between the two every grade of civilisation is found.

South America, backward and thinly peopled, presents a striking contrast to North America, with its denser and intensely progressive population. The explanation is mainly geographical. The density of the forest in the lowlands and the rugged character of the highlands have made the opening of routes very difficult, and have checked the growth of population and the spread of civilisation over a great part of the continent. This is most marked in the forest region, where the native tribes are at a far lower level than were the prairie Indians of North America. It is instructive to compare these backward forest tribes with the relatively high civilisation which the European discoverers of South America found in the Highlands of Peru.

While the geographical conditions were unfavourable to the rapid advance of the native races, the situation of the continent in tropical latitudes was equally unfavourable to its colonisation and development by Europeans. North America, with its great extension in temperate latitudes, made an admirable home for the most vigorous European races, who rapidly multiplied, and filled up the continent. South America, except in the south, was unsuited to Europeans, who confined their settlement to the coast, and did little to develop the interior.

Agriculture and Manufactures. Agriculture is confined to the margin of the continent. In the grasslands horses, cattle, mules, and sheep are bred in enormous numbers, sheep being found in the drier areas—such as Patagonia. Notice that while North America can consume much of the meat it raises, South America has not a sufficient population to do so; also that the difficulties of transport make the preparation of meat extract an important industry, as the value is high in proportion to bulk and the cost of transport. North America, with its excellent communications, adopts less wasteful methods of preserving meat. Hides are an important export from South America. In North America the manufacture of boots and shoes is very important in the towns east of the ranching prairies, but South America is too thinly peopled for manufactures.

In the tropical forest, rubber and other forest produce are collected, and sent down the Amazon. It is easy to see why lumbering has not become important. Felling a tree in the climate of the tropics is a very different matter from felling a tree during the bracing Canadian winter, even if suitable labour were abundant instead of scarce.

The last occupation to note is mining. Many parts of the Andes are rich in minerals, and the gold and silver mines in particular have been worked for centuries. In the east, both the Guiana and Brazilian Highlands are rich in gold, and the latter also produce fine diamonds. The more useful metals only wait for a population to exploit them. The alkaline deposits of the Atacama Desert of Chile are valuable fertilisers in great demand for agricultural purposes.

Races and Religion. The aboriginal races, pure and mixed with European blood, form the bulk of the population, which is estimated at 38,000,000. The Europeans are mainly of Spanish and Portuguese descent, the latter especially in Brazil. Negroes and coolies from India have been introduced for plantation work in the east. In recent years there has been a large influx of Germans into Southern Brazil, and of Italians into the Argentine. The predominant religion is Roman Catholic; the language and general mode of life Spanish or Portuguese.

Venezuela. Venezuela (600,000 sq. miles) consists of three distinct regions: (1) the mountains in the north-west, including the coastal regions bordering the Caribbean Sea; (2) the llanos or grasslands of the Orinoco; and (3) the Guiana Highlands in the south-east.

The climate is tropical in the lowlands, but in the mountains *tierra caliente*, *tierra templada*, and *tierra fria* are well-marked. Still higher in the west are the *paramos*—bleak, treeless pastures, which extend to the snow line. Cinchona is abundant in the higher forests, in the clearings of which are grown potatoes, pulses, and the hardier cereals. In the middle zone the forests contain magnificent tree ferns, and in the valleys and plateaux bananas, coffee, sugar, etc., are cultivated. In the lower or palm forests the most important crop is cacao. Much chocolate is made from local sugar and cacao. Merida is the chief centre in these western mountains.

The less lofty eastern Caribbean ranges do not rise above the forest line. Here are situated the principal inland towns—Caracas, the capital, and Valencia—both in the coffee-growing region, and the ports of La Guaira and Puerto Cabello. A difficult line crosses the coastal range from La Guaira to Caracas, zigzagging 25 miles and climbing 5,000 ft. to reach a town distant only about six miles as the crow flies. From the summit of the pass Caracas is seen, 3,000 ft. below, laid out, like all South American towns, in blocks with rectangular streets of low, one-storied, white, red-roofed houses, set among green sugar plantations, beyond which a parched plain stretches to the encircling mountains.

The llanos, with their vast herds of horses and cattle, have already been described. The forests and minerals, including gold, of the Guiana Highlands should one day become very valuable, and the Orinoco a great commercial highway. At present the chief town, Ciudad Bolivar, is a place of little importance.

The Guianas. Notice in the map how many rivers cross *British Guiana*, the largest being the Essequibo. For 20 miles inland the coast originally consisted of mangrove swamps, flooded at high tide. They were dyked and drained by the Dutch, and these reclaimed lands, in which sugar is the chief crop, are practically the only cultivated or inhabited part of the Colony. The highlands are rich in gold, as well as in forest produce, but cannot at present be developed, owing to difficulties of communication. The capital is Georgetown, on the Demerara River, where rum and molasses are made from local sugar.

Dutch Guiana (46,000 sq. miles), capital Paramaribo, is very similar in character. *French Guiana* (30,000 sq. miles) is little developed, and is used as a penal station. The capital is St. Louis, or Cayenne.

Brazil. The United States of Brazil (3,300,000 sq. miles) is, roughly, as large as Canada, the United States, or Australia. Its potential wealth is enormous, but only the fringe of the country is yet developed. It is essentially a tropical land. Only the extreme south is really fitted for European settlement.

Brazil consists of the vast forested Amazon Lowland, in the equatorial hot wet belt, and of the Brazilian Highlands, a rugged region covered with forests or wide, open grasslands.

The forest region of the Amazon is almost unexplored, and very thinly peopled by Indian tribes. Rubber and other forest produce is collected and sent to the towns, especially to Manaos, but also to Obidos, Santarem, and others, all at the junction of river routes, whence it is forwarded to Para or Belem, the great rubber port. Some forest produce is also shipped from San Luiz, or Maranhão, and Ceara, or Fortaleza, both east of the Amazon estuary.

The agricultural regions of Brazil are along the east coast. Sugar, cotton, cacao, and tobacco are grown in the State of Pernambuco, in the north-east, and exported from the port of that name, and from Bahia or San Salvador, in the neighbouring State of Bahia. Gold and diamonds are abundant in the States of Bahia and Minas Geraes, where all minerals are widely distributed. The latter state is in the grazing zone. Some cotton and much coffee is grown in the State of São Paolo, the capital of which has the same name, and is exported from Santos. Some coal is worked in Rio Grande do Sul, where cattle raising is important.

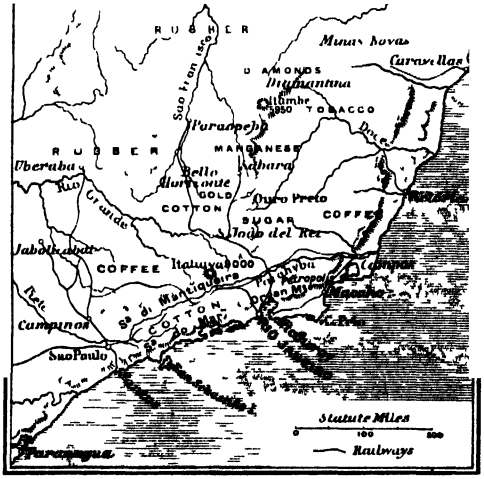
The Federal capital is Rio Janeiro [146], on a harbour of extraordinary beauty. The city, which has a bad reputation for health, is laid out, like most South American cities, on the chessboard plan.

Uruguay. Uruguay (72,000 sq. miles) is a savana land, lying east of the river Uruguay, which flows to the Plate Estuary. Its winters are warm, and the summer heat is tempered by the Atlantic. The chief occupation is the raising and slaughtering of cattle. The slaughtering centres are Montevideo, the capital, and Paysandu, where choice tongues are canned. Fray Bentos, south of Paysandu, makes meat extracts. Much of Uruguay is well suited for wheat growing, which will doubtless develop. The mineral wealth is considerable. Salto is the centre of the mining district.

Paraguay. Paraguay (140,000 sq. miles) lies between the Pilcomayo and the Parana, both joining the Paraguay, which bisects the country. There are magnificent forests in the hillier parts of the country. Much of Paraguay is well suited for agriculture. Yerba maté, or Paraguay tea, a native plant, which is in great demand throughout South America, is an important export. Cotton, indigo, and rubber also grow wild. Sugar, rice, tobacco, maize, coffee, and many fruits, can be cultivated. Cattle, horses, and sheep are bred. The capital is Ascuncion, on the Paraguay.

Argentina. Argentina (1,800,000 sq. miles) largely consists of flat treeless pampas. In the west the country rises to the base of the Andes, where the climate is dry and many rivers end in salt lakes or swamps. The mountain streams make irrigation easy, and as this increases, much fertile land will be brought under cultivation. In the north, Argentina includes much of the forested Gran Chaco, which supplies valuable timber. Patagonia, in the south, is steppe or shingly desert in the east, but becomes wooded towards the Andes. The valleys are generally fertile under irrigation [147].

In the north of Argentina, the climate is tropical, and sugar, cotton, maize, tobacco, etc., are grown. In the pampas region, the climate becomes temperate. The seasons are warmer than in Canada, but in some respects the two countries may be compared. In both a great river opens out the country from the east, forming an outlet for the vast plains, where stock-raising and the cultivation of cereals is important. In a few years Argentina will compete with Canada as one of the great wheat lands of the world. Maize is also largely grown. As in Canada, the advance of settlement leads to the introduction of mixed farming, and the growth of dairy industries. After Australia Argentina is the chief sheep-farming country in the world, but Argentina wool is inferior to Australian.



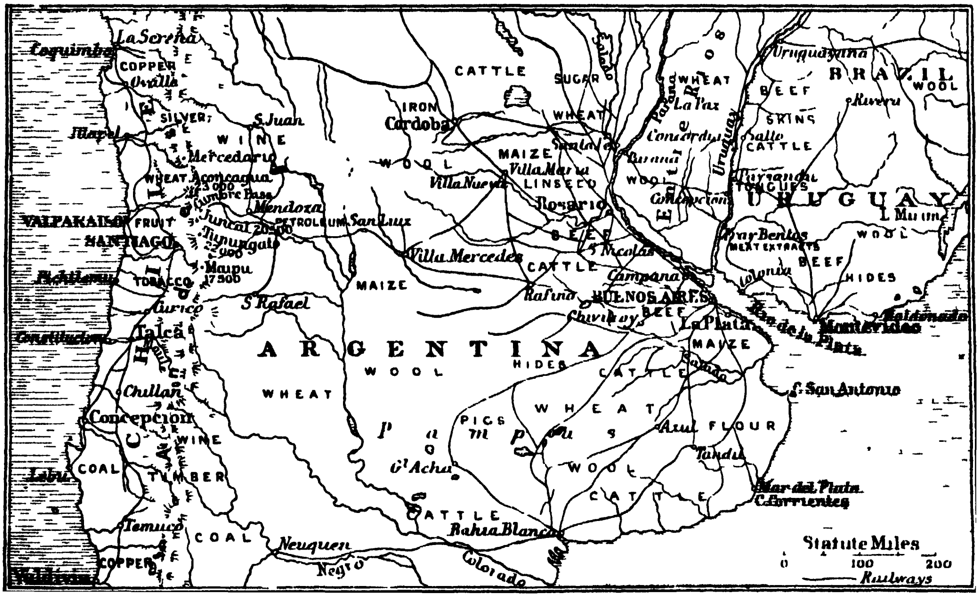
146. THE HINDERLAND OF RIO JANEIRO

Buenos Aires, on the Plate Estuary, the largest city in South America, has grown enormously in the last twenty years. Its miles of docks, spacious streets, handsome buildings, and scores of parks, make it one of the most imposing cities of the New World. Other important towns of Eastern Argentina are La Plata, the capital of the fertile state of Buenos Aires, south of the Plate Estuary, and Bahia Blanca, its southern port. On the Parana are Rosario, the second city in the country, to which the wheat ships can penetrate, Santa Fé, in a rich agricultural region, and Corrienates, in hotter zone, where subtropical crops can be grown.

In Central Argentina the land rises gradually to the west, in parts of which irrigation is necessary. The mineral wealth is considerable, but undeveloped. The chief towns are Cordoba, San Luiz, and Santiago.

Western Argentina is as yet thinly peopled. In the north Tucuman is the centre of a sugar region. The cultivation of the vine is becoming important in the irrigated land at the base of the Andes. Salta and Mendoza are the chief towns of the vineyard districts. Stock-raising and mining are the other occupations. At present the cost of transport to the sea is very high, but this will diminish with the opening of the trans-Andean line to Chile.

Railways can be cheaply built in most parts of Argentina, owing to the flatness of the country. They now connect all the principal towns. The transcontinental line from Buenos Aires to Valparaiso, by Mendoza and the Cumbre Pass, is approaching completion, but a section has still [1906] to be done by mule.



147. THE MOST PROSPEROUS BELT OF SOUTH AMERICA

The Falkland Islands. This group of two large and many small islands forms a British Crown Colony. The rugged surface consists of moorland, which forms good sheep pasture. The strong Atlantic gales make the islands destitute of trees. The only town is Port Stanley.

Chile. Chile (295,000 sq. miles) occupies the western slopes and valleys of the Andes south of 18 deg. S. Between 2,000 miles and 3,000 miles in length, it is only 100 miles wide, but communication across it is made difficult by the presence of the coastal range, which extends as far south as 40 deg. S. Owing to its great length from north to south, and its varied elevation, Chile has a great range of climate.

Chile consists of (1) a rainless northern region, the Atacama Desert; (2) a dry zone, fertile where irrigated; (3) the fertile valley of Central Chile; and (4) the colder, wetter south.

Northern Chile has rich deposits of nitrate of soda, but these occur at an elevation of 2,000 ft., in an absolutely desert region. All necessities of life, including water, must be transported at great expense, so that only the richest fields are worked, and there is no permanent population. The nitrate ports are Iquique and Antofagasta. From the latter a railway runs across the Andes to Lake Titicaca. Copper is abundant, but difficult to work. The mines are often in inaccessible regions of the Andes, and at an elevation where the rarefied air makes exertion fatiguing The chief copper port is Coquimbo.

The fertile valley of Central Chile is the great centre of agriculture and population. All Mediterranean fruits and cereals can be grown south of 30 deg. S. The vine is largely cultivated for wines and raisins. In the centre of the valley is Santiago, the capital, with a fine view of the snowy Andes. Its port, Valparaiso, destroyed by an earthquake in 1906, the great outlet for the valley, 55 miles distant, is reached by a railway 115 miles long, which has to climb the coastal range. Talca, Concepcion, and Valdivia are the other centres of the valley, where many small towns are growing up, each with its distilleries to turn out the cheap spirit—*aguardiente*—which is the curse of Chile. Coal is mined. Southern Chile is as yet thinly peopled. Both the mainland and the islands are densely forested, but as the timber cannot compete with that of Oregon or British Columbia, the process of clearing will be slow. Root crops do well, and the island of Chiloe claims with Peru to be the original home of the potato. Most North European crops can be grown except in the extreme south, which is too wet for cereals to ripen. The mineral wealth is probably considerable. Some gold is worked. The port is Punta Arenas, on Magellan Strait. The island of Tierra del Fuego is partly Chilean, partly Argentine.

Peru. Peru (460,000 sq. miles) is north of Chile on the western and eastern slopes of the Andes. It consists of (1) a desert coastal region, fertile only where crossed by rivers from the Andes; (2) the sierra, or Andean region of mountains, valleys, and plateaux; and (3) the montana, or forested slopes of the Eastern Andes, sinking to the plains of the Amazon.

The coastal desert is fertile where it can be irrigated, producing sugar, cotton, cereals, lucerne, vines, and fruits. Lima, the capital, is separated by eight miles of desert from its port Callao. The line between them is continued over a pass 16,560 ft. to Oroya, whence it is continued to Cerro de Pasco, the silver town in the heart of the Andes. Arequipa, in Southern Peru, finely situated at the base of the volcano El Misti, is separated by 60 miles of desert from its port, Mollendo, the starting point of a line which climbs the Andes over a pass of 14,650 ft. to Lake Titicaca, on the Bolivian Plateau, 12,500 ft. above the sea

The sierra region is about 250 miles wide, and contains many fertile plains and warm, sheltered valleys in which cereals and fruits can be cultivated. The domesticated alpaca and wild vicuña supply fine wool. The mineral wealth, especially in silver, is very great. In the lofty plains enclosed by still loftier mountains are many finely-situated towns, each surrounded by a fertile district. Puno, on Lake Titicaca, in the midst of a silver-mining region, is the terminus of the line from Mollendo, which is continued to Cuzco, 11,000 ft. above the sea, the old capital of the Incas or native rulers of Peru. The rich silver mines of Cerro de Pasco have already been mentioned.

The *montana*, or forest region, is drained by the tributaries of the Amazon Cacao, coffee, etc., are grown in the ravines. The forests produce cinchona and rubber.

Bolivia. Bolivia (570,000 sq miles) continues the sierra and montana regions of Peru. It consists of a lofty plateau in the west, and in the east of the forests of the Eastern Andes and the forests and savanas of the Upper Madeira and Pilcomayo basins.

On the plateau mining is still important, though the famous silver mines of Potosi are declining. Cattle are kept on the grasslands, and agriculture is important in the valleys. Cinchona and rubber are abundant in the forests of the Eastern Andes.

The capital, La Paz, on Lake Titicaca, is connected by a steamer service on the lake with Puno, and by the railways with the coast. It has a large trade in quinine and cacao, both collected from the Eastern Andes.

Ecuador. Ecuador (120,000 sq. miles) consists of (1) a coastal region which includes the rich valley of the Guayas with its cacao plantations, but becomes dry and barren towards the Peruvian frontier; (2) a sierra region, resembling that of Peru, with agriculture and cattle-raising as the chief occupations; and (3) the montana, or forest region, also resembling that of Peru.

On the coast the chief town is the important port of Guayaquil, at the mouth of the Guayas Valley. From Guayaquil a railway climbs to the Andean region, where the usual climatic and vegetation zones are distinguished. There are, as in Peru, many towns in lofty but cultivable basins surrounded by mountains. Of these the most important is Quito, the capital, 9,000 ft. above the sea in a fertile valley bordered by volcanic cones.

Colombia. Colombia (510,000 sq. miles) occupies the north-western angle of South America. The Colombian Andes broaden out into three chains exclusive of the coastal range, and between these are the valleys of the Atrato, Cauca, Magdalena, and of affluents of the Orinoco and Amazon. In addition to the Andean region, with the usual zones, Colombia thus includes the valleys of these rivers, that of the Cauca-Magdalena being the chief artery of a country where roads and railways hardly exist.

The usual range of products is found in the Andes, coffee being the most important. Large herds of cattle are kept in the llanos of the lower river valleys, and there is some mining. The largest town is Bogota, situated in the midst of a lofty savana or plateau of considerable extent (2,000 sq. miles). The ports on the Caribbean coast are Puerto Colombia or Sabanilla, and Cartagena. Barranquilla is the river prot of the Magdalena. Buenaventura is the only important place on the west coast.

Conclusion. Such, briefly surveyed, is our world. The year has brought its changes, startling or imperceptible. Earthquakes have laid great cities in ruins, but they will rise anew from their ashes. A new tunnel pierces the Alps, drawing north and south still a few miles nearer, new railways have been surveyed in many lands, new fields have borne their first harvest, new millions have been added to the future workers of the world. He who would be abreast of events must daily, with newspaper and atlas, note the changes, great or small, which each day brings. Each of these is at once cause and effect, the product of the past, and the parent of the future.

The next series of lessons in this course shows how man uses some of the world's varied products. Many volumes would not exhaust the subject, for man's ingenuity is as unlimited as the bounty of Nature. Each year's figures show the vast increase in the world's wealth, measured by its producing and purchasing power.

Our last thought, like our first, can hardly be other than one of reverence for the great physical laws which hold our world true in its course through space, and give seed-time and harvest in their season, and still more for the imperious law within man himself, which urges humanity onwards towards goals of which even the highest races are but faintly conscious.

BANKING
3

Continued from page 4171

By R. LAING

THE transmission of cash entails a certain loss, and the continued necessity for this in connection with an outlying branch bank in a new country might result in the ultimate closing of that office in consequence of the endless expense and risk. In this country these factors are, of course, very much modified, especially in Scotland, owing to the peculiar advantages which that country enjoys in her note issues.

Scottish Bank Notes. The banks in Scotland are ten in number, all of which are joint-stock companies possessing the right of issue. The amount which each is authorised to issue without security is fixed by the Act of 1845, being the average amount in circulation at that time. The authorised amounts can be (and are) exceeded by the banks against bullion held by the head office. One-pound notes are allowed and circulate largely, while the issues only lapse if they are voluntarily relinquished or if the bank becomes bankrupt. These privileges enable the banks to maintain the branches (numbering, at the close of 1905, 1,161), which are thickly scattered all over the country, and which are found even in the poorest and most sparsely populated localities. The Bank of England notes in the till of an English branch bank represent so much capital unemployed. The notes of a Scotch bank in its tills are nothing but its own I O U's. Until these are issued, the banks are not required to keep a single penny as reserve, which even then does not leave the head office. Again, while the expense in remittance of coin is heavy, it costs little to transmit £1 paper notes.

Scottish Banking. The actual banking business does not in any great degree differ from that in England. The cash credit (an advance made to a person of undoubted probity but of small means on the personal security of his friends, with an ulterior view to an increased note issue, which last, before 1845, cost the bank nothing) has, owing to the increase of individual wealth, lost its great importance; but the efficiency of the note exchanges, whereby a note, should it come into the hands of another bank, is at once returned to the issuer, is still a matter of which Scottish bankers can be justly proud.

The rise of Scotland to its present position from the semi-barbarism of two centuries ago is due in great measure to the note issues of her banks and to the wisdom with which they have been employed, and affords one of the most striking examples extant of a well-managed system of credit, forming, in the hands of an industrious people, the means of transition from poverty to wealth, and of laying the foundations of a lasting prosperity.

The forms in which deposit business is carried on in this country are three in number—deposit accounts and deposit receipts (bearing interest), and current accounts, on which no interest is allowed.

Current Accounts. If any person desire to deposit with a banker a sum of money which he wishes to be able to withdraw when he pleases, he will seek an interview with the latter on the subject. The banker, if the applicant is not already known to him as a person of respectability and integrity, will require some recommendation from a mutual acquaintance (this usually taking the form of a letter of introduction) in order that he may assure himself that the individual to whom he proposes to give the power of drawing upon him is not one who is likely to misuse such a privilege, and indirectly involve the bank's name in some disreputable transaction. A form may be signed by the customer agreeing to certain conditions, one of which may be that a minimum balance of a certain amount must at all times be kept. He will, in every case, fill up a slip showing the particulars of the sum paid in, and be given a cheque book (paying for the value of the penny stamps on the forms therein), and very probably a passbook, in which the sums received and the cheques paid are entered. The client may, however, prefer to have a statement of his account rendered to him periodically, and may take for each sum paid in an initialled duplicate paid-in slip or other receipt.

Should the client desire to remit an amount due by him to some correspondent, he can now, in place of obtaining a money order or bank draft, fill up a cheque form, converting it into an order on his banker for a certain amount, and remit it without further trouble to his creditor. The trouble and risk of paying in cash to his local creditors is also obviated by the use of his cheque book.

Deposit Accounts. If, however, the client is not in trade, and has few payments to make, he can have but little use for a current account, while he may have a large sum for which, at the moment, he cannot find use, and on which he desires to receive interest. In this case the amount will be placed in the deposit ledger and will bear a rate of interest varying with the Bank of England discount rate. A receipt may or may not be issued to the client at the same time.

The bank may, however, on receiving such deposits, grant receipts payable on demand, or at short notice, but keep no ledger account, the receipts being numbered consecutively, and their particulars being entered, when issued, in a register kept for the purpose. An index is attached in which the numbers of the outstanding receipts are shown under the heading of each client. On a deposit receipt being presented for payment, this register is consulted, the particulars agreed, the date of payment entered in the column provided, the interest calculated, any sum to be withdrawn paid, and a new receipt issued for the balance. Such a receipt is never reissued, even although it has only been presented for the addition of interest due. The receipts outstanding may periodically be transferred in brief form to another register, a distinguishing mark being put against the original entry and the receipt marked off, when paid, in the second register.

Deposit Receipts for Fixed Periods. The practice of banks limiting their operations to this country is to confine themselves to receiving deposits at call or at short notice; but banks employing funds in the Colonies, or in foreign countries, obtain a large amount of deposits for fixed periods—say, of six months, or one, two, or more years. This money (which may be obtained through special agents) bears a high and uniform rate of interest. Interest is usually paid half-yearly, or at the termination of the deposit, income tax being deducted by the paying bank from all such interest, and accounted for by it to the Inland Revenue authorities. It is important in connection with the issue of all deposit receipts to fill in the year of issue in a sufficient number of forms at the beginning of a new year, to prevent the possibility of any loss occurring through a receipt being dated a year prior to the actual date of issue.

Overdrafts and Ledger Loans. If a customer of a bank exhausts the balance standing to his credit in the bank books, he may, after ascertaining that the banker is agreeable to such a course, continue to draw cheques, the payment of which leaves him in debt to the bank, the amount due varying from day to day. He is thereupon said to have *overdrawn* his account.

Instead of doing so, he may arrange with the banker for the loan of a certain sum for a definite period (usually against security), the amount of which is transferred to his current account to be drawn against in the same manner as if the actual cash had been deposited. The period for which the loan is granted may vary greatly, but will hardly ever exceed a year, a long outstanding inoperative loan being the particular aversion of any good banker

The expiry of a loan provides an excellent opportunity for revising the conditions under which it is granted, or even of arranging for its repayment, to do which, in the case of a running overdraft, might be taken to imply, unless great tact be exercised, a want of confidence in the position of the client.

Bill Discounting. The discount of bills forms a third method of loan, possessing several distinct advantages. A banker can, if the bills in his case bear good names, count upon receiving their amounts at maturity without fail. A merchant, in accepting a bill, gives his undertaking to pay a specified sum on a certain day. He knows that he will be called upon to do so, and that any failure to honour his own may mean his commercial ruin. He therefore takes good care to provide for such liabilities, although he may regard the repayment of a loan with his banker very differently and, should the latter request this, look upon his action as an unwarranted affront, transferring, if he finds it possible, his custom to another institution. The facility of re-discount of bills with bill-brokers is largely exercised by certain banks, who are thereby easily enabled to raise whatever sum they may at the moment require. The discount of bills on London enables provincial banks to provide themselves with an ultimate means of replenishing their London accounts, while it must not be forgotten that banker's discount exceeds somewhat the true discount of any bill, and that in consequence the return to the banker is greater than appears at first sight.

Calculation of Interest and Discount. The banker's discount on a bill is readily arrived at, being simply the interest on the full amount for the days it has still to run. The calculation of interest on fixed loans is equally easy, but the reckoning of that on an overdrawn account is a more difficult matter. The balance at the end of a day's transactions (shillings and pence over 10s. being taken as £1) is multiplied by the number of days for which it is current, and the result (which gives the days for which £1 would require to be lent to earn an equivalent amount of interest) is entered in a column provided for the purpose. At each change of rate, or at each half-yearly balance, this column is cast and the interest calculated by means of tables. In the case of deposit accounts (where the transactions are few), the interest on each balance current for any time being may be calculated separately

The procedure detailed above cannot be adopted with deposit receipts bearing a varying rate of interest, for which another method is utilised. This is the valuation of the rate of interest due for each day in terms of a common basis of, say, 5 per cent.—a practice best explained by an actual instance.

In the book kept for the purpose the figure of 3630·2 may appear against December 31st, 1905. If the current rate is 2 per cent., the clerk will enter against January 1st, 1906, the figure 3630·6 (2 per cent. being ·4 of 5 per cent.), the interest on any receipt lodged on December 31st and paid on the following day being equal to ·4 of one day at 5 per cent. If on January 1st the rate is altered to 2½ per cent., the figure 3631·1 will be entered against January 2nd. A receipt dated 2nd February, presented for payment on July 30th, if the figures for these dates are 3661·2 and 3720·1 respectively, bears 58·9 days' interest at 5 per cent.

Remittance Business. A very considerable portion of the banker's profits is derived from the commission which he charges for the collection of documents on other towns, or for issuing, when requested, his draft on these places. The commission charged may vary greatly, and if the transactions between the two localities are limited, the means of transit few, and a balancing transaction hard to obtain, the charge made will be correspondingly high. An increase in the charge is in the nature of an insurance against the possibility of loss attending the banker's efforts to find someone with whom he can arrange a transaction to reimburse him or his correspondent.

Sometimes, however, the banker's charges include an insurance against possible loss through failure on the part of his client. He may be asked by a client to accept bills drawn upon him on account of the latter, and if he is satisfied with the business and the security offered in connection with it, he will do so on his commission being paid. Similarly, he may endorse bills for his customers, for a consideration. The object of his acceptance or endorsement is to allow of the bills being discounted or sold by the holders to the best advantage.

It is a very common custom for the clients of a country bank or branch to make their bills payable at the office of the bank's London office or correspondent, in order to facilitate their discount. These will be retired by the London office on receipt of advice from the country banker, a certain charge being made by the latter for the trouble given. A varying charge may be made either yearly or half-yearly on those current accounts which do not show a sufficient running balance to compensate the banker for the work attendant thereon.

Securities and Periodical Payments. The banker invariably undertakes the custody of any securities deposited with him by his clients free of charge, and will also attend to the collection (either with or without charge) of coupons attached to the relative bonds. Due care must be taken to register in diary form the dates on which these coupons fall due, in order that, some little time beforehand, they may be cut from the sheets and forwarded for collection or sale, as the case may be. If the coupons are payable in a foreign country, they will be sent to the London correspondent either for collection or sale (in the latter case the coupons being bought by some dealer in exchange as if they were bills); but those payable in this country will be remitted for collection to the place of payment. Income tax on all coupons is deducted and paid by the banks to Government, forms provided by the Inland Revenue authorities being, in the event of the client wishing to reclaim the amount, completed, signed, and handed to him.

The sale and purchase of securities may be attended to by the banker on behalf of clients who have securities deposited with him, either for safe custody or in security of loans. The business is a profitable one in consequence of the return commission allowed by the stockbroker.

The banker will also undertake to see to the payment of club subscriptions, insurance premiums, pensions and allowances, in accordance with instructions received from his clients. In this connection it is necessary to exercise great care lest any payment is made after the relative instructions have been cancelled. The card system can be advantageously used in connection with such payments. The particulars of the payment and of the authority are entered on the face of the card (the dates of the payments made being detailed on the back), and the cards sorted into a case or file in the order of payment. After the payment has been made, the card is replaced in accordance with the date of the next payment. The system provides at the same time a diary of future and a record of past payments, but requires the exercise of great care, as the accidental misplacement or destruction of a card is attended with serious consequences. [See BUSINESS MANAGEMENT.]

Opinions. The card system is widely adopted in connection with the record of opinions and reports on parties received, although a system of indexed books may be used. The convenience of alphabetical arrangement is very great, but the defects which are referred to above always hold good. While receiving opinions from others the banker will be called upon to give many. In furnishing written reports, he will be careful to use the form provided, which states that the information given is without responsibility. Some banks make, in addition, a practice of supplying such information on unsigned memorandums. The usual form of inquiry asks if the individual is of good standing and respectability, and if he may be considered good for a stated amount, either in the ordinary course of business, as a guarantor, or so forth, according to the nature of the transaction. The banker in his reply will, as far as possible, confine himself to stating whether or not, in his opinion, the name is good for the amount mentioned. He will not, except for a good reason, volunteer any data, while a negative reply should be worded with special care, as, if it can be shown that his client's credit has suffered thereby, he may be liable for damages. Whenever possible the opinion will be given verbally.

Correspondence. The rule regarding the wording of an unfavourable report applies with equal force to correspondence which deals with the refusal of business or similar transactions. The banker will refrain from explanation of the reasons for his decision, which, if unfavourable, should be simply conveyed in a polite expression of regret. In general, the banker will confine himself strictly to the subject-matter of correspondence, and leave any question of policy which does not affect his interests to the decision of his client. No gratuitous responsibility should be undertaken in the matter of giving advice, especially with regard to the buying and selling of securities. If, however, the banker for any reason gives his opinion, he will invariably advise the adoption of the safest course. The foregoing applies with equal force to verbal communications.

Miscellaneous Functions. An important function is the issue by the banker of Bank Credits without recourse, Travellers' Letters of Credit and Circular Notes. The first are issued by the banker on account of his clients (who give what security is deemed requisite) in favour of the merchants with whom these clients deal, or perhaps the bankers of these merchants. The bank issuing the credit undertakes that if the stipulated conditions are adhered to it will accept and pay the relative bills. In this manner the purchaser is enabled to obtain an extended credit, while the seller receives a cash settlement of his debt. The banker is not entitled to cancel any such credit once issued, except with the agreement of the party in whose favour it is drawn. If, for a very particular reason, the banker does cancel any such credit, a sufficient indemnity to cover possible damages will be obtained. Travellers' Letters of Credit, which bear the signature of the individual in whose favour they are drawn, operate as an authority to the correspondents named therein to cash to the person designated his drafts on the issuing bank for the sum mentioned, the amounts so paid being marked on the back of the credit by the paying bank. If, however, the client desires it, he can obtain a supply of Circular Notes (practically credits for £10 and similar amounts), which will be cashed by the correspondents on his endorsing them, provided he produces a Letter of Indication, giving his signature, and containing the names of the paying correspondents

The payments of dividends, coupons, etc., may be undertaken with or without charge (the documents being, perhaps, checked off against lists furnished by the company in question), the bank on occasion dealing with the receipt of application money, calls in connection with company promotions, and the return of any sums not accepted. The clerical labour involved in addressing envelopes, filling up forms, etc., in the case of a large and successful issue is very great indeed, but the work is more monotonous than intricate.

Shares and Similar Securities. All banking business is contrived with a view to the exclusion of any element of speculation, a point that exercises an important effect on the securities which will be accepted in cover of a banking advance. The more easily realisable the security is at all times, the fewer the responsibilities attached and the less risk there is of depreciation, the greater the attraction it will have in the eyes of a bank. Share certificates, with a transfer form attached, either completed in every respect or bearing only the signature of the shareholder, are largely taken; but, for various reasons, registration of the shares into the names of the bank's nominees (usually two of its principal officers) is preferable. Securities which do not possess a market quotation or which bear an uncalled liability are not taken. Bearer bonds of a good class become an excellent banking security on a pledge form being signed. The bank's own shares may form the cover for an advance to one of its shareholders.

Bills lodged for collection bearing good names, or assignations of insurance policies (although the amount of the surrender value may be small and the present value of security therefore not of great amount), are also acceptable, while documents of title relating to merchandise are largely dealt with in certain localities. In these, however, the element of depreciation may be very great, and, in addition, the banker must be thoroughly assured of the good faith of his client, so largely is he dependent on the honesty of the latter's declarations as to the quality of the goods, and sometimes even as to their quantity. The banker will, in connection with such securities, see that insurance is taken out and renewed. The actual ownership of land, houses, and ships is not desirable as security, in consequence of the multifarious liabilities and responsibilities attached to these; and a mortgage bond, or similar document over the property in question will, instead, be made out, giving the bank full power over the property but protecting it from any trouble in the matter. Even in this form, however, the security is not looked upon with great favour, owing to the possibility of an ultimate sale proving difficult.

Personal Securities. The simplest form for personal security is that of a promissory note signed by the debtor and the guarantor, coupled with a letter stating that it is to be held in security of a certain debt. The object of the letter is to connect the debt and the security, rendering the granters of the note only liable for the actual amount of the loan. The note, being made payable one day after date remains operative for six years, when the special prescription applying to bills terminates the obligation.

Guarantees form a more formal and complex form of personal security. Each bank will possess a stock of forms suited for its varying business, while the exact terms used by the different institutions vary somewhat in their wording. The form chosen for any particular case must be carefully perused to see that it covers all possible contingencies in the proposed business.

If a time limit is inserted, and the guarantee is not renewed, or if a guarantee is terminated by notice being given by the guarantor, operations on the accounts must be stopped and no payments in reduction of the debt allowed, should it be decided not to release the guarantor. Any sums paid into such accounts will be held to liquidate the debt, while amounts paid out create a debt which is not covered by the guarantee—*i.e.*, if the guarantor of an overdraft for £4,500 terminates his guarantee, he is absolved from liability if, after he has done so, the banker allows the debtor to pay in amounts totalling £4,500, even although a similar sum is concurrently withdrawn. In the event of a loan covered by personal security being utilised to the full extent, interest is not debited to the account if the client is not considered good for the amount. A surety for £200 and interest may be liable for an amount of interest greatly exceeding the principal sum, provided it is shown in the bank's books in this category; but the moment it is added to the debt and becomes principal, his responsibility for it ceases, and he is only liable for £200, and any interest on this sum not applied.

Security Forms and Banking Law. The printed forms kept in stock will usually cover all the commoner methods of business, those relative to any special transactions being prepared either by the legal department of the bank or by its solicitors. The wording adopted may be altered from time to time in consequence of some legal decision, or of some question arising in the ordinary course of business. The documents may, according to individual practice, or the nature of the transaction, be either completed by the branch officials or by those at the Head Office.

The law connected with the business of banking comprises a fairly large section.

The Bills of Exchange Act is at once the largest and most essential part of Banking Law, but the ordinary legal knowledge (added to if possible) regarding trusts, agency, lien, securities, bankruptcy, debt, and common law should be possessed by the banker. It is not possible to deal with such a list here, and, indeed, such knowledge, although very desirable, is not absolutely essential, the procedure to be adopted in any particular case being usually laid down in some manner for the guidance of officials. It is only necessary to emphasise the point that the student should make himself, as far as possible, acquainted with the intention of each point of law, and, if possible, the history which led to its enactment.

In some institutions a book of regulations in which the duties of officials, the branch routine and returns, and the more essential points of banking law are dealt with more or less fully, is supplied to each branch. From time to time circulars are issued, which, although mainly referring to rates, official appointments, etc., also deal with any important matter which may have arisen, and with the contents of these, together with the book referred to, each official is expected to make himself familiar.

Documentary Bills. Bills of Exchange are known as *documentary bills* when documents of title to some security against which the bill is issued are attached to the draft; bills unaccompanied by such papers being termed "clean." They almost invariably take the form of invoices, bills of lading, and insurance policies for a shipment of goods, although a large amount of scrip bills (drafts with share certificates and signed transfers attached) are drawn. Certificates of Origin, or Consular Certificates, may be included in the shipping documents, if necessary, in consequence of the fiscal arrangements of the country exported to. On entering into such business, a *letter of hypothecation* is signed by the client, allowing the banker to deal with the goods relating to any bill as he may deem desirable. In the ordinary course of business, however, the banker will consult the wishes of his client before taking any steps in this direction, only exercising his right in some emergency—say, the bankruptcy of his customer. In addition to examining the bill itself the documents require scrutiny. The invoice amount should cover the bill, and the packages referred to in it appear on the bill of lading; while it is essential that the whole of the signed copies of the last, together with an insurance policy covering the amount in question, be received. The possession by an unscrupulous individual of a copy of the bill of lading may, through his obtaining delivery of the goods, deprive the banker of his security, while the same result will be arrived at through the loss of a shipment not covered by insurance. If the goods remain in the hands of the receiving banker for any length of time he will require to see that they are properly warehoused and covered by fire insurance from the date the marine insurance expires to the payment of the bill.

Documentary bills are either 'D A" or "D P" drafts. In the former case the drawee obtains, on accepting the bill, the documents attached, but in the latter he must take up the draft under rebate (pay the bill amount less an allowance) if he desires the documents in order to obtain the goods. As the rebate allowed is small, there is little object in rebating a "D/A," or "clean" bill, if any other use can be found for the money.

Head Office Work. The work at the head office, which is distinct from the ordinary branch business, divides itself into several sections. Auditing the branch returns dealing with the book entries will occupy the attention of a large staff, whose duties in some respects are hardly agreeable. The comparison weekly of thousands of entries between, perhaps, a hundred or more branches, with the certain knowledge that to pass an error means the repetition of the monotonous task, is not a fascinating prospect. In this department the weekly statements combining the branch returns will be made up. The returns, apart from those just referred to, will probably be dealt with by what is usually termed the Inspection Department. In addition to the supervision and record of the loan business at the branches, the work in connection with the bank's staff and their movements will be undertaken here, while periodically one or more officials will be despatched from this department to some branch to check the cash and securities on hand, agree with the books the balances of the various accounts, test the accuracy of the bookkeeping in various ways, judge of the fitness of the branch staff and of the suitability of the branch premises, and look thoroughly into all sums lent by the branch. The stationery supply will call for the attention of one or more officials, while the legal department has already been referred to.

ELECTRICAL ENGINEERS

Training in Workshops and in Technical Schools. Mechanical Basis of Engineering. Books on Electrical Engineering

By Professor SILVANUS P. THOMPSON

LIKE every other branch of engineering, electrical engineering, whether viewed as an industry or as a profession, requires of those who would follow it with success a double preparation. For, since its whole existence lies in the application of science to industry, success in its pursuit depends on the mastery both of the science which lies at the bottom of it all and of the practical methods in which that science is applied.

Practical and Theoretical Aspects. The common way of expressing the two aspects of the subject by dividing them into theoretical and practical is not a very adequate classification, because a great part of that which is truly theoretical is to be mastered only by practical studies in the laboratory or in the testing-room, while much of the practical part of engineering, whether electrical or mechanical, is to be mastered not at the bench or the forge, but in the drawing office. Neither is it adequate to divide the training of the electrical engineer into technical and commercial, though both enter into that training, for part of the training of an engineer is to teach him how to reckon out the cost of production, and this is a highly technical study, though it sounds commercial enough.

But if it is not easy to define in terms the two divisions or aspects of the training, all authorities are agreed on the necessity of a double training, without which the making of an engineer of any kind is incomplete.

A Mechanical Basis. Electrical engineering has much in common with mechanical engineering. Indeed, it has been said—though perhaps it is slightly overstated—that nine-tenths of the work of the electrical engineer is mechanical engineering, and only one-tenth electrical. But it is quite certain that a mere study of electricity will never make a man into an electrical engineer. It may make him into an electrician, and good electricians are always needed in the world, though the field for them is more limited. So far as constructive electrical work is concerned, a thorough engineering basis is required. For, in truth, the factory work of the constructive electrical engineer is very much the same as that of the mechanical engineer. Suppose that he has to construct dynamos or electric motors. The machines must first be designed, and all the necessary drawings worked out in the drawing office. Some of these drawings then go to the pattern-shop, in order that the wooden patterns may be made for the frames, bedplates, and other parts that are to be cast. When the patterns are completed, they must go to the foundry to be moulded, and the castings made in cast iron, cast steel, or brass. Other drawings go to the forge in order that the necessary forgings may be produced. When the forgings and castings are ready, they go to the machine shops to be machined, turned, bored, milled, chipped, or filed by the machinists, turners, and fitters. Other parts have to be stamped out. Bolts, screws, keys, nuts, and rivets must be made to hold the parts together. Then the parts must be assembled by fitters, and the machines erected and tested. So far all these processes are just the same as are necessary in constructing steam engines, sewing machines, or pumps. It is purely mechanical engineering. But there are also electrical parts to be made. The magnet bobbins have to be wound with copper wire coils. The armature windings must be made and properly insulated. Commutators have to be built of copper and mica and mounted in appropriate shells. For this part a knowledge of electrical conduction and of insulation is necessary. But it is clear that a majority of the constructional processes are mechanical. One might say the same about the manufacture of arc lamps, of switch gear, of telegraph instruments, and, indeed, of all electric instruments and appliances.

The Double Training. The two essential parts of the necessary training are distinguished according as they are to be acquired:

(1) In the shops or factory;
(2) In the technical school or college.

Neither the factory alone nor the technical school alone can afford a complete training for the engineer, whether mechanical or electrical. The youth who is trained only in the technical school or college is not in general fitted to become anything better than an engineer's clerk or a testing assistant. He lacks the knowledge of practical construction. The youth who is trained only in the shops or factory is not likely to rise above the grade of a fitter or a draughtsman; he lacks the grasp of principles, and has not been trained to exact calculation. In these days of competition the engineer must be trained to think, and not merely to think, but to think in terms of exact and calculable quantities. He must be taught systematically how engineering thinking is done, how formulæ enter into calculations and estimates, and how the formulæ themselves are founded on scientific principles, and how they have to be modified to meet special cases. Mathematics is the art of thinking in exact quantities, and of managing the symbols by which such quantities are represented. Hence mathematics is an absolute essential to all real engineers. Electrical engineers require additional mathematical formulæ to enable them to work out electrical problems.

But engineers must also be trained to work, and to work with precision; they must learn to work in wood, and iron, and steel, and brass. This training they can acquire only by working. Otherwise they will not really know how engineering work is executed. All mechanical engineers ought also to know how engineering work is designed, and how it is tested; and for this purpose they need to be trained in the testing laboratory, where they learn about the strength of materials, and in the laboratory of applied mechanics, where they learn by systematic experiment the application of abstract rules to actual mechanism. Further, electrical engineers must learn in the electrical laboratory, by experimenting with their own hands, the measurement of electrical quantities, the testing of the electrical properties of materials, and the performance of electrical machinery.

Which Kind of Training First? The question most often asked by parents and guardians of the youth who wants to become an engineer is this: Should he go to the works before he attends the technical college, or should he go to the technical college before he enters the engineering works? To this question there is no one answer; the answer must depend on the temperament of the youth, and on the circumstances of the case. There are always plenty of exceptions to any rule. But for the boy of average abilities and ordinary circumstances, the course which experience has shown to be best, in the opinion of those able to judge, has been very clearly laid down by unmistakable authority.

The Educational Report. In April, 1906, there was issued a report by a committee of experts representing the Institutions of Civil, Mechanical and Electrical Engineers, presided over by Sir William White. After taking evidence of over 260 leading engineers and teachers of engineering they agree with very considerable unanimity in the following conclusions:

1. The average boy should leave school at about 17 years of age—much depends on individual development—but should not be under 16 nor over 18.

2. If possible a preliminary stage of practical training in the mechanical engineering shops, of about one year, should precede college training. In some cases this introductory workshop course might be taken after the first year at college.

3. From the first, during workshop training, the youths should be paid regular wages, and keep regular working hours.

4. Evening study might impose too severe a strain on health. Therefore, since it is most important that school studies, particularly mathematics, should not be too soon forgotten, the introductory workshop course should not exceed one year; but in exceptional cases where a practical training of three years or so precedes a college course there must be some systematic tuition, in evening classes or otherwise, to prevent studies from being forgotten.

5. The period of college training for the average boy should be three years. Of the replies received, 73 per cent. say two or three years, while 71 per cent. say three or four years.

6. A sound and extensive knowledge of mathematics is necessary. This, of course, implies that the colleges should require the youths to pass an entrance examination to show that they have at least as much mathematical training as is required, say, in the Matriculation Examination of the London University. Engineers need training in trigonometry, solid geometry, differential and integral calculus. It may be noted that in Germany students are not even admitted to the Polytechnics who cannot begin the calculus.

7. The committee recommend strongly efficient instruction in engineering drawing.

8. After the college training, the youths should have at least three more years of practical training in the shops, part of this being in the drawing office, and the wages paid them after leaving college should be somewhat higher, especially in the later years.

No Premiums. The report of the committee gives no sanction to the pernicious practice of requiring premiums. Premiums are never paid in America or in Germany; in England the survival of the premium system is a curse to the industry

The committee is silent as to the proper organisation of the training in factories, where unfortunately the foremen are often violently prejudiced against teaching the young hands anything, and are not paid to teach them. This is a weak spot in the training of engineers.

Other Plans. In Glasgow and Edinburgh the plan is adopted of teaching the youths in the college during the six winter months, and of drafting them into the factories during the six summer months. In Sunderland the engineering employers have agreed to a similar plan; but in most parts of England the employers do not fall in with this plan.

For the training of engineering workmen, including electrical workmen, the old plan of apprenticeship still exists, boys leaving school at 14 years of age and working in the factories with small wages until 20 or 21. For such youths, the training afforded in evening classes is of service; but few can, without detriment to health, give more than two nights a week, and the training can, therefore, never be thorough.

Posts as switchboard attendants in electric lighting stations do not afford much scope for real training.

There is a small demand for specially trained electro-chemists; and for all electricians a knowledge of elementary chemistry, such as may be acquired in the laboratory of any of the technical schools, is most useful.

Degrees in engineering are a luxury. Few engineering firms attach the slightest importance to them; the training at a first-rate technical school is esteemed far more than a university degree. For those who want to become teachers of engineering, university degrees are, however, of great value in seeking an appointment.

THE BEST BOOKS ON ELECTRICAL ENGINEERING

There will always be a number of earnest young engineers who have not the opportunity of taking out a college course. Also those who have been trained in a technical college will always want to know what are the best sources of information in the different branches of the subject. So wide a subject as electrical engineering cannot possibly be contained in any one-textbook. In fact, the young engineer cannot be expected to buy all the books to which he should refer, and with which he should be familiar. Books of reference, to be consulted in the public libraries or in the libraries of the technical institutes, are to be recommended rather than textbooks which pretend to serve up the whole subject in one volume. For the sake of those who desire further guidance in such reading a list of standard works is here appended. It is confined to books in the English language, and therefore does not include some of the very best and most useful of treatises, which are printed in German.

Electrical Laboratory Work. "Practical Electricity," by Ayrton (Cassell, 7s. 6d.); "Electrical Laboratory Notes and Forms," by Fleming ("Electrician," 7s. 6d.); "Handbook of Electric Testing," by Kempe (Spon, 18s.); "Practical Measurement of Electrical Resistance," by Price (Clarendon Press, 14s.).

Batteries. "Primary Batteries, Their Construction and Use," by Cooper ("Electrician," 10s. 6d.).

Accumulators. "Secondary Batteries, Their Manufacture and Use," by Wade ("Electrician," 10s. 6d.); "Management of Accumulators," by Sir D. Salomons (Whittaker, 5s.).

Arc Lamps. "Electric Lamps and Electric Lighting," by Fleming ("Electrician," 6s.); "The Electric Arc," by Mrs. Ayrton ("Electrician," 12s. 6d.); "Electric Lighting," by Swinton (Lockwood, 1s. 6d.).

Glow Lamps. "Electric Lamps and Electric Lighting," by Fleming ("Electrician," 6s.); "The Incandescent Lamp and its Manufacture," by Ram ("Electrician," 7s. 6d.).

Dynamos and Motors. "Armature Windings," by Parshall and Hobart (Blackwell, 30s.); "Dynamo-electric Machinery," 2 vols., by S. P. Thompson (Spon, 30s. per vol.); "Dynamo Design," by Hobart (Whittaker, 7s. 6d.); "Dynamo Attendants and their Dynamos," by Broadbent (Rentell, 1s. 6d.); "Diseases of Electric Machinery," by Schultz (Spon, 3s. 6d.); "The Dynamo," by Hawkins and Wallis (Whittaker, 15s.); "Electric Generators," by Parshall and Hobart ("Engineering," 31s. 6d.); "Original Papers on Dynamo Machinery," by Hopkinson (Whittaker, 5s.).

Magnetism. "Magnetic Induction in Iron and Other Metals," by Ewing ("Electrician," 10s. 6d.); "The Electromagnet and Electromagnetic Mechanism," by S. P. Thompson (Spon, 15s.).

Wireless Telegraphy. "Signalling Across Space Without Wires," by Sir Oliver Lodge ("Electrician," 5s.); "Electric Wave Telegraphy," by Fleming (Longmans, 24s.).

Electric House Wiring. "Electric Wiring Tables," by Maycock (Whittaker, 3s. 6d.); "Electric Wiring," by Clinton (J. Murray, 1s. 6d.); "Electric Wiring and Fitting," by Drysdale (R. J. Bush, 3s.); "Practical Electric Light Fitting," by Allsop (Whittaker, 5s.).

Electro-chemistry. "Elements of Electrochemistry," by Lüpke (Grevel, 7s. 6d.); "Treatise on Electro-metallurgy," by McMillan (Griffin, 10s. 6d.); "The Electric Furnace," by Moissan (Arnold, 10s. 6d.); "Electric Furnaces and their Industrial Application," by Wright (McGraw, New York, $3).

General Electricity. "The Electrician Primers," 3 vols. ("Electrician," vol. 1, 3s. 6d.; vol. 2, 6s.; vol. 3, 4s. 6d.); "The Electric Current," by Walmsley (Cassell, 10s. 6d.); "Elementary Lessons in Electricity and Magnetism," by S. P. Thompson (Macmillan, 4s. 6d.); "Experimental Researches in Electricity," 3 vols., by Faraday (Quaritch, 48s.).

Photometry. "Industrial Photometry," by Palaz (Sampson Low, 12s. 6d.); "The Art of Illumination," by Bell (Constable, 10s. 6d.).

Tramway Motors and Traction. "Modern Electric Railway Motors," by Hanchett (Street Railway Publishing Co., New York, $2); "Electric Traction," by Rider (Whittaker, 10s. 6d.); "Electric Street Railways," by Houston and Kennelly ("Electrical World," New York, $1).

Electric Railways. "Electric Railways and Tramways," by Dawson ("Engineering," 42s.).

Alternating Currents. "Alternate Current Working," by Hay (Biggs, 5s.); "Notes on Alternate Currents," by Simmons (Cassell, 1s.); "Alternating Currents of Electricity," by Still (Whittaker, 5s.); "Alternating Currents of Electricity," by Lamb (Arnold. 10s. 6d.).

Transformers. "Transformers for Single and Multiphase Currents," by Kapp (Whittaker, 6s.); "The Alternate Current Transformer," 2 vols., by Fleming ("Electrician," 12s. 6d. per vol.).

Polyphase Currents. "Polyphase Electric Currents," by S. P. Thompson (Spon, 21s.); "Polyphase Currents," by Still (Whittaker, 6s.).

Central Electric Stations. "Central Electric Stations," by Wordingham (Griffin, 24s.); "Central Station Electricity Supply," by Gay and Yeaman (Whittaker, 10s. 6d.).

Electroplating and Electrotyping, etc. "Electro-deposition of Metals," by Langbein (Baird, Philadelphia, $4); "Electro-metallurgy Practically Treated," by Watt (Lockwood, 4s.).

Electric Instruments, etc. "Induction Coil in Practical Work," by Wright (Macmillan, 4s.); "The Potentiometer," by Fisher ("Electrician," 6s.); "Electrical Influence Machines," by J. Gray (Whittaker, 5s.).

Electric Bells. "Electric Bell Construction," by Allsop (Spon, 3s. 6d.).

Electrical Theory. "Absolute Measurements in Electricity and Magnetism," by Gray (Macmillan, 5s. 6d.); "Treatise on Electricity and Magnetism," 2 vols., by Maxwell (Clarendon Press, 32s.); "Recent Researches in Electricity and Magnetism," by J. J. Thomson (Clarendon Press, 18s. 6d.); "Elements of the Mathematical Theory of Electricity and Magnetism," by J. J. Thomson (Cambridge Press, 10s.), and "Conductivity of Electricity through Gases," by J. J. Thomson (Cambridge Press, 16s.); "Electromagnetic Theory," 2 vols., by Heaviside ("Electrician," 12s. 6d. per vol.); "Electric Waves," by Hertz (Macmillan, 10s.); "Theoretical Elements of Electrical Engineering," by Steinmetz (Whittaker, 12s. 6d.); "The Electronic Theory of Electricity," by Fleming ("Electrician," 1s. 6d.).

Electric Transmission of Power. "Electric Transmission of Energy," by Kapp (Whittaker, 10s. 6d.); "Electric Power Transmission," by Bell (Whittaker, 15s.).

Electricity Meters. "Electricity Meters," by Solomon (Griffin, 16s.); "Electricity Meters," by Gherhardi ("Electrician," 9s.); "American Meter Practice," by Reed (Spon, 8s. 6d.).

HISTORY OF ART
continued from page 4190

By P. G. KONODY

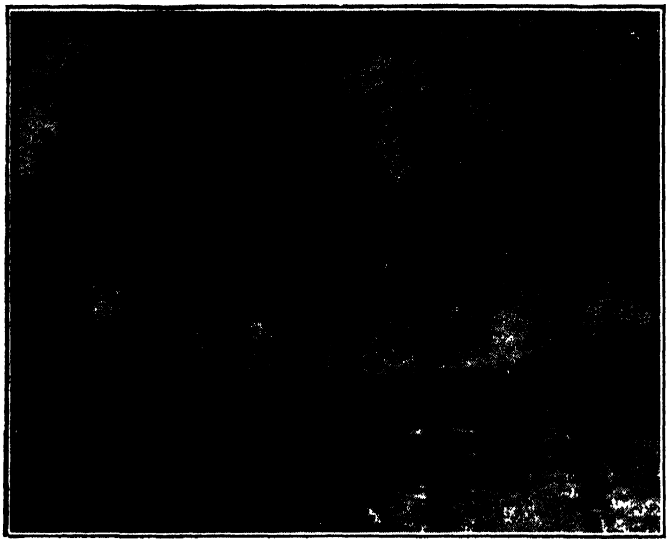
Of all the arts, that of landscape painting is the most modern. It belongs, more than any other, to our own time, though its beginnings can be traced back to the days when Giotto delivered the art of painting from Byzantine formalism, which had no eyes for the beauties of Nature. Indeed, the replacing of the flat gold backgrounds of Byzantine art by the naïve landscape setting of Giotto and his followers is the first link in that long chain of evolution which leads to the discovery of atmosphere and sunlight by Constable, Turner, and the Impressionists. The Giottesques, and all the Italians, even Perugino and Raphael, and in the North the Van Eycks, Memlinc, and all the other Primitives, never painted landscape for its own sake. In their pictures it is always entirely subordinate to the figures, and used either to fill an empty space in a pleasing manner or to enhance and accentuate the sentiment expressed by the figures.

The First Painter of Landscape. Landscape, painted for sheer love of Nature, and for its own sake, did not appear before the seventeenth century, though a near approach to it was made by the Venetians Giorgione and Titian, and in the North, at an even earlier period, by J. Patinir (A.D. 1490–1550). The beautiful scenes from the Cadore country, which form the background of many of Titian's pictures, speak at least of his love for the picturesque district in which he was born and had passed his childhood, and there is at the Pitti Palace at least one drawing from his pen in which the fine scene in the Cadore is rendered for its own sake, without the addition of figures. Patinir took an obvious delight in the careful objective rendering of landscape, to which the figures that enact the scenes of sacred history are mere accessories ; but his view, like that of "Velvet" Breughel (A.D. 1569–1625), who devoted himself to fantastic scenes of Paradise, with minutely executed flowers and animals, was purely objective—that is to say, impersonal and unemotional, and his colour limited to a conventional scheme.

The Classical Landscape. Nicolas Poussin, Rubens, and Claude Lorrain were the first real landscape painters, though one of them, Rubens, touched upon landscape only passingly, to show, as it were, that his genius could cope with every problem that came within the painter's field. The few landscapes he has left us have the same verve and vigorous, swinging brushwork as his figure subjects and great compositions, and range from the heroic and dramatic to the simple and rural. Nicolas Poussin had grown up in the classic atmosphere, and was steeped in the study of the antique and the Italian masters. At the same time he was a close observer of tree and cloud forms, the mastery of which enabled him to rearrange and combine them into formal compositions of arcadian scenes, in which figures and setting were at least co-ordinate in importance. He never rose above a convention which was the very negation of naturalism, and used Nature only as a source whence he drew the motifs for his pictorial inventions. His colour was as cold and formal as his design. He was the father of the classical or heroic landscape.

The Discoverer of Sunlight. With Claude Lorrain (A.D. 1600–1682) figures ceased to be of any importance, and sunlight with its varying effects first became the real subject of the picture. though even Lorrain did not consider Nature unadorned to be worthy of pictorial representation, and continued, like his precursors Nicolas and Gaspard Poussin, to weave its details into well-ordered combinations, from which classic ruins, temples, and columns were never allowed to be absent (86). But with him trees and clouds and winding rivers ceased to be mere forms conventionally coloured. He noted the play of light and shade on these objects, and expressed in masterly fashion the different times of the day—the glow of sunset and the restful coolness of early morning. About two centuries later, his noble compositions were to become the starting-point for the greatest master of modern landscape—for Turner. Equally subjective in his view of Nature was Lorrain's Italian contemporary, Salvator Rosa, who depicted the romantic and turbulent aspect of landscape in the rugged ravines and wind-tossed trees that form the background for his scenes of strife.

Dutch Temperament. It was left to the seventeenth century Dutchmen, Ruysdael, Hobbema, and Cuyp, to establish the claims of landscape as a genre independent of figure painting. Whilst Ruysdael, in following the successful Allaert von Everdingen, sought for the picturesque in Nature, and found it in the wild rocks and seething mountain streams and waterfalls of a country he probably knew only through the work of his popular contemporary, Hobbema was the sympathetic painter of his own country, which he rendered with intimate simplicity, setting down things as he found them, in all their quiet homeliness. But neither Ruysdael, nor Hobbema, nor even the great Rembrandt, who brought the whole passionate intensity of his temperament into his landscapes, could realise entirely the colour of Nature and free their palette of the browns demanded by a time-honoured convention for the painting of



85. THE POND, BY COROT (Louvre, Paris) *Mansell*

foliage. Like all Dutch landscape painters, Ruysdael and Hobbema excelled in the rendering of cloudy skies, and the latter in the subtle characterisation of varied foliage. Cuyp (A.D. 1606–1672) and Paul Potter (A.D. 1625–1654) remain unequalled to this day as painters of cattle, and must be mentioned here, because both of them, and particularly the former, conceived the animals as part and parcel of the landscape in which they live and which they help to complete.

The Dutch Seascape Painters. Finally, there are the seascape painters, Van de Capelle, Simon de Vlieger, and Van de Velde, all of whom appear more interested in the nautical life of the invariably quiet waters than in the moods of the elements by which the modern painter of the sea is generally fascinated. The real subject of the early Dutch marine painters is thus not the sea, but the varied forms of shipping—fishing fleets, sea-fights, the embarking or landing of an army, sailing craft of every description—in short, the life of the sea, The Frenchman Joseph Vernet (A.D. 1714–1789), though, on the whole, still adhering to the idealistic and classicist tradition, was attracted by the stormy, turbulent aspect of the sea, but there is no terror and passion in his storms. The discovery of the moods of Nature was left to the more nervous modern temperaments.

Watteau. Before we turn to England we must mention Watteau, who, in his perfect balance of figures and landscape, in his rendering of soft atmospheric effects, came very near the modern spirit. The curious point about his art is that he gave a convincing air of reality to scenes which only had existence in his own imagination.

Richard Wilson. Landscape painting in England, in the early part of the eighteenth century, followed two directions, one of which aimed at dry, topographic correctness, and is best represented by Samuel Scott, a talented imitator of Canaletto, the other at Italianised classicism. Of this direction, Richard Wilson (A.D. 1713–1782) is the chief disciple. At his best Wilson is a worthy rival of Claude Lorrain, whose intentions and ideals he had made his own Thomas Gainsborough is a kind of halfway house between the old style and the new vision which was to be introduced by Constable. His colouring, based on a pleasing scheme of brown, grey, and gold, is still arbitrary and conventional, but his scenes are no longer composed according to established rules. His are in more intimate communion with Nature; he is attracted by the peaceful charm of the English countryside, which needs no classic ruins for its appeal. At the same time his landscapes have still a trace of the artificiality of the period, and lack that fragrance of the soil which breathes from Constable's canvases.

The Norwich School. An important school flourished towards the end of the eighteenth century at Norwich under the leadership of John Crome, better known as "Old Crome" (A.D. 1769-1821), who has, not without good reason, been called the English Ruysdael. He and his

(National Gallery, London)

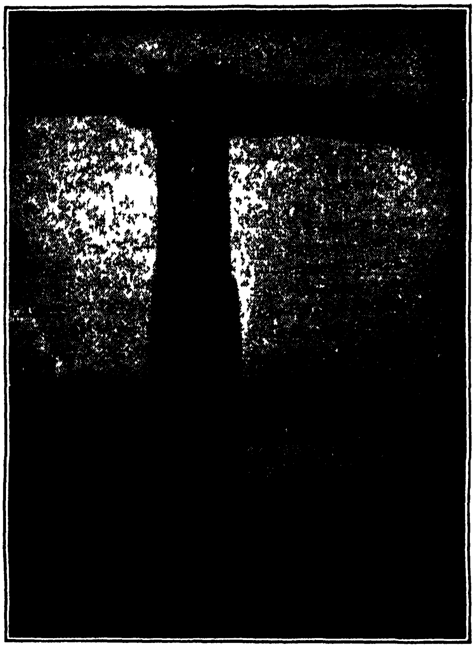
followers, among whom Ladbroke, Stark, and Vincent are the most important, show strong kinship with the Dutch landscape school. The same influence can be noticed in the seascapes of John Cotman, another prominent member of the Norwich school. All these painters went to Nature for their subjects, but to the old masters for their colouring. It was the mission of John Constable (A.D. 1776–1837) to discover the juicy green of meadow and wood, the movement of the foliage in the gentle breeze, and the groaning of the heavy bough in the storm. With him the tree ceased to be mere form—he covered the stem with trembling and sparkling foliage; and the sky was no longer a mere grey background, but a dome of atmosphere spanned over fields and gardens and woods. Constable's instinct for balancing the masses of light and shade, and the "full" and "empty" spaces, was such that he could set aside all the hard and fast rules of academic composition. His ardent love of Nature and of the English countryside is expressed in all his work [87]. French artists and critics immediately recognised that he had opened a new page in the book of art, and hailed in him a master worthy of emulation.

The Barbizon School. Perhaps it was Constable's love of Nature, simple, and devoid of all artificiality, that, about 1830, induced a group of French artists to declare war upon the generally prevailing classicism, and to settle down in the little village of Barbizon, in the Forest of Fontainebleau, in order to live in close communion with Nature, and to prove to the world that in landscape the picturesqueness of the subject counts for nothing, that a landscape need be neither classical, nor heroic, nor romantic, as long as the artist can grasp the spirit and the poetry of Nature, and express in paint the emotions aroused in him by its contemplation. "Truth is beauty, and beauty is truth" was the watchword of this group, whose leader was Theodore Rousseau (A.D. 1812–1867), Troyon, Dupré, Jacque, Daubigny, and Diaz being among the other prominent members; while Corot and Millet are so closely affiliated to the Barbizon school that they are generally counted as belonging to it. Corot strikes the most lyrical note of all painters. He is the poet of the twilight, dreamy and musical, and more occupied with the essence and fragrance of Nature than with solid matter [85]. Rousseau is far more impersonal, a searching student of form and structure, while Diaz connects the Barbizon men with the Romanticists. Troyon and Jacque are noted for their magnificent painting of cattle and sheep, and Millet is the painter of the life of the fields, the ceaseless toil of the peasant in his grim struggle with the soil that is to yield him the sustenance of life. [See "The Sower" and "The Gleaners" on page 342.]

88. DIDO BUILDING CARTHAGE, BY J. M. W. TURNER (National Gallery, London)

He is a notable instance of that new beauty (as opposed to the classic beauty) that is to be found in passionate truthfulness to Nature—the beauty of character expressed by synthetic simplification.

Turner and the Sun. Just as the aims of the Barbizon men had been foreshadowed by Constable, so Turner discovered and turned to account the theories that were to be systematised subsequently by the French Impressionists. In his early work he favoured the heroic landscape; but, in his power of rendering sunlight, he is already at this early period immeasurably ahead of Claude Lorrain, his artistic progenitor, as may be gathered from a comparison of Turner's "Dido Building Carthage" [88] and Claude's "Embarkation of the Queen of Sheba" [86], which are hung side by side at the National Gallery. But if Turner recognised the actual appearance of objects bathed in light and atmosphere, the softening of the outlines, the vibration of the light, he did not apply his knowledge to the service of realism, of landscape "portraiture," as practised later by Claude Monet. He was an exalted idealist, a visionary, who knew how to clothe the glorious inventions of his imagination in real golden sunlight. Characteristic of his attitude is the answer he gave to one who remarked that he had never seen such colours in Nature as appeared in one of his own pictures: "Don't you wish you could see them?" The turning point in the master's art was his visit to Italy, and particularly to Venice. The wonderful atmospheric effects of the lagoon city left an indelible impression on his mind. Henceforth the actual view, the *objects* of the landscape, became quite secondary. The transparency and vibration of the atmosphere, the glory of sunlight, became the real motif of his pictures.



89. BATTERSEA BRIDGE, BY WHISTLER *Mansell*
(National Gallery of British Art, London)

What Impressionism Is. What Turner had achieved, as it were, instinctively, through sheer force of his genius—that is, the analysis of light—was put into what might be called a scientific theory by the French Impressionists, who, in trying to render in paint the full glitter and brilliancy of open-air sunlight, turned to account the results of the scientific research of Helmholtz and Chevreul and the revelations of spectral analysis. The full explanation of the theory of the decomposition of light into its constituents of coloured rays belongs to the sphere of optics. Here it is sufficient to explain that the *technical* reform of Impressionism—for the term embraces other reforms as well—consists of the employment of the primary colours only, which are used in alternate touches and in the right quantities, so that at a certain distance they blend and produce the desired effects. Thus, it is well known that green consists of a mixture of blue and yellow. If, instead of being mixed on the palette, these colours are applied in alternate touches, the effect upon the eye will be a green tone, but a green of far more vibration and greater luminosity than mere green paint. The Impressionist theory has frequently been carried to absurd extremes; but, in the hands of a master like Claude Monet, has yielded results that could not have been achieved by any other method. Of him it may truly be said that light is the one and only subject of his pictures, and nobody has ever come nearer to perfect truth in depicting the glitter and sparkle of sunlight.

Japanese Influences. To-day every country can boast of a large number of landscape painters whose work will live through the ages, but nothing new has been added to the history of the development of landscape art since the advent of Impressionism. Perhaps the next move will be in the direction of a more complete acceptance of the Japanese ideal, which has already exercised a certain amount of influence, notably on the work of Whistler [89]. This Japanese ideal is the realisation by art of the universal soul or spirit which underlies the non-permanent, temporary, and therefore unreal forms of matter. The end is achieved by a very broad but exquisitely beautiful and decorative generalisation, which discards all that is not really essential to convey the idea intended by the artist. The attitude of the Japanese artist is pretty nearly reflected by Whistler's reply in a famous law case, when he was asked whether a picture of his produced in Court was a correct representation of Battersea Bridge—"I did not intend it to be a correct portrait of the bridge; as to what the picture represents, that depends upon who looks at it. To some persons it may represent all that was intended. To others it may represent nothing."

PROCESSES IN RECOVERING METALS

Lead Smelting and Cupellation. Methods of Recovering Silver. Refining Gold. Platinum, Nickel, and other Metals

Continued from page 4127

By A. H. HIORNS

Lead. Lead has been known from remote antiquity, and its use in purifying gold and silver by the process of cupellation is perhaps the oldest metallurgical operation on record. Lead has a bluish-grey colour, and considerable lustre when freshly cut, but this soon diminishes by superficial oxidation. It is very soft, and can easily be cut with a knife and readily marks paper. It is very malleable and ductile, but possesses very low tenacity. It emits a dull sound when struck, but the presence of impurities tends to make it more sonorous. Lead is readily deposited in the form of crystals from a solution of lead acetate by means of zinc, or by electricity. Its specific gravity is 11·37. It begins to fuse at 325° C., but is completely liquid at 335° C. It is a poor conductor of electricity and heat. It is without taste, and emits a certain odour when freshly cut. Lead exhibits in a marked degree the property of flowing when in a viscous state, and advantage is taken of this in the making of lead pipes by forcing the lead through cylinders by means of hydraulic pressure, termed *squirting*. Composition piping contains tin or antimony to harden it.

Lead unites in different proportions with oxygen, of which litharge (PbO) and red lead (Pb_3O_4) are the most important. The sulphide of lead (PbS) is also of great metallurgical importance.

Lead Smelting. The chief ores of lead are *galena* (PbS) and *cerusite* ($PbCO_3$). These ores, especially galena, generally contain silver. The smelting of galena in England and Wales is conducted in reverberatory furnaces. The ore is partially roasted, and then the oxide and sulphide are allowed to react on each other, forming metallic lead. The blast furnace [26] is also used for more complex and refractory ores. In this case it is customary to obtain lead containing silver, regulus often containing copper, and slags.

The lead obtained as above often requires refining. This is done in a reverberatory furnace by exposing the metal to the action of the air, which oxidises the impurities, and these form a dross with some lead oxide, which floats on top of the molten metal. From 30 to 150 tons are refined in one operation. When the lead contains silver it is specially treated for that metal by the *Pattinson* process. This consists of melting the argentiferous lead, allowing it to cool slowly, stirring the while, when the lead separates out in the form of crystals at its freezing point, leaving by far the greater portion of the silver in the liquid portion. Thus, lead containing 3 oz. of silver to the ton may be concentrated up to 800 oz. per ton, which is the practical limit. The process is conducted in a series of nine to fifteen cast-iron pots, each holding eight to fifteen tons. A modification of this method was introduced by Parkes, who added zinc to the argentiferous lead. The zinc separates out on cooling, and carries with it the silver and some lead. These zinc crusts are then submitted to liquation, by which means the lead runs off, carrying with it the silver.

Cupellation. The processes mentioned, therefore, are only concentration processes, and the silver must be separated by cupellation. An English cupellation furnace is a reverberatory furnace with a bed formed of bone ash. When the lead is melted in the oxidising atmosphere of the furnace the base metals are oxidised, while the silver remains unoxidised, and is thus free from all other ingredients, except gold, if that metal be present. Bone ash also has the power of absorbing molten oxides, but not molten silver.

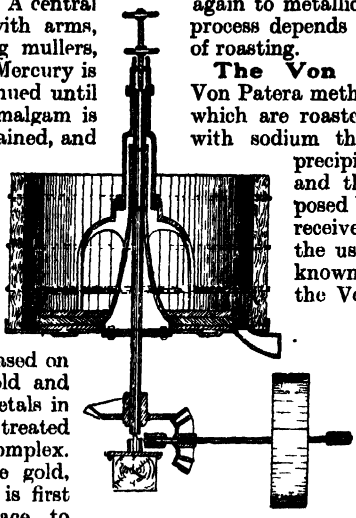
In the German cupellation method the reverberatory furnace is lined with marl, which is a carbonate of lime and magnesia and clay. The air is supplied by means of a pair of inclined twyers fixed in one side of the bed, and the molten oxide of lead flows off through an opening opposite the twyers. This only purifies the silver up to about 95 per cent., so that it is necessary to complete the refining on a bed of bone ash.

Silver. The properties that make silver so valuable are its pure white colour, its softness, sonorousness, extreme malleability, ductility, tenacity, and toughness. It exceeds all other metals in its conductivity for electricity. It melts at 960° C., and has a specific gravity of 10·53. It does not oxidise in air, although it mechanically absorbs oxygen when melted, and gives it out again on cooling. It readily unites with sulphur, forming a blue crystalline sulphide. With chlorine, bromine, and iodine it unites, forming important compounds. It is soluble in nitric and sulphuric acids.

The ores of silver are of two kinds—the silver ores proper, and silver in ores of base metals. Silver occurs as sulphide, chloride, bromide, and iodide, and in various mixed sulphides as well as in the metallic state.

The methods of extraction are (1) by means of mercury (amalgamation processes); (2) by means of lead (smelting processes); (3) by various wet methods.

Amalgamation. The amalgamation process was formerly carried on in the cold in heaps and pits, as it is at the present time in Mexico. The ore is first converted into chloride by means of a copper salt and common salt, then decomposed by mercury, with which it unites to form an amalgam. The mercury is afterwards driven off by heat, leaving the silver pure. The amalgamation method is now conducted by means of stamp batteries and amalgamating iron pans. The ore is crushed by stamps, water being admitted. The ore mud is transferred to settling pits, and then carried to the amalgamating pans. The pans are of various types, and consist of an iron box about 4 ft. in diameter and 2 ft. high [30]. A central cone supports a revolving shaft with arms, from which are suspended grinding mullers, which press the ore to a pulp. Mercury is then added, and the rotation continued until the silver is amalgamated. The amalgam is then removed, washed, dried, strained, and the mercury distilled off in retorts. In ores containing much base metal a preliminary roasting in a furnace is necessary, with the addition of common salt to form silver chloride. In this case the ore is dry crushed, and larger pans are used for amalgamating.



30. AMALGAMATING PAN FOR SILVER RECOVERY

Lead Methods of Recovering Silver. Lead methods are based on the reducing action of lead on gold and silver, with the solution of these metals in metallic lead. As complex ores are treated in this way, the products are also complex. The principal metals obtained are gold, silver, copper, and lead. The ore is first roasted in a reverberatory furnace to remove sulphur, arsenic, and other volatile substances, and then smelted in a blast furnace [26]. The charge consists of roasted ores, pyritic ores, various residues, and slags. The products may be lead (containing gold and silver), regulus (containing lead, copper, iron and sulphur) and slag. The last is either used again if it contain sufficient metal, or, if not, it is thrown away. The fume from the furnace is also condensed for the recovery of lead. The lead containing gold and silver is first submitted to the Pattinson process for concentration of silver, and afterwards cupelled for the recovery of gold and silver. The regulus is roasted, and added to another charge in the blast furnace to remove its contained silver and gold. The second regulus may be treated for copper. The gold and silver are separated by the parting process subsequently described.

Wet methods of extracting silver are based on the principle of converting compounds of silver into a soluble form, and then precipitating the silver by means of a base metal or a compound. The three principal methods employed are Augustin's, Ziervogel's, and Von Patera's.

The Augustin Process. The Augustin process is used for argentiferous regulus and residues, which are first roasted in air to remove sulphur, then with common salt, to form chloride. The next stage consists of lixiviating the roasted ore in wooden vats with a strong, hot solution of common salt, which dissolves the silver chloride. The solution is run off and the silver precipitated by means of copper.

The Ziervogel Process. The Ziervogel process consists of roasting sulphur compounds containing silver at a moderate temperature to form silver sulphate, which is soluble in water. The roasted mass is removed, cooled and lixiviated with water, and the silver precipitated by copper. If sufficient sulphur be not present, then pyrites are added. If the temperature be too low, then the sulphate is only partially formed · if too high, the silver sulphate is decomposed again to metallic silver. The success of the process depends on the proper temperature of roasting.

The Von Patera Process. The Von Patera method is used for chloride ores, which are roasted with salt, and lixiviated with sodium thio-sulphate. The silver is precipitated by sodium sulphide, and the silver sulphide decomposed by heat. This method has received extended application by the use of double thio-sulphates, known as the *Russell* process. In the Von Patera process, any lead sulphate that is present dissolves in the thio-sulphate solution, and is precipitated, along with the silver, as sulphide. In the Russell process the lead is precipitated by means of sodium carbonate. Moreover, it was found that by using a double thio-sulphate of sodium and copper, a more energetic decomposing and dissolving action on metallic silver, silver sulphide, and the combinations of silver with arsenic and antimony took place. Hence, if the roasted ore is first treated with sodium thiosulphate to dissolve the silver chloride, and the residues subsequently treated with copper thio-sulphate solution, much more silver is extracted than by the older (Von Patera) method.

Gold. Gold has a yellow colour, its lustre is proverbial, and it exceeds all other metals in malleability and ductility. Its tenacity is moderately high, but is diminished by the presence of lead, tin, antimony, and some other metals, while copper and silver increases it. Its specific gravity is 19·32, and its melting point 1060° C. Its conductivity stands next to that of silver and copper. It is not acted upon by the atmosphere, by hydrochloric, sulphuric, or nitric acids, or by sulphur compounds. It is soluble in chlorine, aqua-regia, and potassium cyanide.

It occurs in nature in the metallic state in quartz and pyrites, and is frequently found in lead, copper, silver, and other ores, in small quantities. It occurs in sands, in nuggets, and alloyed with platinum, silver, mercury, and certain rare metals. In alluvial deposits it is separated by processes which consist of removing lighter matters by running water, while gold, in virtue of its high specific gravity, is deposited.

Gold quartz is very hard and compact, and contains the gold in veins. The ore is first crushed by rock breakers, and then reduced to a fine powder by the stamp battery, the mortar of which is lined with amalgamated copper plates for taking up the gold. The residual matter is often treated in amalgamating pans. A stamp battery generally consists of five stamps working in one mortar, which is made of an iron casting about five feet long. The feed opening is on one side, and on the other is a fine screen of wire cloth through which the discharge takes place. The drop of the stamp varies from 4 to 18 in., with about 100 blows per minute. In front of the screen are inclined tables covered with amalgamated plates to catch the gold which has not been collected on the plates inside the mortar. The material escaping these plates is concentrated by some kind of shaking machine which separates the lighter from the heavier particles which contain some gold. These concentrates are amalgamated in iron grinding pans. The gold amalgam is retorted to volatise the mercury and retain the gold.

The Chlorine Process. The chlorine process of extracting gold consists of (1) roasting the ore to remove sulphur and base metals ; (2) moistening with water and passing a current of chlorine through it in a wooden vat, having a perforated bottom, which acts as a filter, and through which the gold solution percolates ; (3) running off the solution and precipitating the gold by iron sulphate or other suitable reagent. Ores and residues are usually concentrated before being submitted to the chlorination process. Compressed chlorine is also used and is very effective, but more expensive. The operation is conducted in revolving barrels lined with lead.

The cyanide process of extracting gold was introduced by McArthur and Forrest, in 1887. The ore is first crushed in rock breakers, then in rolls or stamp batteries, then placed in vats to which a 1 per cent solution of potassium cyanide is added, which dissolves the free gold The solution is then removed, and the gold precipitated by means of zinc.

Gold is extracted by smelting processes from rich copper regulus. The method is the same as explained for extracting copper by the Welsh method. The regulus is partially roasted, and then the oxide and sulphide react on each other, reducing the copper and gold, forming an alloy. The copper is deposited by the electrolytic method, when the gold is left, and is afterwards melted with lead and separated by cupellation.

Refining and Parting of Gold. Impure gold is melted in crucibles, and the impurities, if small, may be fluxed off with carbonate of soda and nitre. If much impurity be present, the gold is first refined by adding nitre and borax, a little at a time, and skimming off the slag at the completion. If lead be present, sal-ammoniac and nitre are used. If antimony and arsenic be present, adding nitre and stirring with an iron rod will remove them. Gold may be also refined by passing through the molten metal a current of chlorine, which attacks the base metals and silver, forming chlorides. When much impurity is present, the operation known as parting is adopted. This is usually done, on the large scale, with sulphuric acid, and in assaying, with nitric acid. It is first necessary to alloy the impure gold with about three times its own weight of silver, granulate and boil in white cast-iron pots with sulphuric acid, which dissolves all metals except gold. In the nitric acid method of parting, glass vessels are used.

Platinum. Platinum is a white metal, highly malleable and ductile, soft, and can be easily welded, very tenacious, and has nearly the highest specific gravity of all kinds of matter. Its specific gravity is 21·5. It resists the action of the atmosphere and most acids, and has an extremely high melting point. It occurs in nature, like gold, in the metallic state, in grains, nuggets, and various alloys. It is extracted from its ores by both dry and wet methods.

In the wet method, gold and silver are separated by amalgamation, the residue is digested with boiling nitric acid, then with aqua-regia to form platinum chloride. The solution is evaporated, redissolved in water, and mixed with alcohol and ammonium chloride, when the double chloride of platinum and ammonium is precipitated. This is reduced to metallic platinum in a plumbago crucible.

In the dry method the ore is smelted in a reverberatory furnace with lead ores, thus forming an alloy with lead and platinum, which is afterwards cupelled. The product is then melted on the lime hearth of an oxyhydrogen furnace.

Nickel. Nickel is a brilliant white metal, malleable, ductile, and weldable. Its melting point is about 1,500 C., therefore below that of iron. It is a magnetic metal and one of the hardest, hence its value as a coating for softer metals. Its specific gravity is 8 8. It readily unites with oxygen when heated, but is not readily oxidisable at ordinary temperatures, and resists the action of sea-water better than most metals. It is soluble in hydrochloric, nitric, and sulphuric acids. Nickel, like iron, readily unites with carbon and silicon when fused with them. When carbonic oxide is passed over nickel at 80° C., or less, a volatile nickel carbonyl is formed which may be decomposed at a higher temperature yielding the nickel. The ores of nickel are chiefly sulphides and silicates.

Nickel Extraction. The methods of extraction are several, and include (1) concentration by roasting to form regulus or speise ; (2) the conversion of the above into oxide by wet or dry methods ; (3) the reduction of nickel oxide by carbon. As cobalt is frequently present, it may be practically separated by the superior affinity of nickel for sulphur or arsenic and the greater tendency for cobalt to pass into a silicate slag.

By the wet method the arsenide and sulphide ores are first roasted, and the other elements are separated from nickel by converting the iron into a basic arseniate, the copper into a sulphide, and the cobalt is precipitated with bleaching powder. After filtering, the nickel is precipitated as oxide with lime. This oxide is then reduced with carbon.

The silicate ores of nickel are made into a paste with calcium sulphate or alkali waste, pressed into bricks and smelted in a small blast furnace. The product is a matte (sulphide). This is roasted, fused twice with sand to remove iron and to concentrate the nickel. The nickel sulphide is then roasted to oxide, and the oxide is made into a paste with carbonaceous materials and reduced to the metallic state in iron pots in a reverberatory furnace.

In Canada, pyritic ores are found containing about equal amounts of nickel and copper. The ore is first roasted in heaps and then smelted with coke in a water-jacketed blast furnace to produce a rich copper-nickel matte. This is re-melted and blown in a Bessemer converter to remove sulphur and iron, the latter completely and the former only partially, leaving a rich matte of copper and nickel. This is then roasted and reduced in the usual way to form a copper-nickel alloy.

Mond's Carbonyl Process. Dr. Mond found that when carbonic oxide is passed over recently-reduced nickel at a temperature below 150° C., a compound ($Ni[CO]_4$) termed *nickel carbonyl* is obtained. A method is thus available for the separation of nickel from its associated metals. An oxidised ore or roasted pyrites is heated to 400° C. in water gas, which reduces the nickel to the metallic state. The nickel is then allowed to fall over shelves in a cylinder, kept at 80° C. or less, through which a current of carbonic oxide is ascending, thus forming nickel carbonyl. This is conveyed to a series of tubes and heated to 180° C., whereby the carbonyl is decomposed and nearly pure nickel is deposited on the walls of the tube.

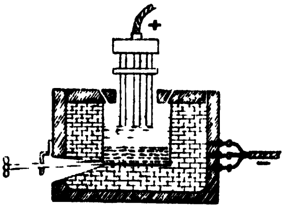
Nickel, when reduced from its oxide, is always wanting in malleability and ductility. It is rendered malleable by adding to it when melted a small portion of magnesium or manganese. Nickel cast into slabs is largely used as anodes in nickel-plating, but wrought plates are better, being less soluble and more uniform in structure.

Cobalt. Cobalt is a metal of a steel-grey colour, with a reddish cast, and very similar to nickel in many of its properties, but of greater rarity and higher cost. It is used in alloys and for electroplating.

Aluminium. Aluminium is a white, somewhat soft metal, of considerable lustre, highly malleable and ductile, a good conductor of heat and electricity, with a high specific heat and low specific gravity. Its elasticity and tenacity are a little higher than silver. It is highly sonorous. The atmosphere has little action upon it, dilute nitric and sulphuric acids do not affect it, but hydrochloric acid dissolves it readily. It is also soluble in solutions of soda and potash. It is chiefly used for purposes where lightness is required.

It occurs in most silicates, and those in which alumina predominates are used for its extraction. As oxide it occurs in corundum, and as fluoride in cryolite.

Alumina was first extracted from its ores by forming the double chloride of sodium and aluminium and displacing the aluminium by sodium. It is now extracted by electrolysis or by electric smelting, through the agency of electricity in both cases. The Hall and Heroult processes are among the most successful. They are identical in principle and both patented in 1886, one in America and the other in France. The Heroult cell [31] consists of a carbon-lined box, itself forming the cathode, while the anode is formed of a bundle of carbon rods. The bath consists of molten cryolite holding alumina in solution. The temperature of the bath is about 800° C., and an electric pressure of 3 to 5 volts is sufficient. The current density employed is about 700 amperes per square foot of cathode surface. The yield is 1 lb. of aluminium per 12 electrical horse-power hours. The alumina used is prepared from bauxite or an impure oxide of iron and alumina by a chemical process. The Cowles process for the extraction of aluminium had a considerable commercial success, but is now, we understand, not carried on. It employed a granular body of high resistance which, being interposed in the current, produced great heat. The alumina is mixed with this resistance material, which is carbon, and by its reducing action at the high temperature employed reduced the alumina to aluminium. It is essential that the air be excluded. This method is now confined to the preparation of aluminium alloys.



31. HEROULT CELL FOR ALUMINIUM

Zinc. The metal zinc has a bluish-white colour, a highly crystalline fracture, and a melting point of 420° C. It soon tarnishes in air, and is readily volatile at a little above its melting-point. Its specific gravity is 7·15. It contracts but little on cooling from the liquid state, and is therefore an excellent metal for casting. In the cast state it is known as spelter, and in the rolled state as zinc. It is malleable only between 100° and 200° C. Common zinc is somewhat soluble in boiling water, and readily so in dilute acids. Although zinc readily oxidises it does not combine with sulphur by direct union. The chief impurities in commercial zinc are lead, arsenic, iron and cadmium. The chief ores of zinc are *zinc-blende* (ZnS) and *calamine* ($ZnCO_3$).

Zinc, being a volatile metal, is extracted by a method of distillation. The ore is first calcined to form oxides, then placed in retorts with anthracite (carbon) and strongly heated. The oxide of zinc is reduced and the metal condensed in fireclay retorts [29]. For rolling it is necessary that zinc should be refined, which is done on the hearth of a reverberatory furnace, made to slope down to a cavity at one end, into which the zinc flows. The bulk of the lead sinks to the bottom, leaving not more than 1·1 per cent. in the zinc. Iron is not removed by this process. Zinc is used for gutters, cisterns, baths, chimney tops, roofing, etc. It is largely used for coating sheet iron, termed *galvanising*.

Tin. Tin is found in nature as oxide, and Cornwall has been from a remote period noted for its tin mines. The ore first undergoes a mechanical preparation to concentrate it. After this it is calcined to remove volatile matter, and then smelted in a reverberatory furnace with anthracite coal to reduce the metal. The products are tin and slag. The tin contains various impurities, and is refined by liquation and poling. By liquation the tin flows out, leaving much of the foreign matter behind. The poling causes evolution of gas, which agitates the metal and brings the impurities to the surface, forming a dross. The varieties of commercial tin are *common* or ingot tin, and *refined* or grain tin. Tin plate is sheet iron coated with a layer of tin to prevent oxidation of the iron. The best iron plates are produced from ore smelted with charcoal, and termed *charcoal plates*. Copper is also tinned in some cases, as for cooking utensils, to prevent the food being contaminated with copper salts. Phosphor-tin is tin alloyed with 4 to 6 per cent. of phosphorus, and used for making phosphor-bronze.

Tin is a white metal of low tenacity but great malleability. When a bar of tin is bent it produces a crackling sound known as the *cry of tin*. It is very prone to crystallise, and when the surface is washed with aqua regia the crystals are clearly seen ; this is termed *moiree metallique*. The specific gravity of tin is 7 3, and its melting point 232° C. When tin is just melted and allowed to cool, the surface remains bright if the metal be pure, but the presence of lead, iron, etc., tends to impart a frosted appearance. The impurities in common tin are lead, iron, arsenic, copper, bismuth, tungsten, and sometimes manganese and zinc. Tin is a poor conductor of electricity. It is capable of assuming an allotropic form, crumbling to powder when exposed to a very low temperature.

Antimony. The chief ore of antimony is stibnite (Sb_2S_3). This sulphide may be largely separated from the rock in which it occurs by liquation. This is done on the concave hearth of a reverberatory furnace, which is lined with charcoal to prevent oxidation. Antimony was formerly called *regulus of antimony*, and in this country is extracted by reduction in crucibles by metallic iron. The metal is purified by fusion with nitre, or by melting and stirring with an iron rod.

Antimony is a bluish-white metal, highly crystalline and brittle, with a specific gravity of 6·7. The surface of the cast metal shows characteristic fern-like markings. It expands on solidifying, and imparts this property to many of its alloys. It melts at 632° C. It does not oxidise in air at ordinary temperatures, but, when heated, unites with oxygen to form the white oxide, Sb_2O_3.

Antimony is too brittle to be used alone for most purposes, but it is of great service as a constituent of certain alloys. It is used to harden lead and tin. It is very valuable in type metal, imparting the property of expansion so necessary for obtaining a sharp and well-defined impression of the letters when printing.

Arsenic. Arsenic is a brittle metal of a steel-grey colour and metallic lustre. Its specific gravity is 5·7. It is a poor conductor of heat and electricity, and in the pure state is without taste or odour. It is very volatile, and burns in air with the formation of the white oxide, As_2O_3. It is a constituent of shot metal and other alloys. It is a valuable bronzing agent. The ores are sulphides, but it occurs chiefly in ores of other metals, such as those of nickel and cobalt. It is extracted from its ores in retorts, from which, on being heated, the arsenic sublimes and is collected.

Bismuth. Bismuth is a comparatively rare metal, associated chiefly with ores of nickel, copper, and silver, from which the crude metal is separated by liquation, or smelted by roasting and reduction in crucibles with iron and carbon. The raw metal is refined with nitre. Bismuth is a reddish-white metal, highly crystalline and brittle. Its low melting point and its property of expanding during solidification make it useful as a constituent of certain alloys, such as fine solder and type metal. It melts at 268° C., its specific gravity is 9·8 in the solid and 10 in the liquid state. It burns in air with a bluish-white flame, forming bismuth oxide (Bi_2O_3). Bismuth, like lead, may be used as a solvent metal in the process of cupellation. It is used in the construction of thermo-piles, in fusible alloys, and in some kinds of type metal and stereo metal.

Mercury. Mercury, or quicksilver, occurs in nature in the metallic state and in *cinnabar* (HgS). The metal is extracted from its ores by a distillation method. The ore is heated in a special furnace, and the vapours of mercury condensed in condensing chambers. The crude metal may contain lead, bismuth, zinc, cadmium, and other impurities. It is purified by covering the metal with dilute nitric acid, and allowing it to stand some time ; the acid gradually dissolves out the base metals, together with some mercury. It is finally redistilled, and is thus made practically pure.

Mercury is a silver-white metal, liquid at ordinary temperatures, and boils at 360° C. Its specific gravity is 13·6. It is not affected by air or oxygen at ordinary temperatures, but if any discoloration occurs on shaking it in a bottle it indicates that impurities are present. It is used somewhat in gilding, but chiefly in the extraction of gold and silver, and in the construction of thermometers, barometers, etc. In dentistry, mercury is a constituent of dentists' preparations and alloys.

Magnesium. Magnesium is a metal very similar to aluminium, but whiter and lighter, its specific gravity being only 1·74. It melts at 750° C., and boils at about 1,100° C. It is rather more oxidisable than zinc. It is best worked at a temperature of 450° C. Magnesium wire is made by forcing the heated metal through holes in a steel plate, and magnesium ribbon is made by passing the metal between heated rolls. It is used in the refining of some metals, owing to its great affinity for oxygen and other non-metals. It is a constituent of some alloys, such as magnalium, which is composed of 100 parts aluminium and 10 to 30 parts of magnesium.

MANDOLINE. BANJO. AUTOHARP. DULCIMER

Construction of Instruments. Position of Player. The Strings. Tuning. Fingering and Special Effects. Exercises

By ALGERNON ROSE

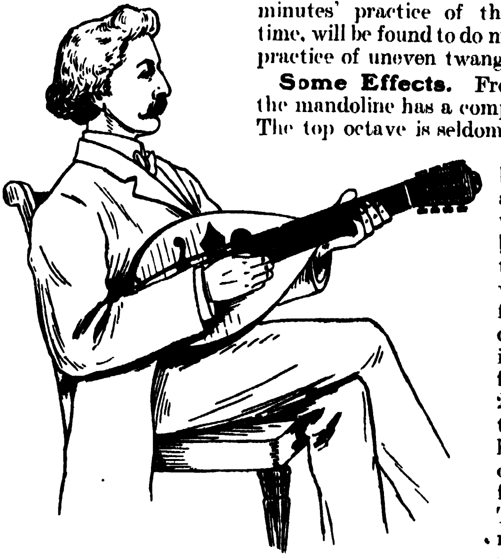
THE MANDOLINE

The mandoline derives its name from the word "mandorla," an almond, the shape of which nut suggested the outline of the body of the instrument. There are two kinds of mandolines—those with four pairs of strings, known as the "Neapolitan," and those with five pairs, called the "Milanese." As the five double-strung instrument is rarely met with, we will devote our attention to the Neapolitan variety.

The Strings. The top string is E, the second A, the third D (called the Bourdon), and the fourth G, the lowest pair being gut strings overspun with silver or copper wire. Therefore the tuning of each pair resembles the tuning of the single strings in the violin—namely, in fifths. The D strings are of steel, also covered; but the A and E strings are of plain steel.

The small metallic bars which cross the fingerboard beneath the strings (there are usually 27 of them) are known as *frets*. Between each fret the space represents one note on the pianoforte, or a semitone in music. In manipulating the fingerboard, the player must be careful with his left hand to place down each finger as firmly as possible, or the metal strings will chatter against the frets and cause an unpleasant buzzing. Play with the finger-tips; they will get sore at first, and contact with the wires will produce corns, but the student will not long be inconvenienced by this.

Position. The position of the player is like that of the guitarist. Sit on a chair; cross the right leg over the left, or put the right foot on a high stool. Hold the body of the mandoline firmly between the knee and the chest, so that the player's right forearm may move freely. The head of the instrument (containing the tuning pegs) should project a handspan beyond the left shoulder. Be careful to keep the right hand and wrist firm, so as to clear the strings and bridge. Keep both elbows down. [1]



1. HOW TO HOLD THE MANDOLINE

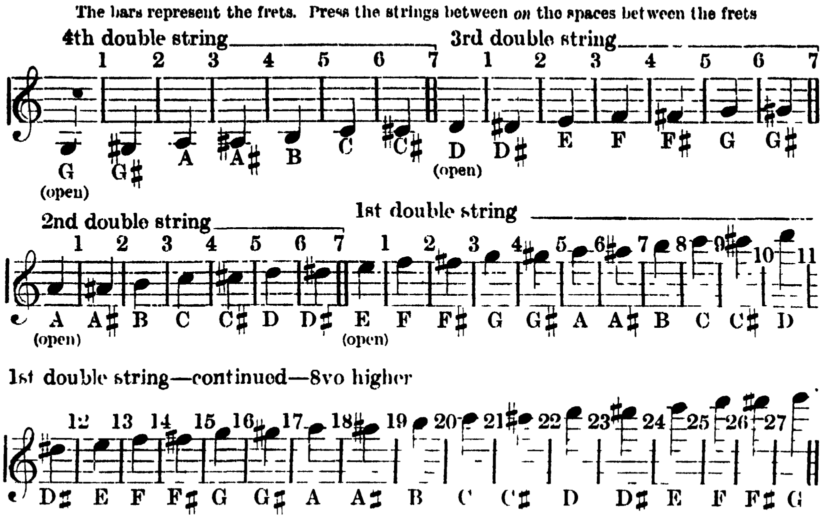
The strings are set into vibration by the use of a *plectrum*. One of real tortoiseshell will last for months, but the genuine article is not easy to obtain nowadays, celluloid, which is less durable, being sold in its place. With the plectrum the instrument is played either *tremolo* or *pizzicato*. The former method sustains the tone and the latter breaks it. The tip of the plectrum should be flexible, and the wide end quite firm. Hold it at right angles to the strings with its flat side in a line with them, or place it between any pair of strings. While grasping the plectrum firmly, keep the rest of the hand limp.

To tremolo properly, it is unnecessary to use force. Strike the strings gently, first down and then up. Make the motions of the same strength, so that both wires are struck equally. Do not attempt to tremolo fast before being able to do so evenly and slowly. In other words, before trying to run, learn to walk. We have heard of a beginner tying a watch to his ear and regulating the speed of his tremolo by its ticking. Fifteen minutes' practice of this kind, keeping strict time, will be found to do more good than an hour's practice of uneven twanging.

Some Effects. From bottom G upwards, the mandoline has a compass of four octaves [2]. The top octave is seldom used.

It should perhaps be here mentioned that a knowledge of musical theory is presupposed [see page 37]. When the student has played with the plectrum the first octave of the different major scales indicated in the course for the violin [page 2121], he should repeat them with the left hand alone. Hammer out each note on the frets with the fingers. Try to produce as much tone as possible without touching the strings with the plectrum. This is an excellent exercise for strengthening the fingers of the left hand and making their movements independent of each other. The effect produced by a good mandoline player who by practice has made his little finger apparently as strong as his first is not unlike that of the soft percussion stop in a Mustel harmonium.

Another mandoline effect which must be studied is the *slur*, known also as the ***legatura***. This is indicated in notation by a curved line



2. COMPASS OF THE MANDOLINE

linking together two or more notes. To insure the tremolo continuing without the slightest break, the player, at the beginning of a slur, strikes the strings once only. By gliding the fingers of the left hand firmly up or down the fingerboard, the tone is then carried from one note to another without further stimulus

Another speciality of the mandoline is the *echo* effect. As the word implies, it is an iteration, softly, of a chord or arpeggio already played. The way to get this is simple. The plectrum, being held by the thumb and first finger, leaves disengaged the second, third, and fourth fingers. After striking with the plectrum loudly, draw the disengaged fingers across the four strings in an upward direction.

The production of harmonics is a distinct charm of the mandoline. These dulcet sounds are elicited by touching the string lightly immediately above the fourth, fifth, seventh, or twelfth frets. At the same time strike with the plectrum. Then take both the hands off so as to set the string free to continue the vibration.

Another distinctive feature in mandoline playing is the *strappato*. In English this means to wrench or pluck off. Strike the intended chord downwards, arpeggio fashion, then bring the plectrum quickly upwards across all the strings. As a close to a brilliant march or other similar music, it gives a good finish, and should, therefore, not be overlooked by the ambitious player.

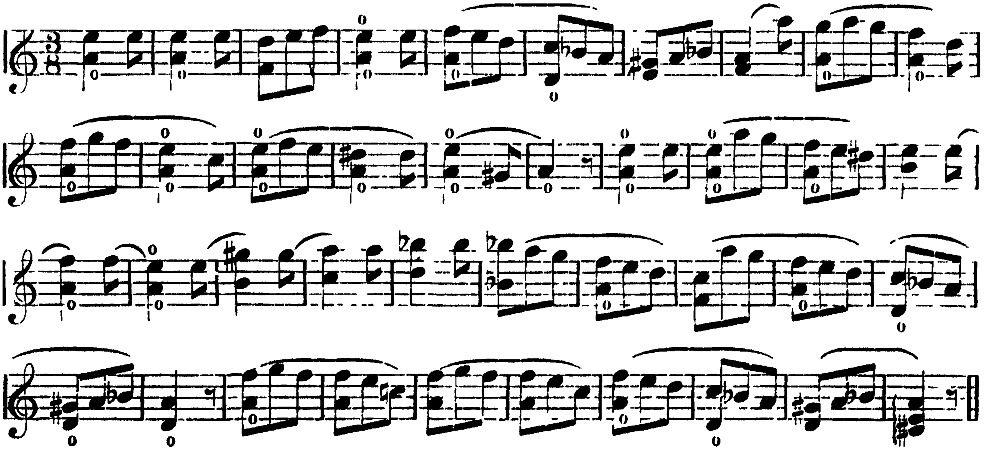
A Fault to Check. One word in conclusion. A common fault in practising a solo instrument is the tendency to disregard precision in time, by hurrying over an easy passage and slowing down when any difficulty occurs. The best remedy for this is ensemble playing. A beautiful quartet, for which good music has been written, can be formed by associating together a first and second mandoline, a mandola, and a guitar, the latter playing the bass part [Ex. 1]

The best known examples of employment of the mandoline in the orchestra occur in Mozart's "Don Giovanni," Handel's "Alexander Balus," and Paisiello's "Barber of Seville."

Ex. 1

TARANTELLA (Italian Dance)

Practise slowly at first. Gradually work up the time till it is presto



THE BANJO

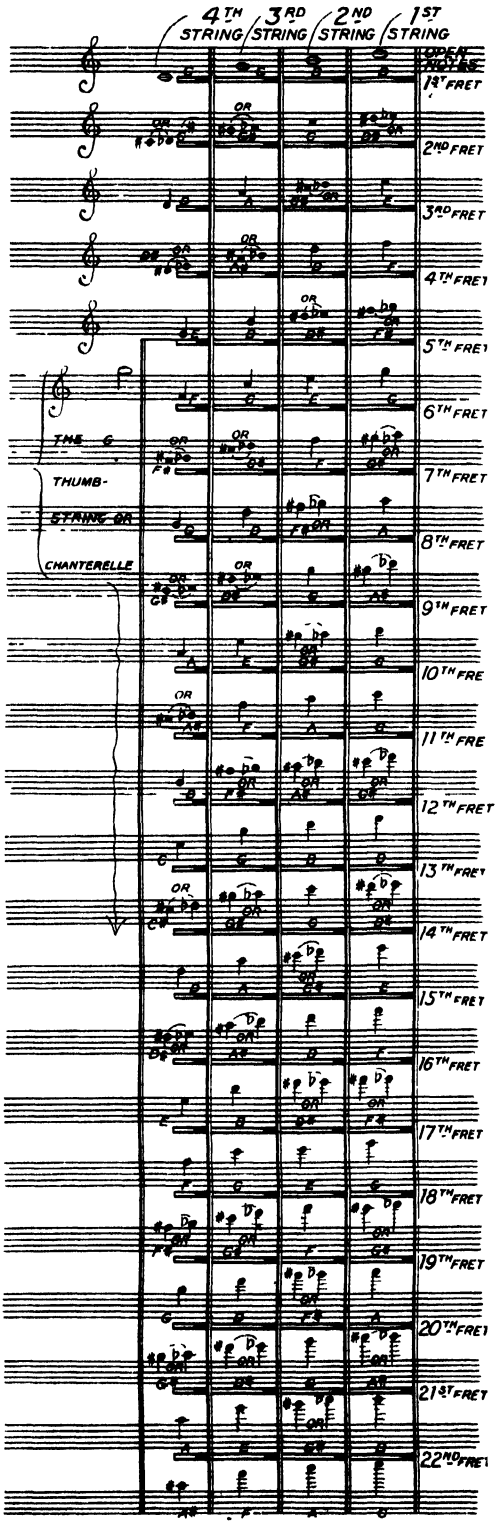
The banjo is in no way descended from the European lute or guitar family. It is of African origin, and through the negro slaves of the Southern States of North America the banjo gradually became popular with our white transatlantic cousins. From America it came to Great Britain and the European continent.

The banjo is characterised by its circular body, or hoop. The head of the banjo is open underneath like a tambourine, or like the half gourd used in many negro instruments as a resonator. Without a fairly deep rim, or hoop, the banjo would lose much of its tone. The rim, therefore, acts as its sounding-board From the hoop extends a long neck, sometimes called the "handle." This is usually of walnut, the upper surface being overlaid with an ebony fingerboard, across which, at lessening intervals, are narrow ridges of metal called "frets."

Construction. A peculiar feature in the construction of the banjo is the way in which its shortest string is placed. This is known as the "chanterelle," or, literally, its "singing" string. Instead of being in its natural order, as the top string is in European instruments, it is put next the lowest and longest string on the fingerboard. This is suggestive. The thumb of the negro, constantly employed for climbing, is said to be rather longer than that of the white man. At all events, this is the thumb-string, and expert banjoists are as dependent on the thumb for their success as was any gladiator—in another sense—in the arenas of ancient Rome. The thumb-string on the banjo being shorter than the other four, its tuning peg is situated two-thirds of the way up the neck instead of at the head. Advanced players sometimes favour six, seven, and even nine stringed banjos. But the beginner will learn the ordinary instrument, which has five strings. Their pitch is an octave lower than the notes indicated in music printed for them.

Tuning. Tune the fourth string to the C on the piano, second space bass clef. That is the actual sound, although in the music it is represented as C, first ledger line below treble staff. Having done this, tune the third string a fifth above the fourth, to G in the fourth space bass clef. Next adjust the second string a third above G—namely, B. Now tune the third string a third above B, to D. Do not tune each by the piano. Only use it to test the strings when they are tuned. As soon as the C string has been adjusted to the pitch, its seventh will give the G for the third string. Likewise, the fourth fret of the G string, when tuned, will give the B for the second string, and the third fret of the B string will give the D for the first. Now stop the fifth fret of the first string and tune the thumb-string in unison with it. If this is done properly, it will be an octave higher than the open G of the third string.

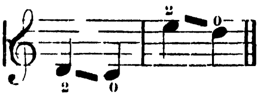
The banjo is best played sitting. Cross the right leg over the left. Rest the fore part of the hoop on the leg. The near side of it should be in contact with the player's chest, and thus be



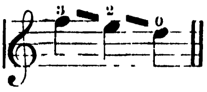
held firmly. The handle, which now inclines over the left shoulder, is manipulated by the fingers of the left hand. Rest the little finger of the right hand on the vellum sounding-board, in a line with the bridge.

There are two general methods of banjo playing. The first, and more usual, is by picking, or plucking, with the tips of the fingers of the right hand. The second method, which increases the sound for concert playing, is by the thimble. This is worn over the nail of the first right finger. With it the strings, instead of being pulled, are struck downwards.

Exercises. Begin with the exercise on the open strings. Grasp the handle with the thumb and second joint of the first finger. Keep the left fingers clear of the strings. Remember that the right thumb is used for the three strings on the left. The first finger is employed for the second string, the second right finger for the first string. But the third finger is only used occasionally, as in chords or arpeggio passages.



1. SINGLE SNAP



2. DOUBLE SNAP

Now study carefully the proper fingering for the left hand. It may seem complicated at first, but after a certain amount of practice it should become automatically correct. All the sounds which the five strings produce on pressure of the twenty-two frets are noted in the accompanying table. The "chanterelle," or thumb-string, being higher in pitch, has intervals shorter than those of its neighbour [See last page.]

Reference to this diagram should enable the student to finger out for himself any music he wishes to study.

The easiest scale to play on the banjo is G major, with one sharp, F. This is the natural key of the instrument. Therefore learn that scale first. The fingering is shown in 3.

Observe that, when the first finger of the left hand covers the first fret, the hand is said to be in the *first position*. Now let the first finger fall on the second fret. The hand is now in the *second position*. According to the way the hand progresses along the fingerboard, so is it in the *third, fourth,* or *fifth positions*.

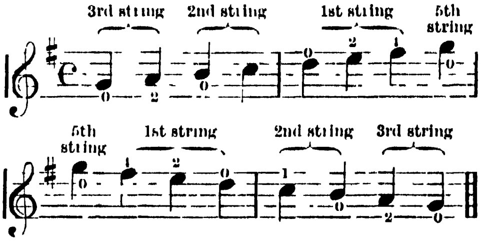
The Strings. Bear in mind that the strings cannot be pressed too strongly by the fingers of the left hand if a good tone is to be acquired. There is a marked difference between the quality of an open string and of the same string when stopped by the finger of an ordinary amateur. The reason is because the pressure, or stress, on the string at the point where it goes over the top-nut, and is pulled back by the reverted head of the instrument, is enormous. Try to make each finger a top-nut.

The popular "breakdown," or step-dance, known as "Old Virginny" may now be practised [Ex. 1].

Next proceed to the scale of C major. Later on, study all the sharp and then all the flat scales. With perseverance, difficulties will be overcome.

Meanwhile, the intelligent student will study that feature in banjo playing known as the *snap*. This is indicated in notation by a straight line drawn from one note to another [1].

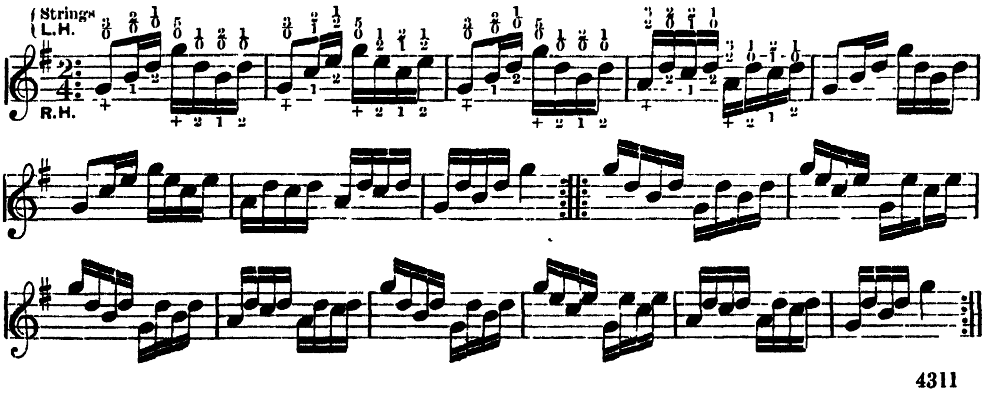
Produce the first sound by plucking the string with the right hand. Then, with the left finger snap—or pizzicato—the note which follows. Having succeeded in doing the *single snap* neatly, try playing the *double snap*. As before, pluck the first note with the right hand. Then, with the left, snap the *two* following notes [2].



3. FINGERING OF G MAJOR

Owing to the presence of frets, it is easy on the banjo to transpose the sounds of the strings by placing the first left finger across them. To do this properly, the thumb must be at the back of the neck, away from the chanterelle, so as to act as a lever.

Ex. 1 "OLD VIRGINNY"



Barré. This method of transposition is termed *barré.* According to the position barré, so it is indicated in the music as 1 P.B., 2 P.B., 3 P.B., etc. The first finger must be planted firmly, seeing that it cuts off a vibrating portion of the neck and forms a fresh top-nut, or *capotasto.* Beyond this new top-nut, the second, third, and fourth fingers stop the notes as required.

When a slur in the printed music ties one note to another by a curved line, the way of playing is to slide the finger which stops the first note firmly on to the second while the string is vibrating. What is technically known as the *slide* is the longer slur. Of this there are several kinds. In playing barré, the fingers forming the notes beyond the bar should, like the first, press firmly. If, on the contrary, they touch the strings above the frets very lightly, the effect is that of a silvery note at a higher pitch. This is known as a *harmonic.* It has a bell-like or fluty character. The principal harmonic notes on the banjo are obtained by touching softly the fifth, seventh, and twelfth frets, or the seventeenth fret on the thumb-string. So as to be easily read, harmonics are usually written an octave lower than they sound. The harmonic at the nineteenth fret of the thumb-string is analogous to the seventh on the third string.

The Vibrato. We have so far dealt with various ways of stopping the notes; but, besides pressing them down firmly, the student who desires to be a good banjo player will practise diligently until he acquires the ability to cause each finger of his left hand to make the string throb or quiver sympathetically. This delightful effect is known as the *vibrato.* Not only is the pulsating tone pleasant, but its production seems to reinforce and intensify the sound of the instrument. Regard the tip of the finger as a fulcrum. Press the first joint gently forward and backward. Do not jerk the string. The necessary rapidity of motion requires practice, especially as regards the weaker fingers. The only way is to repeat the exercise patiently day after day until the knack is acquired. It will probably come when least expected. When once learnt, it is not forgotten. The time occupied in obtaining it is well spent, because it is not easy to exaggerate a good vibrato on a stringed instrument, whereas the same effect applied to the voice too often becomes a wearisome mannerism, which militates against the success of the vocalist.

Varieties of style of manipulation in banjo playing done with the right hand are known as the *tremolo, fanning, thimble playing,* and the *rasp.* An even tremolo is nearly as difficult to learn at first as is the vibrato for the left hand. It is produced by the tip of the first finger very quickly beating the strings to and fro. At the same time, the lower notes, furnishing either accompaniment or melody, are played by the thumb. Fanning, although somewhat similar, is more deliberate than the tremolo.

Thimble playing is employed when a powerful tone is required. The first finger strikes the strings with the thimble instead of twanging them, the thumb meanwhile plucking alternate notes in the usual fashion. A further development of this branch of study is known as *thimble rolling.* Like everything artistic, it usually requires considerable practice to obtain a good effect. Although the harpist keeps his nails very short, the banjoist, like the Chinese mandarin, must cultivate his for playing the rasp. This is produced by passing the finger-nails of the right hand lightly across the strings, either with the back of the hand up or the palm up and the nails reversed.

Sufficient has been said to show that, although the rudiments of banjo playing are easy to acquire, the instrument is not easy to master thoroughly, and amongst its exponents are not a few players of extraordinary skill.

But the student will find that its difficulties will vanish with persistent, well-ordered practice.

THE AUTOHARP

This instrument is in shape like the zither rather than the harp. The distinguishing feature in its construction is that the strings are crossed at right angles by bars parallel to each other. By means of spiral springs, each bar is kept clear of the wires below except when pressed down. An arrangement of pieces of felt then damps the vibration of certain strings, allowing the others to sound freely.

Place the autoharp on a flat table, taking care that the spikes do not scratch the surface, with the straight side of the instrument inclining towards the player at an angle so that the outlines of the fingerboard and bass side represent roughly the letter V. Every string is numbered underneath on the sounding-board. Corresponding numbers are printed over each note in music arranged for this instrument. No previous knowledge of notation is therefore necessary.

The Strings. Of the twenty-four strings to be found in the usual type of autoharp, those nearest the player are of covered wire. These strings represent the pedal notes, or roots, of chords formed on pressing the bars and sweeping the strings. With the left hand press down the bar nearest the tuning pins. Set the strings in motion by guiding the thumb of the right hand along them. The notes which sound are C, E, G, wherever they occur throughout the compass, the other notes being silenced by pads of felt underneath the bars [1*a*].

Now depress the next rod, marked B. Sound the strings. The chord heard includes every D, F♯, A, and C in the scale [1*b*].

The third bar, marked C, leaves open every G, B, and D in the compass [1*c*]

All strings which sound E, G, B vibrate when the fourth bar, marked D, is put down [1*d*].

The fifth bar, marked E, sounds every A, C, E [1*e*].

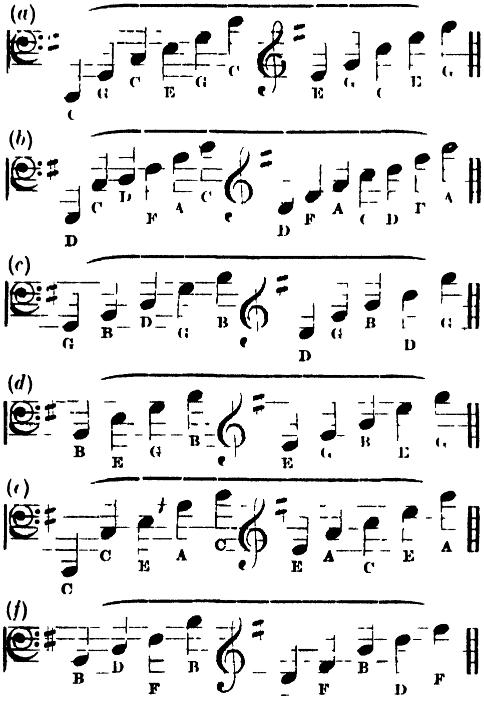
Lastly, when the sixth bar, marked E, is pressed, it allows every B, D, and F♯ to vibrate [1*f*].

All melodies for the simple autoharp are written in the key of G, with one sharp, F.

The compass usually consists of twenty-four or twenty-five strings, being the diatonic scale of G, to which are added the pedal notes of C and D, and harmonic sounds can be obtained by touching the G string (4) lightly above the frets (beyond the bars)

Although the autoharp may be played by those who know nothing whatever of musical notation, in the hands of a musician who understands the principles on which its mechanism is arranged it is something more than a mere toy. He can elicit some beautiful effects from it, inasmuch as the third bar gives the tonic chord of G major, the second the dominant, the first the subdominant, the fourth the relative minor chord of G, the fifth the relative minor chord of the sub-dominant, and the sixth bar the relative minor chord of the dominant.

To show what can be done in the way of autoharp music, we may mention that the so-called "Erato" autoharp has a compass of three full octaves from C to C, containing all the semitones, and its elaborate mechanism enables thirty-six different chords to be played—namely, the twelve major, twelve minor, and twelve chords of the seventh.



1. AUTOHARP EFFECTS

Use of the Ring. For sweeping the strings, an ordinary zither or banjo thumb-clip of celluloid, called a *ring*, is used. If the ring is too small, it will make the player's thumb sore; if too large, it will spoil the accuracy and firmness of tone. Therefore, see that it fits. By holding up the thumb and sweeping the strings with the tips of the other fingers, a delightful pianissimo effect is obtained. To silence the sounds, put the flat of the left hand on the strings.

Tuning. But the charm of the instrument will be entirely lacking if the strings are not in good tune. Be careful to get a tuning hammer, or key, which is of hard metal, and fits the pins properly. If it slips on the pins, the latter will be racked and gradually loosened, and the instrument soon spoilt. An easy guide to the tuning is to follow the notes indicated on a piano or harmonium. When the player gets accustomed to the sounds required, the help of a keyboard instrument may be dispensed with, and the tuning done from a G pitch-pipe or tuning-fork.

On the autoharp with six bars, the G string is usually the ninth from the left. In some instances it bears the number 4, pedal notes being marked with Roman numerals to distinguish them from the diatonic intervals above. But the letter of each note is printed on the instrument itself, so that one cannot make a mistake.

If 4 is the number of pitch G, the strings 6, 8, and 11 will give the notes B, D, and the octave G, found under the third bar, marked C. Press down this bar and keep it down with a paper-weight while tuning these strings, so as to shut off the sounds of the others. Put the tuning hammer on the pin of B (No. 13), an octave above B (6), which tune next; then tune pedal B (IV.) two octaves below. Deal in the same way with the three D's, 8, 15, 1. Tune 18 and III. with pitch G (11) and its octave (4). Now release bar C, and tune the intermediate notes with their octaves. Test them with the bars of C major ("A" bar), and the dominant of G ("B" bar). As the same strings are employed in forming the relative minor chords, it follows that, when the strings sounded on pressing the first three bars are tuned correctly, they will accord also when the other bars are used.

Autoharp Score. In the music printed for the autoharp, a number and capital letter will be found indicated over each note. The number refers to the string and the point where, in sweeping a chord from left to right, one must be careful to finish each movement. These successive top notes not only complete each chord, but, in doing so, furnish the melody. The capital letter above each number in the music, showing which bar is to be pressed down with the left hand, has no reference to actual notes, the G major chord being usually labelled "C."

It is easy to arrange any simple tune which does not contain sharps or flats for the ordinary autoharp. Therefore, get a musical friend to transpose the top line of a hymn or other straightforward melody into the key of G. Then write above each note the number of its string on the autoharp, putting over the number the letter of the bar to be pressed down. The player's ear will guide him to the choice of the right bar. He will thus be able to furnish himself without expense with his own special stock of autoharp music. As an illustration of this, we give the charming old country tune known as "The Dusty Miller," the drone bass of which through-

Ex. 1

out is the tonic chord of G major [Ex. 1]. If the air is memorised at the piano, and then sung to the autoharp, all the player has to do is to press down the third bar (C), and continue sweeping the strings as an accompaniment to the voice, the left hand releasing the bar wherever an asterisk occurs, so as to admit of the notes not in the G chord being sounded by the right hand.

First, therefore, play each note, using only the "C" bar. When this can be done smoothly, change the harmonies by putting down the various bars at different times according to the letters indicated underneath the notes. The effect of concluding the tune with the relative minor chord of G and the relative minor chord of the subdominant (bars E and D) is quaintly appropriate. Make this final sweep (bar C) from right to left.

DULCIMER

The dulcimer is a flat, trapesium-shaped, double sounding-board, the upper one being perforated by a couple of sound-holes and provided with two bridges, across which the strings are stretched. Two, three, or more strings of brass, or steel, are grouped together and tuned alike to represent one note. On English instruments there are usually ten long notes, each one made up of several strings; and ten shorter notes.

Position and Tuning. The dulcimer is usually played standing. It should be placed on a table, slightly higher at the farther than the near side, so that the shortest strings, which are farthest away, may be manipulated as easily as the longest, in front of the player. Suitable tables are usually supplied with the dulcimer when it is sold, and care should be taken that the floor is level, so that the instrument may rest firmly.

The method of tuning the English dulcimer is to accord the group of strings nearest the player with the G below second ledger line, treble clef. The wrest pins are on the right of the player. Each one must be first threaded through the eye and a loop made at the other end of the string to fasten over the hitch pin on the left. Then with the tuning hammer, coil the wire carefully round the string to the right till the pitch is raised sufficiently. But get all the strings on first, the thickest towards the bass and the thinnest towards the treble, and draw them up slackly before attempting to get all to standard pitch. Watch the bridges and see that they keep even. The compass of the diatonic dulcimer, on which learners generally begin, comprises usually 22 notes, from the G named to the G, 4th ledger line above the treble staff, or three octaves in all. Having, with the help of a piano or harmonium, got the six lowest notes—G, A, B, C, D, E—in tune with the white notes on the keyboard, the student, observing that the compass extends from G to G, will doubtless conclude that the whole of it should be tuned to accord with G major, in which all the F's are sharp. But it is the custom with dulcimer players to tune the two lower F's natural, and only to have the top one sharp. This will be found a convenience, as the beginner usually starts with exercises in the key of C major. But different dulcimer players vary in their modes of tuning. The strings are numbered on the right from 1 up to 22, from the lowest to the highest note, unisons being grouped under one number.

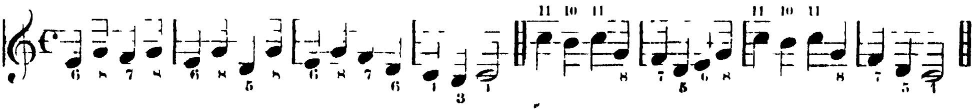
The Beaters. These are two sticks which are held in the hands as for playing the kettledrum, and require considerable elasticity of wrist to manipulate properly. The ends are provided with pads of leather, soft on one side and hard on the other, for use in getting "piano" or "forte" effects. All the different ways of right and left hand manipulation employed in tympani playing can be applied to the dulcimer. It is well to practise the various rolls with the sticks on the top of a wooden table, so as to get a greater facility apart from sound. It saves time and constant tuning, and can be practised almost anywhere. The general rule is to use the sticks as alternately as possible.

Rapidity in execution can be learnt most quickly by drum practice. But besides striking with regularity and velocity, the player must hit the right strings. In course of time, the diligent student will learn to do this automatically, and to graduate also the force of each blow, so that the beaters get crescendos and decrescendos of sound, and maintain the loudest or softest quality of tone, as marked in the music. But there is this peculiarity in dulcimer playing—which sets it apart from all other musical instruments and invests it with that savage attribute so dear to the hearts of the Magyars—the sound cannot be effectively shut off directly a note is struck, so that a confused jangle, to some ears, results, akin to playing on a piano with the "loud" pedal down the whole time.

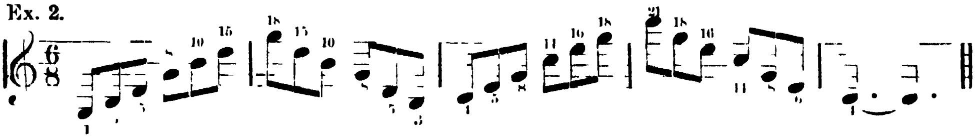
Whether this effect is really unmusical is a matter for discussion, but it makes the dulcimer particularly interesting as the only link we have in this respect between Oriental and Occidental proclivities. Lest the absence of damping should set the musical mind of the beginner against the dulcimer, it is as well to note here that this instrument possesses considerable artistic possibilities. As far back as the end of the seventeenth century Habenstreit, of Eisleben, was a noted virtuoso on the dulcimer, and, since his day, many highly-gifted musicians have astonished and charmed large audiences by similar skill.

Key of C Major. Write out the scale of C major, beginning at C, 1st ledger line below staff, and continue it for two octaves, numbering the first C "4," and so on. Now, with alternate beaters, ascend and descend the scale, striking the notes in slow time, to the ticking of a clock or metronome, and with equal force, beginning softly and gradually increasing the strength as well as the speed. Having got the names and numbers of the notes well into the mind, a diatonic melody written for the voice in the key of C can be learnt without difficulty, although the student has had no musical training. Take, for instance, the melody known as the "Vesper Hymn." [Ex. 1.]

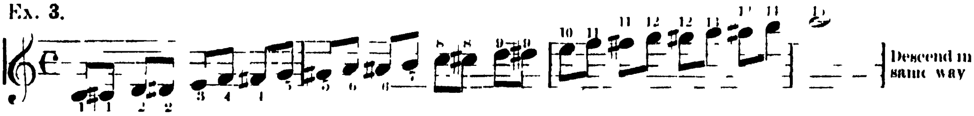
Ex. 1.



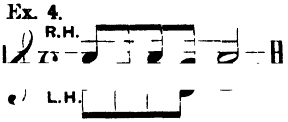
Ex. 2.



Ex. 3.



Ex. 4.



Having confined the rhythm to duplex time (4/4 or 2/4), the beginner should next accustom himself to playing triplets. In this, on every fourth note, the accent is shifted from one hand to the other. [Ex. 2.]

Chromatic Dulcimer. The advanced student will endeavour as soon as possible to avail himself of an instrument giving the chromatic intervals. This is effected by a different disposition of the bridges, so that the vibrating length of the strings between the 1st and 2nd bridge, and the 2nd bridge to the tail pins, admits of different instead of the same sounds from one length of string. The longer stretch, on the right-hand side of the player, now produces the diatonic notes, whilst the shorter stretch on the left hand gives the chromatic sounds. The compass of the chromatic dulcimer is an octave less than the English instrument from G to G. It starts from C, 1st ledger line below staff, and goes to C, 2nd ledger line above it. But the intervening notes contain all the necessary half-tones to enable the instrument to be played in any key. Instead of C being No. 4, it now becomes No. 1, but the chromatic notes are always numbered with the diatonic, so that C and C♯ are both designated "1." Try the chromatic scale. [Ex. 3.]

The student can now begin to practise the scales in all the major and minor keys. After going up and down C major, sound the cadence given in Ex. 4.

Then go to G major. After transposing the cadence a fifth higher on paper, repeat it. Next go into D major, and so on through the different scales, until familiar with each key. Then tackle the minor scales. Endeavour to make the executive ability in manipulating the beaters keep pace with the facility required for reading.

So that ascending and descending runs in double notes may be executed rapidly and evenly, the ambitious student should practise scales in 3rds, 6ths, octaves, and 10ths, slowly at first, gradually augmenting the pace. The remarkable bravura capabilities of this instrument are shown in the Swiss dance (dated 1826) of the Canton of Appenzell, arranged for violin, dulcimer and 'cello, quoted in Sir John Stainer's "Dictionary of Musical Terms."

Mandoline, Banjo, Autoharp, and Dulcimer concluded

APPLIED CHEMISTRY

Chemistry and Commerce. The Chemical Industries. The Various Processes in Applied Chemistry. A Short Dictionary of Chemical Terms

By CLAYTON BEADLE and HENRY P. STEVENS

IT is in the domain of pure science or pure research that great discoveries of industrial importance unexpectedly come to light. In such cases, the leading principle stimulating the chemist, the biologist, and the physicist is the love of knowledge for its own sake. When engaged in some particular investigation, the unexpected frequently happens, side issues arise which lead the investigator into fresh paths, and, although he may not attain the special object in view, his labours are not wholly disappointing. But such is not always the case, for many have worked and devoted a life of self-sacrifice without achieving any marked degree of success, and those who have striven for the attainment of some particular industrial object have, at times, failed utterly. But cases of failure may often be attributed to the lack of a proper combination of *theory* and *practice*. To perform a chemical operation in the laboratory is a very different thing from carrying it out on a large scale in the factory.

We shall endeavour briefly by way of introduction to refer to various operations performed, often unconsciously, by the chemist in the course of his analytical work, and at the same time common to most, if not to all, chemical industries.

Lixiviation. This is the separation of the soluble from the insoluble, as in the process of extraction by water. Example: soda recovery.

Extraction. In its general acceptance, this is the use of solvents, such as ether, alcohol, carbon, disulphide, benzene, petroleum, etc., as in the removal of fatty or greasy matters. Example: removal of wool fat from wool.

Subsidence, or Levigation. This consists in the separation of (insoluble) particles from watery solutions, etc., due to gravitation. The largest particles subside first, then the next in size, and so on, thus effecting the separation of (*a*) solid from solid; (*b*) solid from liquid; and sometimes (*c*) liquid from liquid. Examples: (*a*) clay washing; (*b*) clarifying effluents; (*c*) oil and water.

Levigation by Wet Grinding. This is the grinding of insoluble substances to a fine powder when wet, and separation by subsidence. Example: minerals for paints.

Evaporation. This is the removal of water either (*a*) "spontaneously," as under the influence of air, wind, sunshine, etc.; or (*b*) by the direct, or (*c*) indirect application of heat; or (*d*) by the use of vacuum pans with or (*e*) without heat.

Examples: (*a*) evaporation of salt from sea water, and the drying of hand-made paper; (*b*) soda recovery by Porion system; (*c*) "Stove," or table salt from brine; (*d*) concentration of sugar solutions and glycerine by multiple effect systems; and (*e*) drying of glue.

Distillation. This consists in the separation of a mixture of volatile and non-volatile (or less volatile) substances by the application of heat. Fractional distillation is applied to various liquids containing mixtures of substances having different boiling points, whereby one is separated from the other, the lower boiling constituents distilling over first.

Sublimation. This can be either spontaneous, as when snow disappears without melting, or induced by heat, as in the purification of salammoniac or naphthalene. It involves the direct conversion of a solid into a vapour, and, if necessary, its subsequent condensation again to a solid.

Filtration. This is the removal of solid impurities from liquids by passing or forcing the liquid through media such as cloth, paper, asbestos, sand, etc., which retains the solid and allows the clear liquid to pass, or the same operation as performed in the filter press for the purpose of separating out the waste liquid from the valuable solid matter which it may contain, or vice versâ.

Centrifugal force is taken advantage of as a means of separation, as in the centrifuge for removal of liquids from crystals.

Crystallisation. This is a means of separation dependent on the crystallising out of solids from liquid solvents, when the solutions are brought below their saturation point. The crystals may be removed by filter pressing, ladling, running off liquid, or by centrifuges. Examples: water softening, separation of lead and silver.

Calcination. This is the operation of heating solids without fusing them, or where only partial fusion takes place, as in the manufacture of cement, ultramarine, and the recovery of spent liquors. More or less synonymous terms are igniting, burning, firing, and roasting by means of the muffle out of contact of the fire gases and burning material.

In certain cases the material operated upon is sufficiently combustible to supply the necessary heat for its own calcination, as in the case of recovered ash by "rotary roasters."

Refrigeration. This is the use of cold to prevent or arrest chemical action, as with meat preservation, or to control bacterial growth, as in the case of lager beer fermentation.

Continued

SHORT DICTIONARY OF TERMS IN APPLIED CHEMISTRY

SEE ALSO SHORT DICTIONARIES ACCOMPANYING THEIR SPECIFIC SUBJECTS

ACIDIMETRY—The determination of the amount of acid in a substance.

Albumins or **Albumens**—A group of albuminoids soluble in water. Egg albumin (white of egg) is an example.

Albuminoids—Organic carbon compounds containing hydrogen, oxygen, nitrogen, and sometimes sulphur, and of very complex nature. They are essential both to animal and plant life.

Albuminoid Ammonia (in water)—Ammonia obtained by distillation with alkaline permanganate by Wanklyn's method.

Alcohol—Generally understood to mean ethyl alcohol, C_2H_5OH, a constituent of alcoholic beverages, and obtained by the fermentation of sugar. The term is also applied to substances of similar composition.

Aldehydes—Substances obtained by the careful oxidation of alcohol.

Alizarine—One of the colouring matters of madder (*Rubia tinctoria*), the other being purpurin. Also prepared artificially from coal-tar.

Alkalimetry—The determination of the amount of alkali in a substance.

Alkaloids—Bases obtained from plants and possessing highly poisonous or medical properties.

Alloy—An intimate mixture (possibly containing compounds) of metals with one another.

Alum—A double sulphate of alumina and another metal, crystallising in the regular system with 24 molecules of water. The name is often applied in commerce to sulphate of alumina alone.

Amalgam—An alloy of mercury with another metal or metals.

Amorphous — Without crystalline structure.

Aniline—A colourless oil obtained indirectly from coal-tar and belonging to the class of primary amines.

Aniline Dyes—Dyes obtained from aniline. The term is often incorrectly applied to all coal-tar dyes.

Animal Charcoal or **Bone Black**—A substance obtained by carbonising bones.

Animal Oil or **Bone Oil** — An oil obtained by distilling bones.

Anthracene—A white crystalline solid from coal-tar and the mother substance of the alizarine dyes.

Antichlor—Sulphites and other substances added to destroy any residues of chloride of lime left in a fibrous material after bleaching.

Antifebrin—Acetanilide; an antipyretic.

Antipyretic—Medicinal substance to allay fever.

Antipyrine—Phenyl-dimethyl pyrazolone; an antipyretic.

Apatite—A mineral phosphate and fluoride of calcium.

Aqua-fortis—Nitric acid.

Aqua-regia—A mixture of one part nitric acid and four parts hydrochloric acid.

Argol—Crude bitartrate of potassium.

Asbestos—A fibrous mineral substance used in making fireproof articles.

Ash—Mineral matter left on burning organic substances.

Asphalt—A natural mineral bituminous substance.

Aspirator—A machine to draw a current of air or other gas through an apparatus.

Assay—The determination of the quantity of a constituent contained in a substance.

-Ate—The termination of the names applied to salts of acids containing oxygen.

Autoclave—A digester or closed vessel in which liquids can be heated above their boiling points.

Azo—The group $N-N$ characteristic of a large number of colouring matters derived from coal tar.

BALSAMS—The exudations of plants consisting of resins, volatile oils, aromatic acids, and other substances.

Base—A metallic oxide or organic radical having the power of combining with an acid.

Basic—Having the properties of a base

Bauxite—A naturally occurring hydrated oxide of alumina.

Beaker—A tumbler-shaped vessel of thin glass.

Benzaldehyde—Oil of bitter almonds: C_6H_5CHO.

Benzene—A liquid volatile hydrocarbon (formula C_6H_6) contained in coal-tar.

Bittern—The mother liquid that remains after common salt has crystallised out from sea-water.

Blacklead—Plumbago or graphite; a form of carbon.

Bleach or **Bleaching Powder**—Chloride of lime or calcium hypochlorite.

Blue-stone—Sulphate of copper.

Boiled Oil—Linseed oil which has been heated with litharge, manganese borate, or other substances, so that it has become thick and viscous.

Boiling-point—The temperature at which a liquid boils, the pressure being that of a normal atmosphere unless otherwise stated.

British Gum—*Dextrin*.

Bunsen Burner Gas-burner having holes at the bottom for the admission of air.

Burette—A graduated glass tube provided with a stop-cock at the bottom for measuring fluids.

CALCINATION—The operation of ignition or heating till nothing but a mineral residue or calx remains.

Calc-spar—Native crystalline calcium carbonate.

Calibration—The process of ascertaining whether a vessel or other measuring apparatus holds or delivers the exact volume marked upon it.

Caliche—Impure native nitrate of soda or Chili saltpetre.

Calomel—Mercurous chloride.

Calorie—Metrical unit of heat, being the amount of heat required to raise one gramme of water 1° C.

Calorimeter—Apparatus for measuring heat, usually the amount of heat developed by substances when burnt.

Caramel—Brown colouring matter obtained by heating sugar or glucose.

Carbide—A compound of metal with carbon—as calcium carbide.

Carbohydrate—A compound of carbon, hydrogen, and oxygen, the relative proportions of the two latter elements being the same as in water—as sugar.

Carbolic Acid—Phenol: C_6H_5OH. A constituent of coal-tar

Carbonyl—The group CO— that is, a group composed of a carbon and oxygen atom in combination.

Carborundum—An extremely hard substance containing carbon and silicon.

Catalysis—The effect by which two substances are enabled to react in virtue of the presence of a small quantity of a third substance termed a *catalytic agent*.

Contact Action—A synonym for catalytic action. See *catalysis*.

Centinormal — One-hundredth of normal strength.

Chamber Acid—The crude sulphuric acid which collects on floors of the lead chambers; of a strength not usually exceeding 70 per cent. of pure acid.

Chili Saltpetre—Sodium nitrate.

China Clay—Kaolin, the purest variety of clay.

Chloride of Lime—Bleaching powder or calcium hypochlorite.

Cinnabar—Native sulphide of mercury or vermilion.

Cochineal—The body of a female insect which produces red dye-stuff.

Collodion—A solution of soluble nitrocellulose in a mixture of alcohol and ether.

Colloid—A substance in the amorphous non-crystalline state — as india-rubber, glue, colloidal silica, cellulose.

Colophony—See *rosin*.

Commercial Chemicals — Such as have not been specially purified.

Compound—A substance composed of two or more elements in combination with one another.

Condenser—Apparatus for condensing a vapour to a liquid, consisting commonly of a tube surrounded by a jacket of cold water,

Constitution—The mode in which elements are combined with one another in a compound.

Corundum—Native alumina or oxide of aluminium of the same composition as sapphire and ruby.

Creosote—Substance obtained by distilling wood or coal-tar.

Crucible—Cup-shaped vessel of fire-resisting material in which substances can be strongly heated.

Crude Product—Unpurified material obtained in chemical manufacture or laboratory work.

Cryolite—A native fluoride of aluminium and sodium.

Crystals—Characteristic geometrical shapes bounded by plane surfaces in which most solid substances occur, especially when separated from solution or on solidification.

Crystalline Systems—The six classes into which all known crystalline shapes are grouped.

DEAD OILS—The name applied to that portion of the coal-tar distillate which sinks in water.

Decantation—The process of pouring off the clear liquid after the solid matter has settled to the bottom.

Decinormal—One-tenth of normal strength.

Deliquescence—The absorption by a substance of moisture from the air, at times in sufficient quantities to cause it to liquefy.

Density—The mass of a unit volume of a substance. See also *specific gravity*

Dephlegmator—A type of reverse condenser chiefly used in distilleries for freeing alcohol from water.

Desiccation—The process of drying.

Desiccator As used in analytical work, a glass vessel with ground closely-fitting lid containing a hygroscopic substance such as calcium chloride, strong sulphuric acid or phosphorus pentoxide, so that any body placed inside rapidly loses its moisture and dries.

Dextrin—A gummy substance obtained from starch by the action of diastase.

Dextro-rotatory—Rotating the plane of polarisation of light to the right.

Dextrose—Grape sugar, a six-carbon sugar obtained from starch.

Diamines—Diamido compounds: compounds containing two amido (NH_2) groups or their derivatives.

Diastase—An unformed or soluble ferment which converts starch into sugar.

Digester—See *autoclave*.

Digesting—The process of heating together a solid and a liquid so as to give them every opportunity of reacting with one another.

Distillate—That portion which passes into vapour and collects in the receiver when a substance is distilled.

EFFLORESCENCE—Formation of a powdery deposit on crystals through loss of water or of a powdery crystalline deposit on the surface of a porous body, as in the case of nitre on the surface of the earth in India.

Electrolysis—Separation of a chemical substance into its constituents by an electric current.

Elementary Analysis—The determination of the proportions in which the elements are contained in a substance.

Elutriation—Washing a finely-powdered substance by repeated treatment with fresh water.

Endothermic Compounds — Compounds in the formation of which heat is absorbed.

Enzyme—Unorganised ferment

Equivalent Weights—Weights of substances which will combine with or replace one part of hydrogen. The equivalent weight of a compound will be a simple fraction, usually one-half, of the molecular weight.

Ester—An ethereal salt.

Ether—Usually understood to mean ethyl ether. A highly volatile and inflammable organic liquid $(C_2H_5)_2O$ The term is also applied to all substances of similar composition, and even to esters or ethereal salts.

Ethereal—Pertaining to ether; thus by an *ethereal* solution is meant a solution in ether.

Ethereal Salts—A salt of an acid in which the hydrogen is replaced by ethyl (C_2H_5) or other radicals, just as a metal replaces the hydrogen of an acid to form metallic salts.

Eudiometer—A gas analysis apparatus

Excess—A reagent is present in excess when more than sufficient has been added to react with the portion ot a substance under examination.

Exothermic Compounds — Compounds in the formation of which heat is developed.

Extraction—Removal of one constituent from a mixture of substances by means of a solvent in which the remaining constituents do not dissolve.

FAT—Natural product composed of ethereal salts, such as glyceryl, stearate, palmitate, and oleate.

Fatty Acids—Acids formed on the saponification of fats. The generic term is now applied to several series of organic acids, including acetic and formic acids.

Fehling Solution—Solution of copper sulphate with Rochelle salt and caustic soda; used in testing for sugars.

Ferment—A nitrogenous organic substance with or without organised structure and power of reproduction.

Fermentation — Chemical process brought about by ferments.

Ferric or **Ferri Salts**—Salts of iron containing the trivalent iron atom.

Ferrous or **Ferro Salts**—Salts of iron containing the divalent atom

Filtrate—The clear liquid obtained by filtration.

Filtration—The separation of a solid from a liquid by passage through a porous medium.

Flask—A globular-shaped vessel of thin glass.

Fluxing—Melting or fusing.

Foots—The deposit of impurities formed in the process of clarifying oils.

Forchammer Process—Determination of amount of acidified permanganate required to oxidise organic matter in a sample of water (water analysis).

Fraction—A portion of a distillate which has passed over during a definite range of temperature.

Free Acid—An acid not in combination with a base.

Free Ammonia (in water)—Ammonia, probably in combination as a salt, sometimes termed *saline ammonia*, and obtained by distilling the water with sodium carbonate.

Free Base—A base not in combination with an acid.

French Chalk—Steatite or soapstone. A hydrated magnesium silicate.

Fusel Oil—Fermentation amyl alcohol formed in small quantities during alcoholic fermentation.

Fusion Mixture—A mixture of equal parts of sodium and potassium carbonates, which fuses at a lower temperature than either separately.

GAS LIQUOR—An aqueous liquor rich in ammonium salts obtained in the purification of coal gas.

Glauber's Salt—Sodium sulphate.

Glucose—See *dextrose*.

Glucosides—Naturally occurring vegetable substances which split up on hydrolysis, yielding glucose and another substance which is not a carbohydrate.

Gluten—A sticky, nitrogenous substance obtained by washing out the starch from wheat flour.

Glycerine or **Glycerol**—An oily liquid with a sweet taste, in reality an alcohol obtained by the saponification of natural fats and oils.

Gooch Crucible—One with a perforated bottom on which is a layer of asbestos so that the precipitate may be filtered, washed, and dried.

Grape Sugar—See *dextrose*.

Graphite—Blacklead; a form of carbon.

Gum—An amorphous carbohydrate characterised by its sticky properties and obtained from the natural exudations of plants.

Gun-cotton—Nitrocellulose obtained by treating cotton with a mixture of strong nitric and sulphuric acids.

Gypsum—Native crystalline calcium sulphate.

HALOGEN—One of the following four elements—chlorine, bromine, iodine, or fluorine.

Hardness of Water — The soap-destroying powder due to dissolved salts.

Homologues—Organic compounds of analogous composition to one another—for instance, methane, ethane, and propane are homologues.

Hydrate—A chemical substance having water in combination with it.

Hydrocarbon—A compound of carbon and hydrogen.

Hydrolysis—A type of chemical decomposition brought about by various agencies, but always accompanied by absorption of water.

Hydroxide—A compound consisting of a metal or radical in combination with hydroxyl groups—for instance, copper hydroxide $Cu(OH)_2$, alcohol or ethyl hydroxide $C_2H_5(OH)$.

Hydroxyl—The group (OH).

Hygroscopic Substance—One which absorbs moisture from the atmosphere.

Hypo—A prefix denoting a smaller proportion of oxygen.

INDICATOR—Substance used to indicate the completion of a reaction in titration processes — for instance, methyl orange.

Infusion—A liquid obtained by treating a vegetable substance with a solvent to dissolve out some of its constituents.

Inorganic Compounds—All compounds excepting those of carbon.

Isomeric Substances—Those having the same percentage composition, but different properties:

Isomerism—The phenomena exhibited by isomeric compounds.

-Ite—The terminal ending of names applied to salts of acids containing less oxygen than those ending in *-ate*.

KELP—The ash of certain seaweeds used as a source of iodine.

Kieselguhr—A porous silicious substance, with absorbent properties.

Kjeldahl Estimation—A method of determining nitrogen, especially in organic substances.

LACTIC ACID—An acid formed in the souring of milk by the action of a ferment on the milk sugar.

Lactose—See *milk sugar*.

Lævo-rotatory—Rotating the plane of polarisation of light to the left.

Lamina—A thin sheet or plate.

Laughing Gas—Nitrous oxide.

Leblanc Process—A method of making washing soda from common salt.

Lees—The deposit at the bottom of a vessel in which wine is fermented.

Lime—Calcium oxide obtained by burning limestone or calcium carbonate.

Liquation—The separation of bodies by heating and allowing the more fusible to melt and flow away.

Liquor—A general term applied to liquids containing dissolved matter.

Litharge—Lead oxide.

Litmus—A colouring matter obtained from a lichen and used as an indicator.

Logwood—The hard wood of a tree, which yields a red dye.

Lye—An alkaline liquor containing the caustic alkaloids or their carbonates.

MALTOSE, or **MALT SUGAR** — A sugar produced by the action of diastase on starch.

Marsh Gas—Methane (CH_4); the fire-damp of the miners.

Marsh's Test—A test for arsenic.

Measuring Flask—A flask which, filled to a mark on the neck, contains a measured volume of liquid.

Melt—A fused mass of crude product obtained by heating.

Mercuric Salts—Compounds of the higher oxide of mercury (HgO).

Mercurous Salts—Compounds of the lower oxide of mercury (Hg_2O).

Meta—A prefix used to distinguish one isomer from another.

Metal—An element which will combine with oxygen to form a base.

Methane—See *marsh gas*.

Methyl Orange—The sodium salt of an aniline dye; used as an indicator for strong acids.

Microcosmic Salt—Hydrogen sodium ammonium phosphate $HNa(NH_4)PO_4$.

Milk Sugar—A sugar found in milk.

Millon's Reagent—A solution of mercuric nitrate containing nitric acid.

Mineral Acid—This term usually includes sulphuric, hydrochloric, nitric, and other acids of inorganic origin.

Minium—See *red lead*.

Molecule—A word meaning little mass; the smallest particle of gaseous matter that can exist by itself.

Mordant—A substance used in dyeing to aid in fixing the dye on to the fibre.

Must—A crude liquor expressed from fruit.

NATIVE—Occurring in a natural state.

Nessler's Solution—A solution of mercuric iodide in potassium iodide, prepared according to a special recipe. It gives a yellow-brown colour, with even minute traces of ammonia, and a precipitate with larger quantities.

Nitre—Potassium nitrate.

Nitro-cellulose—Nitric esters of cellulose, such as gun-cotton.

Nitro-compound—One containing the nitro group (NO_2).

Nitrometer—A form of gas analysis apparatus used in the estimation of nitrous oxide in vitriol.

Nordhausen Sulphuric Acid—The fuming acid $H_2SO_4SO_3$.

Normal Acids and Alkalies—Solutions containing an equivalent weight in grammes of the substance in question dissolved in one litre of water at 15° C.,

Normal Solutions — Solutions of standard strength based on a sytem of chemical equivalence.

OLEFINS—A group of hydrocarbons of general formula C_nH_{2n}, where *n* is any integer; for example, olefiant gas.

Organic Compounds—All compounds of carbon, with the exception of the monoxide and dioxide, which are usually reckoned as inorganic compounds.

Oxidation—The process of adding oxygen or subtracting hydrogen from a substance.

Oxide—A compound of an element or radical with oxygen.

Oxidising Agent—A reagent for adding oxygen to or withdrawing hydrogen from a substance.

Ozone—A form of oxygen containing three atoms to the molecule.

PARAFFINS—A group of hydrocarbons of the general formula C_nH_{2n+}, where *n* is any integer; for instance, marsh gas (CH_4).

Pearlash—Calcined potassium carbonate.

Permanent Hardness—Hardness of water not removed by boiling, and generally due to the presence of dissolved sulphates.

Permanent White – Precipitated barium sulphate.

Peroxide—An oxide containing more oxygen than the common oxide.

Phenol—Carbolic Acid (C_6H_5OH).

Phenol-phthalein—An organic synthetic dye stuff used as an indicator for weak acids.

Pickling—A term applied to the process of soaking a solid in a liquid.

Pinch-cock—A spring clip for closing a piece of indiarubber tubing.

Pipeclay Triangle—A triangle clay pipe-stem held with iron wire, and used for supporting crucibles.

Pipette — Graduated glass tube for measuring liquids.

Plaster of Paris—Hydrated calcium sulphate or gypsum, from which part of the water has been removed.

Plumbago—Blacklead or graphite, a form of carbon.

Potash or Caustic Potash—Potassium hydroxide.

Precipitant—A substance used to bring about the formation of a precipitate.

Precipitate—A solid substance formed in a solution by a chemical reaction.

Proof Spirit—An antiquated and cumbrous standard of strength for alcohol. The density of proof spirit works out to ·91984 at 60° F. It contains 49·24 per cent. of alcohol by weight.

Proximate Analysis—The determination of the ingredients in a mixture of substances.

Prussian Blue—A pigment formed of complex cyanides of iron.

Pyrites—Native sulphides of iron, and of iron and copper.

Pyrolusite—A mineral containing crude oxide of manganese.

QUALITATIVE ANALYSIS — The process of ascertaining the nature of the constituents of a substance.

Quantitative Analysis—The process of ascertaining the proportions of the constituents of a substance.

Quartz—Crystalline silicon oxide or silica (SiO_2).

Quicklime—Calcium oxide (Cao).

RADICAL or **RADICLE**—A complex group of elements playing the part of, and reacting as, a single element.

Reaction—The chemical action of one substance on another.

Reagent—A substance, generally in solution, used to bring about a characteristic chemical reaction.

Red Lead or **Minium**—The oxide of lead (Pb_3O_4).

Reducing Agent—A reagent for adding hydrogen or abstracting oxygen from a substance.

Reduction—The process of adding hydrogen or withdrawing oxygen from a substance.

Reichert's Process—The standard method for estimating volatile fatty acids in butter.

Resin or **Colophony**—A resinous substance left in the retort after the distillation of crude turpentine.

Resins—A class of vegetable solids of brittle and glass-like fracture.

Rider—A small V-shaped wire which is shifted from one position to another on the beam of a balance, instead of putting weights into the pan.

Rochelle Salt—Sodium potassium tartrate.

Rock Crystal—Quartz.

Rock Salt—Native sodium chloride or unrefined common salt.

Rouge—Finely ground ferric oxide (Fe_2O_3).

SALINE—Partaking of the nature of a salt.

Saline Ammonia (in water).—See *free ammonia*.

Salt—Generic term for the product of the combination of an acid with a base.

Salt Cake—Crude sodium sulphate; the first stage in the manufacture of soda by the Leblanc process.

Sampling—The operation of removing a small portion or sample representative of the whole.

Sand Bath—A shallow metal tray containing a layer of sand on which vessels may be heated.

Saponification—The process by which a soap (metallic salt of a fatty acid) is obtained from a fat. The term is applied also to the hydrolysis of any ethereal salt with the formation of an alcohol and a fatty acid or its salt.

Saturated Solution—A solution containing as much substance dissolved in it as the liquid will take up.

Semi-normal—One half of normal strength.

Silicious—Composed of, or partaking of the nature of, silica or sand.

Slag—A fusible silicate formed in the process of obtaining metals from their ores.

Slaked Lime—Lime slaked; that is, treated with sufficient water to form calcium hydroxide.

Smelt—Cobalt blue. A silicate of cobalt.

Soap—The metallic salt of a fatty acid, generally oleic, palmitic, or stearic, or a mixture of these.

Soda Lime—A mixture of soda and lime, used for absorbing carbon dioxide gas.

Soft Soap—A potash soap or potassium salt of a fatty acid, hard soaps being sodium salts.

Solvent—Liquids used for dissolving substances.

Soxhlet Apparatus—An automatic apparatus for the extraction of fatty substances with volatile solvents.

Specific Gravity—The ratio of the weight of a substance to the weight of an equal volume of water.

Standard Solution—Solution of definite strength, usually normal or decinormal.

Steam Oven—An oven surrounded by a steam jacket.

Still—Distilling apparatus.

Suction Gas—See *water gas*.

Sulphonic Acid—An organic acid containing the group SO_3H.

Superphosphate—A manurial substance containing monocalcium phosphate.

Synthesis—The building up of a compound from its elements, or from simpler substances.

TALC—A substance of similar composition to French chalk.

Tartar Emetic—Potassium antimony tartrate.

Temporary Hardness—Hardness of water removed by boiling, and due to bicarbonates. See also *hardness*.

Thermometric Scales—Those commonly used are the Centigrade and Fahrenheit scales.

Thio—A prefix showing that oxygen in the substance has been replaced by sulphur.

Tincal—Crude borax.

Titration—The process of adding a measured amount of a solution of one substance to another until the reaction between them is complete.

Turmeric—Yellow colouring matter.

Twaddell Degrees — A technical method of reckoning the specific gravity of a liquid. Thus, Degrees

$$\text{Twaddell} = \frac{\text{specific gravity} - 1{,}000}{5},$$

water = 1,000

ULTIMATE ANALYSIS—The separation of substances into their constituent elements.

Ultramarine An artificial blue colouring matter resembling ground lapis lazuli.

U-tube—Glass tube in the shape of the letter U, and used for absorbing gases.

VACUUM DESICCATOR—A desiccator from which the air can be exhausted.

Valency—The combining capacity of an element or the number of hydrogen atoms or their equivalents with which an atom of the element in question will combine.

Vermilion—Sulphide of mercury; used as a pigment.

Vitriol—Sulphuric acid.

WASH-BOTTLE — Bottle or flask with which a jet of water can be directed on to a precipitate for the purpose of washing it.

Washing — Treating a substance (usually a precipitate) with successive quantities of a solvent, such as water, in order to dissolve soluble impurities.

Water Gas—A mixture of hydrogen and carbon monoxide gases obtained by passing steam over red-hot coke.

Water Oven—*Steam oven.*

Wax—An ethereal salt of a fatty acid, and a monohydric alcohol (alcohol with a single hydroxyl group).

Weighing-bottle—A small stoppered bottle in which a substance can be weighed out of contact with the surrounding air.

Weldon's Process—A process for the recovery of manganese from still liquors, and hence indirectly a method for making chlorine.

White Arsenic or **Arsenic**—Arsenic oxide (As_2O_3).

White Lead—Basic carbonate of lead.

YEAST — A vegetable (organised) ferment which is capable of converting sugar into alcohol.

ZINC WHITE—Zinc oxide (ZnO).

A FIGHT FOR THE WORLD'S CROWN

France in the Middle Ages—continued. Mediæval Italy. The Struggle between Pope and Emperor. The Rise and Fall of Rienzi. A Great Period of Art

By JUSTIN McCARTHY

IN 1590 Henry won a victory over the Leaguers, under the Duke of Mayenne, at the famous battle of Ivry, and in 1593 succeeded to the throne, having in July of that year professed himself a Catholic, the profession being celebrated with great pomp at St. Denis. In 1598 a peace was concluded between France and Spain, who had been at war for a long time, and in the same year Henry signed the famous Edict of Nantes, by which he secured to the Protestants liberty of conscience and equal treatment by the law

The Famous Henry of Navarre. Henry had already proved himself one of the great warrior princes of France, and he now showed that he had high qualities for civil government. When he came to the throne, the landed aristocracy managed the affairs of the provinces according to their personal will and after the most arbitrary fashion as regarded the imposition of taxes and compulsory service. Henry threw his heart into these questions, and accomplished many splendid reforms. He instituted also a system of road-making, by which he opened up all parts of his kingdom to business enterprise and traffic, and thus developed industry and prosperity throughout France.

In his great work of reform Henry was well supported by his minister, Maximillian, Duke of Sully. Sully had accompanied Henry in his flight from the French Court ; had gone with him afterwards into his wars : had proved himself a brilliant soldier, and helped to win victory at Ivry, and other battles. Sully set himself at once to repair the ruined financial system of the State. Within ten years he reduced the National Debt to less than one-sixth of what it represented when he took charge of the national exchequer. During his time, he raised the revenue of the State to more than double its annual amount, while he took care that the navy and war departments were put into a satisfactory working condition. The great reign of Henry came to an end on the 14th of May, 1610. He was murdered by a man named François Ravaillac, who had been a schoolmaster, had become bankrupt, and, after long imprisonment, had joined a monastic order. It is believed that Ravaillac was driven by fanaticism to kill the sovereign who was giving religious liberty to his subjects. It has been well said by a French historian that Henry was the greatest, and, above all, the most essentially French of all the sovereigns of France.

International Arbitration. Among some of his projects was the idea, revived at intervals since his time, of a confederation of European states, at which all international questions should be settled by inquiry and arbitration, without an appeal to arms. Like many other great soldiers, he was at heart a lover of peace, and was filled with a conviction that an international tribunal could be formed by whose careful consideration and judicious decisions reason and equity could be made to triumph, without the uncertain services of the sword.

ITALY

Italy remained for centuries in a condition of almost incessant civil war among a number of rival states such as Rome, Venice, Milan, Naples, Sicily, and others—when the Italians were not engaged in endeavouring to repel invaders from their own shores

In 800, Pepin, the son of Charlemagne, was crowned Emperor of the Romans, and another descendant of Charlemagne, Louis II., came to the aid of Pope Leo IV. against the Saracens, and, for a time, checked their progress. Eight kings of the Carlovingian line were acknowledged in Northern Italy, but their rule ended in 887, and they were followed by ten Italian kings—kings in name, at least—dukes of different parts of Italy. In 961, Berengar II. was deposed, and Otto of Saxony was crowned King of Italy at Milan and Emperor of Rome at Rome From that time the Crown of the Roman Empire, later called the Holy Roman Empire, was claimed by the sovereigns of Germany for many centuries

During all these long struggles Rome had continued to be the seat of the Papal power; but even the power of the Popes had not been able to secure the great city as their permanent place of residence during the whole of the Middle Ages, for in 1307 the Papal Chair had to be removed to Avignon, in France, where it remained until 1370, when it was restored to Rome by Pope Gregory XI.

The Papal Fight for Temporal Power. Throughout the Italy of the Middle Ages two great forces dominate, forces which, in the eyes of the idealists of the time should unite to govern the world, forces which, as a matter of fact, were mostly set in steady opposition. These two forces were the Pope and the Emperor. The heir of Peter and the heir of Cæsar strove for the world's crown instead of guarding it with the sword and the keys. The conflict of these great chiefs split all Italy into two great factions, they themselves afterwards subdividing by different political and local causes in very bewildering fashion. The struggle of the Guelphs and the Ghibellines contributes much to the most fascinating history of mediæval Italy. Though the names of the two factions are now always associated with Italy, they had their origin in Germany. That country, steadily conquering portion after portion of the Roman Empire, gave to subjugated Europe an aristocracy of

German names, and gave to Italy besides the names of the two great parties whose feud rent every Italian city and divided many an Italian household.

The Wars of the Two Factions. Otto of Freising, writing of the middle of the twelfth century says, "Up to the present time two families have been famous in the Roman Empire, about the parts where Gaul and Germany meet—the Henries of Waiblingen and the Welfs of Altdorf." The name of the little town of Waiblingen and of the family of Welfs were Italianised into the forms we now know as Ghibelline and Guelph. Through the perplexing and intricate history of mediæval Italy, with its many independent cities and little principalities all warring one with another, these two names of faction are ever to the front. It is not easy to estimate precisely what the two terms signify. Speaking roughly, the Ghibellines stood for stern authority and the Guelphs for popular liberty; but the exact significance of the terms varied under varying conditions. Broadly, the Ghibellines were the party of the Emperor, and the Guelphs the party of the Pope A hostility that dawned with the expedition of Frederick Barbarossa against Italy in 1154 persisted through the ages, and its influence is perhaps not yet altogether extinct.

While Pope Innocent III. was giving the law to every kingdom of Europe; while the Emperor Frederick II. was the most brilliant figure in his brilliant Court, and was coming under the excommunication of Guelphic pope after Guelphic pope; while from Frederick's death in 1250 to 1309 no Emperor was recognised in Italy, the Guelphs and the Ghibellines continued to rage against each other.

The Dream of Rienzi. During the years when the Papal seat was at Avignon was seen the rise and fall of Cola de Rienzi. This remarkable man was born of humble parents, in 1313, but was from his childhood an eager student of the great Latin Classics, and he became filled with a passionate desire to restore the Roman people to their ancient position of independence and glory He found Rome suffering under an aristocratic rule during the intervals of its invasions and captures by foreign powers. The death of his brother by the wanton act of a noble, and the knowledge that he could obtain no redress, gave a sudden stimulus to his revolt against the power of the nobles. In 1347 he succeeded in inducing the citizens of Rome to rise against the aristocratic Senate. The Senatorial rule was for the time completely overthrown, and Rienzi was made Tribune, a position which was practically that of Dictator. He endeavoured to bring about the realisation of that dream which was yet to remain a dream for some centuries—the unity of Italy, with Rome for its centre of government.

He prevailed upon the other states of Italy to send delegates to Rome to consult on measures for the construction of a great Italian confederation. The scheme was received with enthusiasm, and on August 1st, 1347, two hundred deputies assembled in the Lateran Church, and Rienzi was crowned Tribune of the new Federation on April 15th. But the delegates, like Rienzi himself, had been carried away by enthusiasm, and had not estimated the immense power of the aristocrats. Rienzi defeated the nobles in a bloody battle in November, but, filled with the pride of victory, he tried to enforce obedience, and became unpopular. The Pope declared against him, and after only seven months of his exalted position the bright dream faded, and the Tribune had to seek refuge in Naples, where he remained for two years leading a life of religious seclusion.

A Failure due to Success. He then determined to go back to Rome and continue his efforts for the overthrow of the nobles. He first went to Prague to ask the support of the Emperor Charles IV., but was sent by him as a prisoner to Pope Clement VI. By the intercession of Petrarch he was released, and the new Pope, Innocent VI., who had succeeded, wishing to crush the nobles, sent Rienzi to Rome with Cardinal Albormoz. Now might have come the triumphal hour of the people's Tribune. But Rienzi seems to have been carried away, for the first time, by personal ambition, and his second success led him into the desire to win for himself a supreme position. He formed a body of soldiers into a guard of his own, and headed a procession into Rome in August, 1354 His general bearing seems to have convinced a large number of Romans that he was an ambitious self-seeker rather than a devoted patriot; where he was once adored he was now detested, and in a sudden burst of fury a number of the populace surrounded his house and put him to death.

The career which had opened so brilliantly came to this ghastly end on October 8th, 1354, when Rienzi had hardly passed his prime. There can be no question that he was a man of great ability and force of character, and that he had then dreamed a dream for that unity of Italy which has in our days become a living reality. In 1370, Gregory XI restored the Papal throne to its place in Rome.

The Times of Dante. The years at which we have been taking a rapid glance form a period during which some of the greatest names in Italian art and letters came into their full lustre. Dante Allighieri, one of the great poets of all time, was born in Florence, in 1265. In 1289 he took part in the battle of Campaldino, but he seems soon to have given up military life for politics, in which he sided with the Guelph party. When that party later became divided into Blacks and Whites, his sympathies were with the Whites, or more moderate Guelphs. When the Blacks triumphed, Dante and others—among them the father of Petrarch—were exiled from Florence, in 1302. Dante went first to Verona, then to other parts of Italy, and, it is said, to Paris, and finally to Ravenna, where he died on September 4th, 1321, and was buried by his friend Guido. Of his many works those best known to English readers are the "Divine Commedia" and the "Vita Nuova," which tells of his love for Beatrice.

Petrarch, another great Italian poet, was born in Arezzo, in 1304. He lived for many years at Vaucluse, near Avignon, during the years when the Papacy was established at Avignon, and it was there that he first met the Laura to whom his famous sonnets are addressed. He died in Italy—at Arqua—in 1374. There were other great names in literature and, of course, very many in painting and sculpture, which arose in Italy during succeeding generations, but those of Dante and Petrarch will vindicate the claims of the Italy of the Middle Ages to rank with the Italy of the days of Virgil and Horace.

Italy under Five Rulers. The history of Italy now becomes for a long time a narrative of the struggles between rival rulers and families at home for the possession of Italian regions which had been lost, or for further conquests. The Italian peninsula was divided among five different rulers The Kingdom of Naples, the Duchy of Milan, the Republics of Florence and Venice, and the Papacy at Rome held the country as independent powers. The states were, however, not held continuously by the same line of rulers, for there were frequent changes of masters. Venice was ruled for the most part by a hereditary Grand Council, and her long contest with Genoa to become the ruling power of the Mediterranean had ended in success for Venice. The Emperor Charles V. of Germany, and Francis I. of France, rivals in their efforts for power in Italy, kept the country long distracted.

The Sack of Rome. Francis regained possession of Milan in 1515, but some years after the Emperor was again successful; in 1524 he drove the French forces out of Italy, and during the long struggle the French King was actually taken prisoner at Pavia. The sack of Rome by an army made up chiefly of Lutherans and Spaniards, fighting for the Emperor, and the foreign occupation of Rome, lasted for several months, and distracted the great historic city by successive and horrible scenes.

The family of the Borgias, which was one of the most powerful in mediæval Italy, came originally from Spain. Alfonso de Borgia, a bishop, accompanied Alfonso of Aragon, whose secretary he was, to Naples. Later on he was chosen as Pope, with the title of Callixus III. His nephew Rodrigo became Pope in 1492, as Alexander VI. Before he ascended the Papal chair he was the father of many children, of whom Cæsar, his fourth child, and Lucrezia, his fifth, were the most famous. Cæsar Borgia was born in 1476 and died in 1507. His active life lasted only about four years. His ambition was to reconstruct a Kingdom of Central Italy, of which he should be the head; and it seemed for a time as if he would succeed. But the death of his father in 1503—it was believed by poison—was fatal to Cæsar's plans. Pope Pius III. was succeeded by a great enemy of Cæsar's - Pope Julius.

Cæsar was imprisoned in 1504, but escaped two years later, and went to Navarre, where he was killed while in command of the Royal forces in the following year at the age of thirty. About him was written Machiavelli's famous "Principe." He was a lover of art and letters, and the patron of Lionardo da Vinci.

The Medicis. During the fifteenth century the family of the Medici had become practically the rulers of Tuscany. With Cosimo de Medici (1389-1464) began the glorious epoch of the family. He obtained for Florence, which was still—at least nominally—a Republic, a temporary safety from invasion and something like peace from civil strife. He devoted much of his time and wealth to the encouragement of letters and art; he adorned the city with magnificent buildings, and established some great libraries. He was the grandfather of the famous Lorenzo de Medici, called "The Magnificent," most famous as the patron of Michelangelo.

To a younger branch of the family belonged the next important ruler of Florence, Cosimo I., who at one time enjoyed the distinction of the title of "The Great." Cosimo had much ability, energy, and statesmanlike capacity, and had inherited the love for literature and art of some of his predecessors. He was, on the whole, a just ruler, though in his personal dislikes he was severe and capricious. He was made Grand Duke of Tuscany in 1570, and was crowned by Pius V. He died four years later.

TECHNICAL DRAWING continued from page 4206

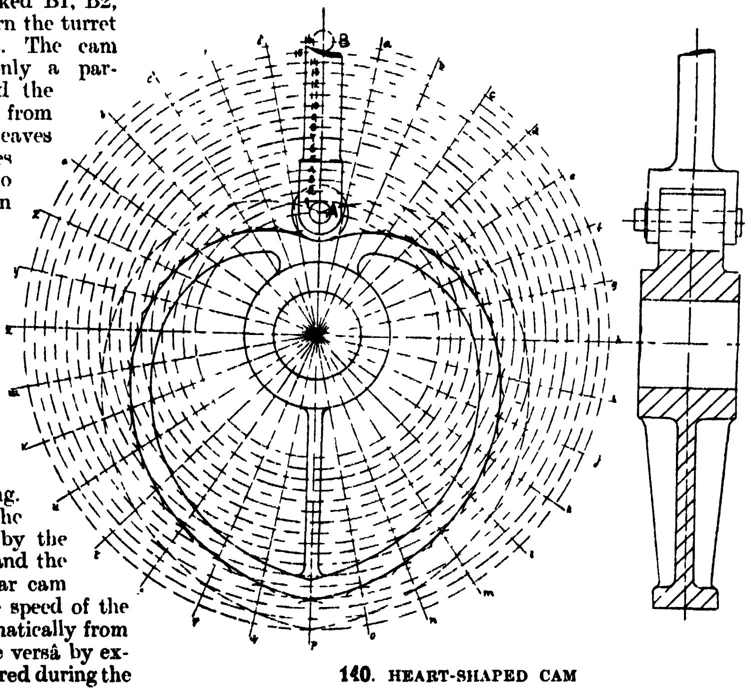
By JOSEPH W. HORNER

Cams. After the detail drawing of the frame of a machine has been completed, the minor details are drawn out on separate sheets as previously explained. Fig. **141** illustrates a working detail drawing of the cams of an automatic screw machine. The views shown comprise a separate detail of each cam and a general lay-out of the cams upon the drum which carries them. The drum is circular, but its periphery is developed in order to figure thereon the exact measurement for spacing the cams. The turret of the automatic machine described on page 3632 in MECHANICAL ENGINEERING is controlled by a series of cams somewhat similar to those we now illustrate in **141**. The cams are of tempered spring steel, and are secured to the drum by means of ½-in. screws; the working face of each cam has a bevelled edge arranged so that the turret roller may clear the face of the drum and yet have complete contact with the cam. The drum is 30 in. diameter, the length of its periphery or circumference is therefore 94·248 in. The width of the drum is 10 in., which allows for a total travel of the turret of 9¼ in. A line marked zero is the base from which all measurements are taken when spacing the cams around the drum.

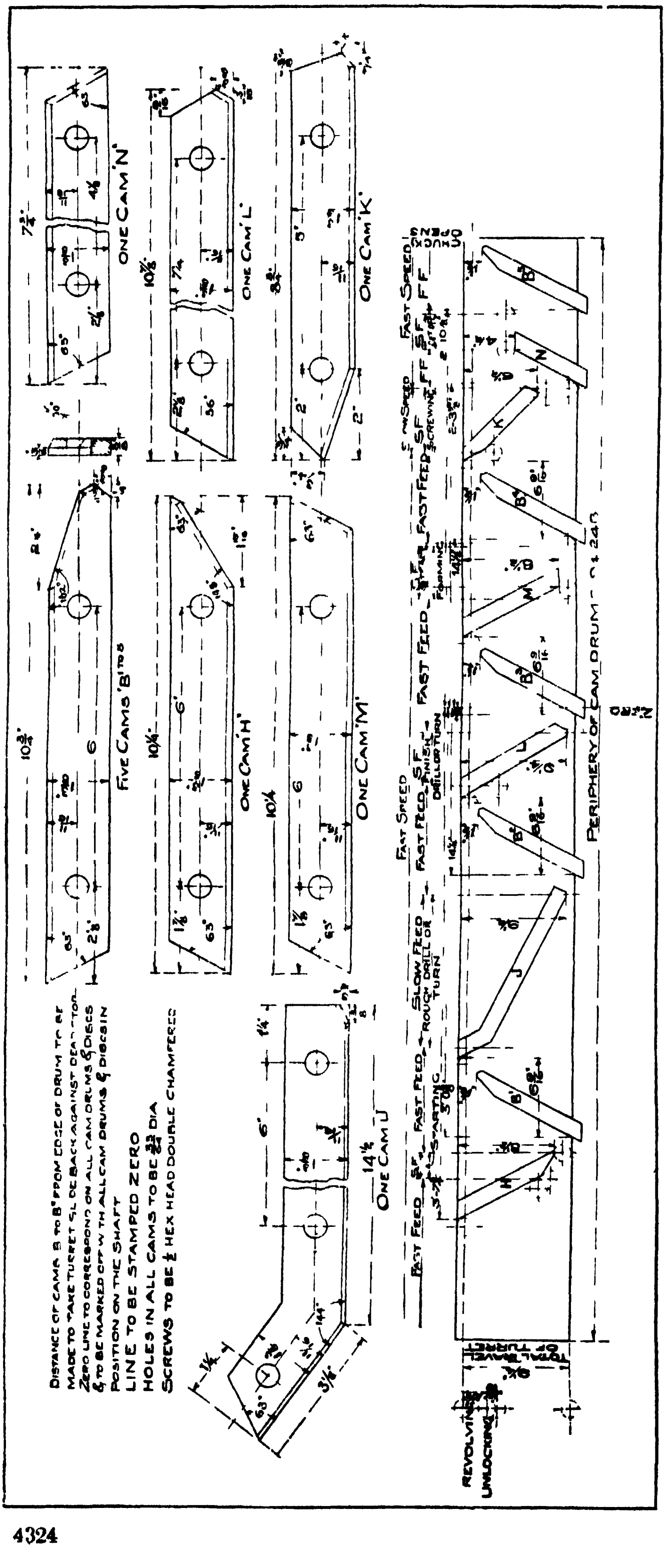
The cams marked H, J, L, M, and K are used for feeding the turret forward for various operations, while the cams marked B1, B2, B3, B4, and B5 return the turret from the operations. The cam marked N gives only a partial return feed, and the turret is stationary from the time cam N leaves it until cam B5 catches the turret roller to complete the return feed. This period is taken up by the cutting off of the finished screw from the stock bar in the chuck. There is a somewhat similar period of rest between cam M and cam B4, which is taken up by the forming tool coming into action and retiring.

The speed of the turret is governed by the speed of the drum and the angle of the particular cam in engagement. The speed of the drum is varied automatically from fast to slow and vice versâ by external means as required during the revolution; the slow speed is used while a screw is being actually machined, the other cutting operations being performed, at fast speed. All the return feed cams, B1 to B5, are set at an angle of 63 deg. for quick return, while some of the forward feed cams, U in particular, have a very much smaller angle, and consequently feed considerably slower; in fact, the angle of the cam is designed to suit the rate of feed, and this is determined by the nature of the work to be done by the active tool in the turret. The duty of each cam is stated on the general lay-out. The illustration [**141**] is reproduced from an actual working drawing supplied by Messrs. Alfred Herbert, Ltd., Coventry.

Heart-shaped Cam. The cams in the preceding example are single acting—that is, they do not separately complete the reciprocal movement of the turret. In many mechanisms it is essential that a single cam shall complete a forward and backward stroke, when it takes the form of a revolving plate properly shaped to give the required movement. Fig. **140** shows a heart shaped cam, designed to give a uniform reciprocating motion to a vertical rod. To mark it out properly, we first consider the path to be traced by the centre of the roller which is on the rod. Draw circles for the shaft and the boss of



140. HEART-SHAPED CAM



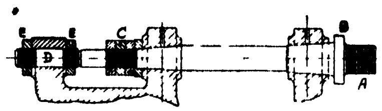
Distance of cams B to B' from edge of drum to be made to take turret slide back against dead stop.
Zero line to correspond on all cam drums & discs & to be marked off with all cam drums & discs in position on the shaft
Line to be stamped zero
Holes in all cams to be 33/64 dia
Screws to be 1/4 hex head double chamfered

141. CAMS FOR AN AUTOMATIC SCREW MACHINE

the cam, lay off the thickness of the cam rim above the boss, which thickness may be one-quarter the diameter of the shaft, and then describe the roller and its rod. The stroke or travel of the rod A B is measured off and divided into any given number of parts (say 16), dotted circles are drawn through these points, as shown, using the shaft centre as a common centre; then divide the circumference of the outer circle into 32 equal parts, *a*, *b*, *c*, etc., and draw radial lines to the centre. The theoretical curve of the cam passes through the intersections of 1*a*, 2*b*, 3*c*, 4*d*, 5*e*, and so forth, such a curve being the true path of the roller centre. To obtain the actual outline of the cam, a series of arcs are struck from the intersections, the radii of the arcs being the radius of the roller. A line touching all these arcs and having a smooth curve is the outline required

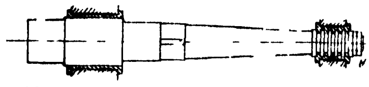
Small cams are frequently formed from flat sheets of metal, but large ones are made with rims and ribs as **140** The outlines of cams can be varied to give variable speeds, periods of rest, slow speeds, and quick return motions, etc In *crushing machinery* cams are often used to lift a weight, which drops freely when the apex of the cam leaves it. In such cases the cam has no return face.

Spindles. Spindles are small shafts, used in machine tools and light machinery They are generally short, and have special provision for adjustment and lubrication. Fig. **142** shows a spindle as fitted to a lathe headstock. The front end, A, is screwed to receive the faceplate, and a collar, B, is made part of the spindle in order to stop the faceplate always in the same position. The coned necks in the two front bearings are arranged so that when wear takes place the necks may be drawn into the bearings and the slackness taken up without lowering the centre of the spindle. The back lock nuts, C, are for drawing the spindle into the bearings; the back cone is smaller than the front cone so as to pass through the front bearing. The third bearing carries a stop pin, D, the function of which is to prevent the conical parts from jamming in the bearings when end thrust occurs. It is fitted with adjusting nuts, E. The taper of the cones may be from 1 in 4 to 1 in 6, measured on the diameter.

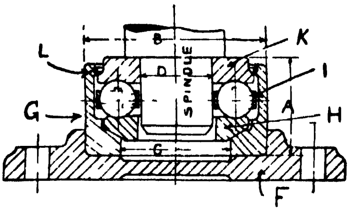


142. LATHE SPINDLE WITH CONES

Another spindle is indicated in **143**, where end thrust is taken in a *thrust bearing*. A number of collars are turned on the spindle to fit into a corresponding number of recesses in the back bearing; both the front and the back bearings are divided and fitted with caps, so that adjustment can be made for wear. The bearings are parallel, and lock nuts, A, are provided for the purpose of taking up wear on the faces of the thrust collars. This is a common form of spindle on heavy lathes where the end thrust is considerable.

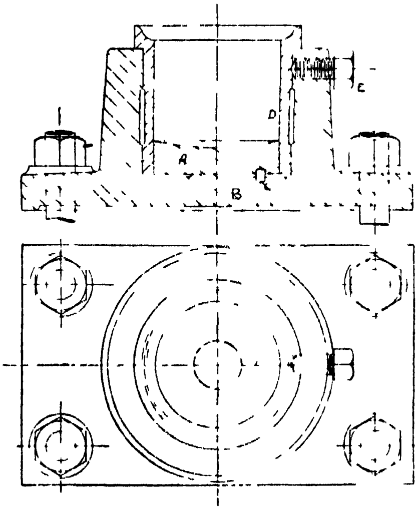


143. LATHE SPINDLE WITH THRUST COLLARS



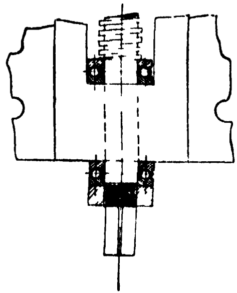
144. BALL-THRUST FOOTSTEP BEARING

Thrust Bearings. The most efficient thrust is that made with steel balls, for in such construction rolling friction takes the place of sliding friction. Fig. **144** illustrates a ball-thrust bearing arranged at the bottom end of a vertical spindle. This is made by the Hoffmann Manufacturing Co., Chelmsford. The construction is simple and entirely self-contained; the baseplate F can be made to suit any machine, or it may be part of a machine. The ball thrust proper is composed of an outer cast-iron casing, G, recessed into the baseplate F; a cone or floating disc, H, which automatically adjusts itself in its seating and so ensures an equal load upon all the balls; a ring of balls held in a retaining cage, I, a hardened steel cup, K, and a retaining wire, L. The retaining cage I prevents any friction between the balls themselves; it is so designed as to float upon the balls, and therefore it does not bear upon either the cup K, the cone H, the casing G, or upon the spindle itself to cause friction. The retaining cage also enables the complete ring of balls to be handled without the balls falling out, a great convenience when putting a bearing together or dismantling. The retaining wire L keeps all the parts together. It is not necessary to key either the cone H or the cup K in place, as the friction between them and the balls is so slight that the friction between them and their seats is ample to prevent rotation. The steel balls are "Hoffmann balls," and are guaranteed to be within one ten-thousandth part of an inch of standard, both as to sphericity and size. These bearings do not provide for side support of the spindle, but only for end thrust; they are made in heavy, medium, and light types. A table of sizes of the medium type is given on page 4327.



146. PLAIN FOOTSTEP BEARING

Footstep Bearing. An ordinary footstep bearing is shown in **146**, which provides for end thrust and also for side support of the spindle, but is not so efficient as the previous example. The thrust is taken upon a concave steel disc, A, laid upon the baseplate B, and kept from turning by the pin C; the disc A is kept in a central position by the gun-metal bush D, which bush also gives side support to the spindle; the set screw E keeps the bush from turning.



145 BALL-THRUST WASHERS

Ball-thrust Washers. A common device to take end thrust on light spindles is to have several washers arranged between the end bearing and a collar on the shaft. A better method is illustrated in **145**, which shows an application of two Hoffmann ball-thrust washers to the feed screw of a lathe slide. The ring of balls is held in a retaining cage as in **144**; hardened steel washers are provided for the balls to run between; these bearings are made with a hole five-thousandths of an inch larger than standard, so as to allow the spindle to revolve freely inside the washer. The end of the spindle is screwed and fitted with a circular nut, which is kept from revolving by a pin passing through both nut and spindle.

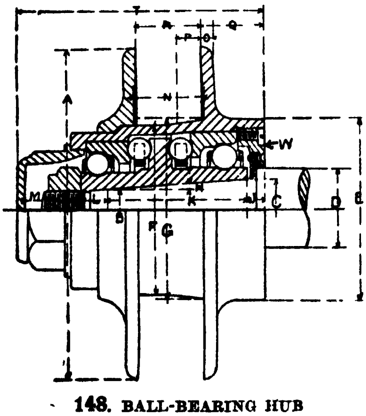
Ball-bearing Hubs. A good example of a ball bearing which takes both end pressure and journal pressure is shown in **148**. It is known as the Hoffmann patent *ball-bearing hub*, and is specially designed for motor-cars and vehicle wheels of all kinds. There are four rows of balls in each hub: the two outer rows take the journal load whilst the two inner rows take end thrust in either direction. The load is taken in each case at right angles to the axis of rotation of the ball, and a perfect rolling action is attained with a consequent minimum of friction. The cone piece is of hardened steel ground out internally to a taper which fits the axle and is held on by a nut and pin in the usual manner. When this nut is removed, the wheel, with the bearing complete, can be taken off the axle. The removal of the wheel with bearing does not interfere in any way with the adjustment of the ball bearings. When it is required to dismantle the bearing, it is done easily by unscrewing the disc nut W at the inner end of the hub, and withdrawing the bearing from that end. The balls are held in retaining cages and do not fall out when the bearing is taken to pieces. Leather washers are fitted to the disc nut in order to exclude dust. A table is given on this page showing the leading dimensions of the heavy type. They are also made in medium and light types.



148. BALL-BEARING HUB

The use of ball bearings as a means of reducing friction between moving parts has wide applications apart from the examples given, but the principles of design and construction do not materially alter.

Roller Bearings. Another anti-friction appliance is the roller bearing, the underlying principle of which is identical with the ball bearing—that is, the substitution of rolling friction for sliding friction. Bearings are made having solid rollers interposed between the shaft and its seating; such bearings when properly designed are a great improvement on plain bearings having sliding friction, but they are not perfect. To obtain the best efficiency and the longest life out of a roller bearing the rollers must be flexible, so as to present even bearing surface along their entire length. The irregularities incidental to the running of shafting and axles prevent the uniform distribution of load over the full length of the bearing, resulting in unequal wear and distortion of the rollers

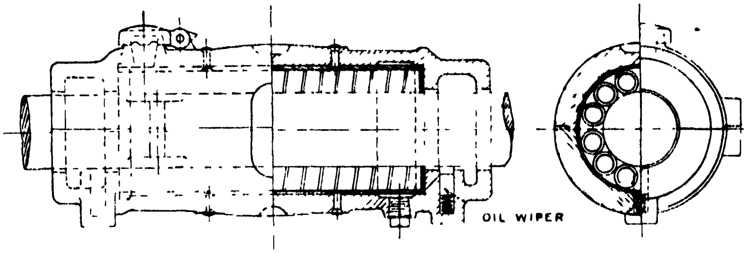
149. WAGGON ROLLER BEARING (Hyatt Roller Bearing Co., Ltd.)

when they are made solid, and consequently rigid. There are several methods of making rollers flexible, one of the best of which is adopted in the Hyatt *flexible roller*. This roller is made from a strip of steel wound into a coil or spring of uniform diameter; it is applicable to all speeds and loads, and can be made of thin material for light loads and high speeds, and of thicker material for heavy loads and slow speeds. The roller acts as an oil reservoir and the spiral grooves as oil carriers. If dirt or other foreign matter get into the bearing it is squeezed into the inside of the roller away from the bearing surfaces.

Eccentric Bearing. Fig. **147** shows an application of the Hyatt flexible roller. It is a drawing of the eccentric bearing of a cotton gin. The bearing is not concentric with the shaft, but the centres are ⅝ in. apart, which gives a reciprocal throw of 1¼ in. to the socket A. This movement is virtually a cam action and is carried out at the high speed of 1,000 revolutions per minute. The eccentric B has a split-steel sleeve fitted to it, this being ground to give a true and hard bearing surface for the rollers. A similar sleeve or lining is fitted inside the strap C. The rollers lie between the sleeves and are kept in place by a retaining cage, which holds them in such a way as not to restrict their operation but simply to prevent them from getting too far out of line. The split sleeves are shown in detail, and they are kept from turning by pins as indicated in the general views. The strap C is in halves to facilitate removal, and it has bronze end-plates fitted. The bearing is kept flooded with oil.

Waggon Bearing. A unique yet entirely successful application of the Hyatt roller is given in **149**, which is a copy of a working drawing. It represents a waggon axle-box as made for the North Eastern Railway Company. The journal is 5 in. diameter and 9¼ in. long; the end of the axle is reduced in diameter and a steel ring is shrunk on in order to keep the sleeve in place. The outer and inner sleeves are split and ground true as in the previous example; the rollers are kept in a retaining age. A bronze thrust block is fitted in the end cover of the box, and also an oiling ring to ensure the lubrication of the thrust block. The external arrangement of the box is normal; there is the usual dust-guard at the inner end and the usual formation of spring seat on the top. The box has grooves for double horn plates as shown. This bearing after being in use for a twelvemonth is still in perfect condition. This class of bearing is widely used in a lighter form for small cars and mine trucks, and very frequently in such cases the wheels are loose on the axles and contain the roller bearing in their bosses.



150. SWIVEL ROLLER

Swivel Bearing. Great saving in power is effected when roller bearings are applied to line shafting. Fig. **150** illustrates the construction of one fitted to such a bearing as is shown in **61** on page 3265. The construction is generally as the preceding examples, but the inner sleeve is omitted. Small metal wipers are fitted at each end to prevent oil from creeping along the shaft, and so getting outside of the bearing. Such a bearing is suitable for high speed shafting. The scope of the Hyatt flexible roller is much wider than the examples we give. In motor-car work alone it is used very extensively.

Sketches. Freehand sketches are made for simple details in order to avoid the time and labour of making scale drawings. The sketch should show proportionately the different sizes of the article depicted, but it need not be made to scale. Fig. **151** shows a sketch made for a repair job. Considerable art and practice is required to make an intelligent sketch of this nature. It is necessary to give all the information required for the complete manufacture of the article. Many cases of repair are most urgent, and no time can be spared for a second visit to the scene of the breakdown if all particulars be not taken at first. In the case illustrated [**151**] the "Onward" arrives in harbour with her port paddle wheel damaged, and it is highly important that she should leave with the next tide. Sketches accordingly are made from measurement of the broken parts, and new ones are manufactured therefrom in the shortest possible time. Insufficient or inaccurate information on the sketch is a most serious matter.

151. DETAIL SKETCH

Duplicating Sketches. Sketches are also made to supplement working drawings when the latter are to be used a second time in the shops but are not strictly correct in some detail. For example, a second machine may be required to be made from a certain set of drawings, and improvements or modifications are desirable; such alterations may not warrant the making of a fresh set of drawings yet the workmen must have definite information to work to, and a record must be kept of both machines. A convenient procedure is to make sketches of the modifications required, and to attach such sketches to the drawing. The office record is obtained by the simple process of making the sketch with ordinary copying ink, and press copying into a book just as one would copy a letter. The reference on the bottom right-hand corner of **151** indicates that the sketch is copied on page 325 of sketch-book No. 3.

Value of Sectional Paper. Sectional paper, or *squared paper*, as it is sometimes termed, is of great assistance in making sketches to scale; it can be obtained in various qualities and rulings. A number of vertical and horizontal intersecting lines are printed faintly upon the paper, the effect of which is to cover it with a quantity of small squares drawn to some definite scale. By the use of this paper fairly elaborate sketches may be made to scale without the use of instruments. Such paper is useful in many ways, one of which is the plotting of lines and curves to show the fluctuation of factors or values; the results of experiments, and tests may be seen at a glance when properly laid down on squared paper in the same manner as we see the variations of a recording barometer.

Another use for sectional paper is the construction of calculating charts; these are used to facilitate calculations by eliminating tedious arithmetic, and they are quite as useful to the draughtsman as is an ordinary slide rule. The strength of gear wheels, belts, columns, etc. can be plotted on a chart in such a way that any two factors being given, the third may be read directly from the chart without calculation.

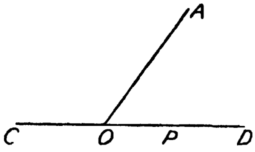
TRIANGLES

Classification of Triangles with respect to their Sides and to their Angles. Equality of Two Triangles. Isosceles Triangles

By HERBERT J. ALLPORT, M.A.

Proposition 2. Theorem

If two adjacent angles be supplementary, the exterior arms of the angles are in the same straight line.



Let the adjacent angles COA, DOA, be supplementary.

It is required to prove that CO and DO are in the same straight line.

Proof. If CO and OD are not in the same straight line, produce CO beyond O to any point P. Then

∠s COA, AOP are supplementary (*Prop.* 1).

But

∠s COA, AOD are supplementary (Hyp.).

$\therefore \angle AOP = \angle AOD.$

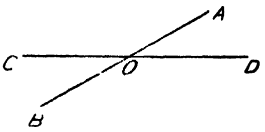
∴ the line OP must fall along the line OD.

But OP is in the same straight line with CO.

∴ OD must also be in the same straight line with CO.

Proposition 3. Theorem

If two straight lines intersect, the vertically opposite angles are equal.



Let AB, CD intersect at O.

It is required to prove that

(i.) $\angle DOA = \angle COB$.
(ii.) $\angle COA = \angle DOB$.

Proof.

∠s DOA, COA are supplementary (*Prop.* 1).
∠s COB, COA are supplementary (*Prop.* 1).
∴ ∠s DOA and COB are equal.

In a similar way it can be shown that ∠s COA, DOB are equal.

TRIANGLES

1. *Rectilineal figures* are figures which are bounded by *straight* lines.

A *triangle* is bounded by *three* straight lines; a *quadrilateral* by *four*; and a *polygon* by more than four.

A rectilineal figure is
  equilateral when it has all its sides equal,
  equiangular when it has all its angles equal,
  regular when it has all its sides equal and also all its angles equal.

2. A triangle is
  equilateral when all three sides are equal,
  isosceles when two sides are equal,
  scalene when all the sides are unequal,
  right-angled when one of its angles is a right angle,
  obtuse-angled when one of its angles is obtuse,
  acute-angled when *all its angles* are acute.

NOTE 1. Any angular point of a triangle may be looked upon as *the* vertex of the triangle. The side opposite to this angle is then called the *base*. In the case of an isosceles triangle the intersection of the equal sides is generally taken as the vertex.

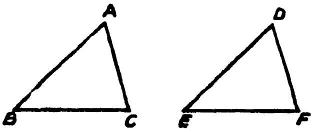
NOTE 2. In a right-angled triangle the side opposite to the right angle is called the *hypotenuse*.

NOTE 3. The three sides and three angles of a triangle form the six *parts* of the triangle.

Two triangles are said to be *equal in all respects*, or *congruent*, when the six parts of the one are equal respectively to the six parts of the other.

Proposition 4. Theorem

If two triangles have two sides of the one equal, respectively, to two sides of the other, and have also the angles contained by these sides equal to one another, then the triangles are equal in all respects.



Let ABC and DEF be two triangles in which

$$AB = DE$$
$$AC = DF$$
$$\angle BAC = \angle EDF.$$

It is required to prove that the Δ ABC = ΔDEF in all respects.

Proof. Place the ΔABC on the ΔDEF so that the point A falls on the point D, and the line AB falls along the line DE. Then, since AB = DE, the point B must fall on the point E.

Also, since the ∠ BAC = ∠ EDF, the directions of their other arms must coincide; so that AC falls along DF. And, because AC = DF, the point C must fall on the point F.

Hence, we have shown that the Δ ABC can be placed on the ΔDEF so that the three angular points of the one coincide with the corresponding angular points of the other.

∴ the Δ ABC = the Δ DEF in all respects, *i.e*,

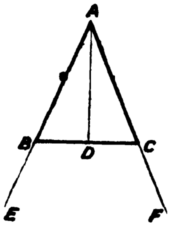
$$BC = EF$$
$$\angle ABC = \angle DEF$$
$$\angle ACB = \angle DFE$$

Δs are equal in area.

Proposition 5. Theorem

The angles at the base of an isosceles triangle are equal.

Let ABC be an isosceles Δ, in which AB = AC.



It is required to prove that

∠ABC = ∠ACB.

Proof. Suppose AD is the straight line which bisects the ∠BAC, and meets the base at D.

Then, in the △s BAD, CAD,

BA = CA

AD is common to both △s,

included ∠BAD = included ∠CAD.

Therefore, △BAD = △CAD in all respects [*Prop.* 4].

Therefore, ∠ABC = ∠ACB.

Corollary 1. If the equal sides of an isosceles triangle are produced, the exterior angles so formed are equal.

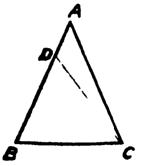
In the figure, ∠CBE = ∠BCF.

For they are respectively the supplements of the equal ∠s ABC, ACB.

Corollary 2. If a triangle is equilateral it is also equiangular.

Proposition 6. Theorem

If two angles of a triangle are equal, the sides which are opposite to these angles are equal.



Let ABC be a △, in which

∠ABC = ∠ACB.

It is required to prove that AC = AB.

Proof. If AB is *not* equal to AC, one of them must be the greater. Suppose AB > AC, and from BA cut off BD equal to AC. Join CD.

Then, in the △s ACB, DBC

AC = DB

BC is common to both △s

included ∠ACB = included ∠DBC.

∴ △ACB = △DBC in all respects (*Prop.* 4).

Hence the △s are equal in area, so that the part is equal to the whole; which is impossible.

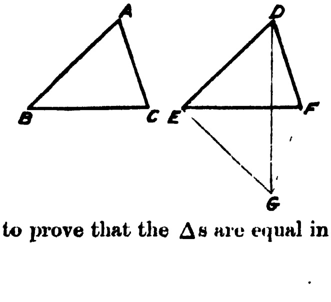
∴ AB and AC cannot be unequal, so that AB = AC.

NOTE. The above method of proof, which consists in showing that the proposition *cannot be untrue*, is called *Reductio ad Absurdum*.

Corollary. If a triangle is equiangular it is also equilateral.

Proposition 7. Theorem

If the three sides of one triangle are respectively equal to the three sides of another triangle, the triangles are equal in all respects.



Let ABC, DEF be two △s, in which

AB = DE

AC = DF

BC = EF.

It is required to prove that the △s are equal in all respects.

Proof. Place the △ABC so that the point B falls on the point E, and the side BC falls along EF. Then, since BC = EF, C must fall on F.

Let the △ABC fall on the side of EF away from the point D, GEF being the new position of ABC. Join DG.

Then, since DE = GE,

∴ ∠EGD = ∠EDG [*Prop.* 5];

and since DF = GF,

∴ ∠FGD = ∠FDG [*Prop.* 5].

∴ whole ∠EDF = whole ∠EGF, *i.e.*, ∠BAC.

Hence, in △s ABC, DEF

AB = DE

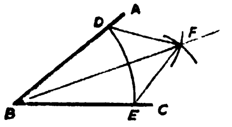
AC = DF

included ∠BAC = included ∠EDF.

∴ △ABC = △DEF in all respects [*Prop.* 4].

Proposition 8. Problem

To bisect a given angle.



Let ABC be the angle to be bisected.

Construction. With centre B, and any radius, describe an arc of a ⊙ cutting AB, BC, at D and E. With centres D and E, and any radius which is seen to be greater than half the arc DE, describe two arcs cutting at F. Join BF. Then the ∠ABC is bisected by BF.

Proof. Join DF, EF.

In the △s DFB, EFB,

DF = EF, since they are radii of equal ⊙s.

FB is common to both △s.

BD = BE, being radii of the same ⊙.

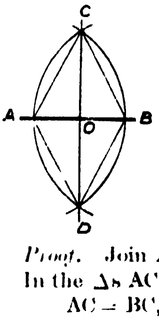
∴ the △s are equal in all respects (*Prop.* 7);

so that ∠DBF = ∠EBF,

i.e., ∠ABC is bisected.

Proposition 9. Problem

To bisect a given straight line.



Let AB be the line to be bisected.

Construction. With centre A and any radius which is seen to be greater than half the given line, describe an arc. With centre B and the same radius describe an arc cutting the first arc at the points C, D. Join CD, cutting AB at O. Then AB is bisected at O.

Proof. Join AC, AD, BC, BD.

In the △s ACD, BCD,

AC = BC, being radii of equal ⊙s.

CD is common to both △s.

AD = BD, being radii of equal ⊙s.

∴ ACD = BCD (*Prop.* 7).

Then, in the △s, ACO, BCO

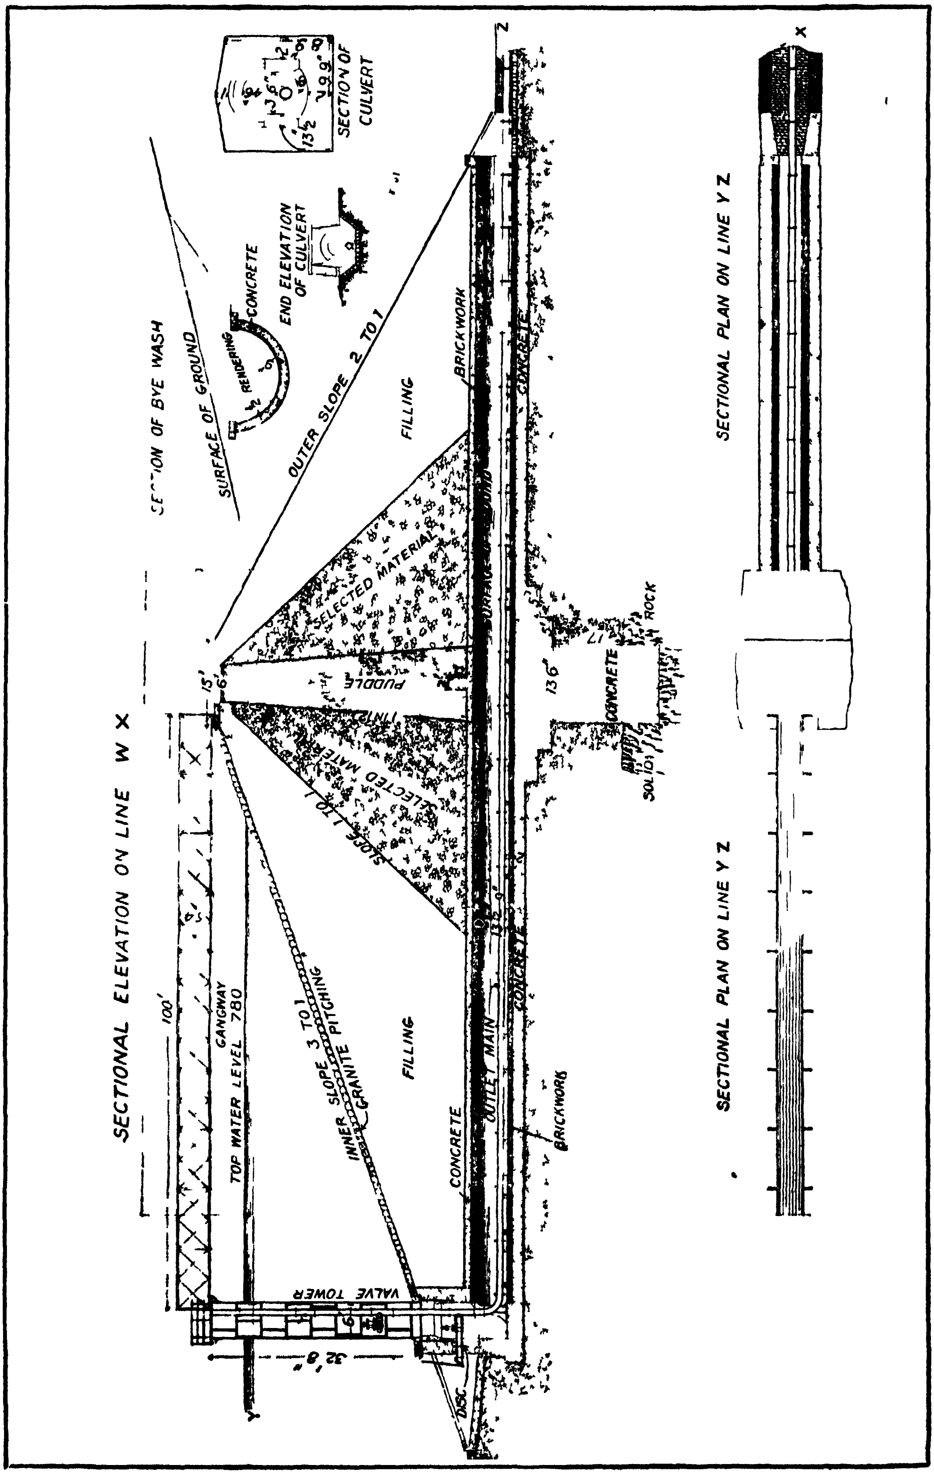
AC = BC,

CO is common.

∠ACO = ∠BCO.

∴ AO = BO (*Prop.* 4).

Continued



18 EARTHEN DAM FOR IMPOUNDING RESERVOIR

WATER STORAGE & SERVICE

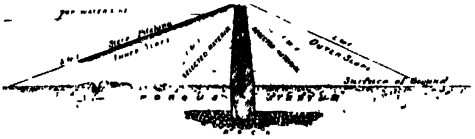
Earthen Dams and their Construction. Profiles. Calculation of Stresses. Service Pipes and Joints

WATER SUPPLY
continued from page 4100

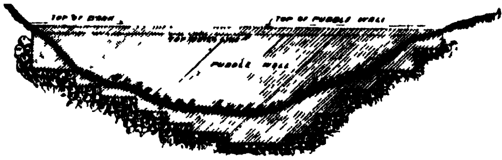
By Professor HENRY ROBINSON

Earthen Dams. The most common form of dam is that composed of earth, with a central puddle wall, as shown in **19** and **20**. This central puddle wall is supported on each side by banks of specially selected material of as clayey a nature as possible, the full width of the bank being made up with whatever other material is obtainable. The width of the bank at the top depends on the height, and also on the weight of the material of which the dam is constructed, but does not, as a rule, exceed 15 ft. or 16 ft., unless a road is required along the top of the bank, in which case the width must be regulated by the requirements of the road.

Puddle Walls. The central puddle wall is the most important part of the work, as on its soundness the water-tightness of the reservoir depends. Even a small leak may rapidly become enlarged by the constant stream of water passing through it, and may eventually be so enlarged as to cause complete failure. The thickness of the puddle wall depends on the nature of the clay employed, the minimum thickness being about 5 ft. or 6 ft. at the top, and at the surface of the ground being about one-fifth of the depth of water to be retained. The longitudinal section [**20**] shows the method of stepping, or benching, the foundation level of the puddle wall. After the position of the dam has been decided, it is necessary to sink trial holes along the line of the puddle wall, to ascertain the nature of the strata. If it is rock, all fissures must be carefully stopped with good concrete or masonry, and all springs should be led by pipes to the toe of the down stream bank, as if they are not diverted from the bank they will break out at other places and cause trouble. The depth to which the trench should be carried depends on the nature of the stratum, which must be sound and impervious. The trench is sometimes made with vertical sides, and sometimes with battered sides, as shown by dotted lines in **19**, it being considered that any settlement of the wall tends to consolidate the puddle more effectually than when the sides are vertical. The clay used for the puddle must be carefully prepared and well ground in a pug mill, being conveyed quickly and deposited in position in layers, which should not exceed 6 in. in thickness, each layer being well rammed and trodden down, care being taken to clean thoroughly and rough up the surface of the puddle in the trench before adding the next layer. It is necessary to cover the puddle after the day's work, and to water the surface the next day, in very dry weather, in order to prevent cracking.



19. EARTHEN DAM (CROSS SECTION)



20. EARTHEN DAM (LONGITUDINAL SECTION)

As the puddle wall is carried up, the supporting banks are brought up with it. The banks should be made in layers of between 6 in. and 9 in. thick, being well rolled, and, in very hot weather, watered. Steam-rollers can be of great assistance in consolidating the bank. The slope of the bank of selected material varies, but is generally about 1 to 1. The slope of the inner bank is as a rule from 2½ or 3 to 1, and is paved with stone pitching, or concrete slabs, in order to resist the action of waves. The outer slope is generally about 2 to 1, and is turfed or sown with grass.

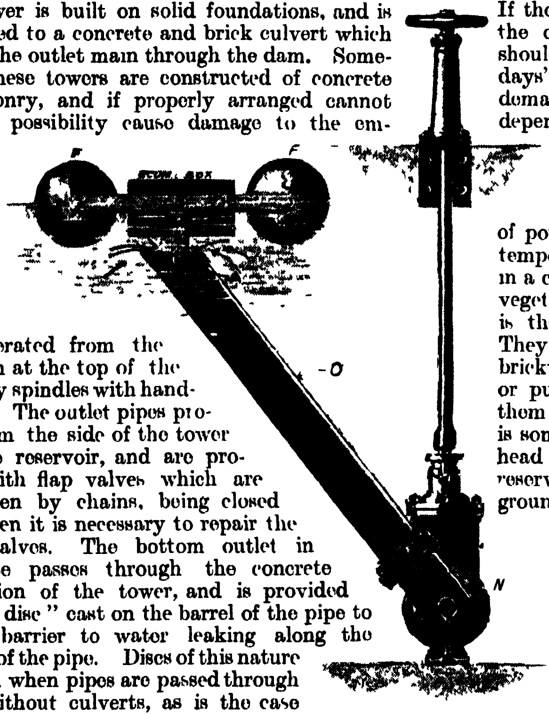
Height of Dam. The height of the top of the dam above the highest water-level depends on the waves, which seldom exceed 4 ft. The height of the waves depends on the "fetch," or length of water surface exposed to wind from any particular direction. A formula known as Stevenson's wave formula may be useful:

$$H = 1\cdot5\sqrt{D} + (2\cdot5 - \sqrt{D})$$

where H = height of wave in feet; D = fetch in miles.

Composite Dams. Dams constructed partly of earth and partly of concrete or masonry have been employed in this country, but more frequently in America. The liability of uneven settlement, and consequently of cracking in the concrete, is the chief objection to them. One form of composite dam is that where a concrete, or rubble, wall takes the place of the central puddle wall.

Outlets. The outlet from a large reservoir has to be placed near the bottom, to enable the water to be drawn off in times of drought, or when it is necessary to carry out repairs. As a rule several outlets with valves are provided, so that the water may be drawn off at different levels and the quantity regulated. The number of outlets depends on the depth of the reservoir. The outlets are operated in such a manner as always to draw the water from about 3 ft. below the surface, thus obtaining it clear and free from floating debris. The lowest outlet is used only in cases of drought or for repairs, as the water is sure to contain a certain amount of sediment. An arrangement of outlets is shown in **18** which is taken from the contract drawing of works carried out by the writer. There are three outlets, each being provided with a sluice valve contained in an iron valve tower standing inside the reservoir at the toe of the bank. The tower is built on solid foundations, and is connected to a concrete and brick culvert which carries the outlet main through the dam. Sometimes these towers are constructed of concrete or masonry, and if properly arranged cannot by any possibility cause damage to the embankment by leakage or settlement. The outlet valves are operated from the platform at the top of the tower by spindles with hand-wheels The outlet pipes project from the side of the tower into the reservoir, and are provided with flap valves which are held open by chains, being closed only when it is necessary to repair the sluice valves. The bottom outlet in this case passes through the concrete foundation of the tower, and is provided with a "disc" cast on the barrel of the pipe to form a barrier to water leaking along the outside of the pipe. Discs of this nature are used when pipes are passed through dams without culverts, as is the case with shallow reservoirs of about 20 ft. and less. The outlet pipes of deep reservoirs should be laid in culverts, as shown in **18**, of such dimensions that a man can inspect the pipes periodically. The joints of pipes that are laid in culverts can be either spigot and socket, or flanged; but when laid through a bank for shallow reservoirs they must be flanged and jointed, of extra thickness, and provided with fish webs, so that they form, when bolted up, a continuous girder.



21. FLOATING OUTLET

Syphon Outlets. Syphon outlets are employed to draw water from small reservoirs. The syphon-pipe, with air and charging valves on the summit, is carried over the dam to a point lower than the bottom of the reservoir. The depth to which this point must be carried depends on the friction to be overcome in the pipe to enable the required quantity of water to be discharged. Fig. 21 shows a form of outlet known as a *floating outlet* or *floating arm*, often used in storage reservoirs or water tanks. By arranging the floats, F, the water can be drawn off at any required level below the surface, thus preventing floating debris entering the main. The arm, O, is supported by the floats, F, and is pivoted at the point P. When the valve, N, is opened, the water is drawn off at the point A, the floats falling with the water.

Service Reservoirs. Service reservoirs are required in or near a town to maintain the service in case the mains from the source of supply, either storage reservoir or pumping station, reveal any defect, and have to be repaired, or when a fire has to be extinguished. If the town is dependent on one main, the capacity of the service reservoir should be sufficient to ensure two or three days' supply at the rate of the maximum demand Large cities should never be dependent on a single main. Service reservoirs are generally covered to prevent the possibility of pollution by dust in the air, especially if they be placed in or near centres of population, by birds, leaves, etc. The temperature of the water is kept uniform in a covered reservoir, and the growth of vegetation is prevented. About 14 ft is the usual depth of water in them They can be constructed of concrete or brickwork, rendered with cement inside, or puddled with clay outside, to make them watertight. Bituminous sheeting is sometimes used as a lining where the head of water is considerable or when the reservoir has to be built in very bad ground. The covering may consist of light brick or concrete arches supported on piers. On the top of the arches a foot or two of earth is laid Inlet, outlet, and washout valves are placed in suitable positions The two first-named should be as far apart as possible, so as to produce circulation. An overflow is provided, and also small ventilators to effect movement and replacement of the air. The cost of an ordinary service reservoir may be taken at about £5 to £6 per thousand gallons.

Stand-pipes. In place of a service reservoir to afford the supply to cisterns at a high level the water is often pumped through a *stand-pipe*, which consists of two vertical pipes connected by a bend at the top, so that a continuous flow of water passes from the pumps through the upcast pipe, over the top, and to the supply pipes on the other side through the downcast. The height of the stand-pipe is governed by the level of the buildings the tops of which have to be reached.

The idea of giving to the cross section of masonry dams a shape of uniform stability and strength is of French origin. A dam has two faces, namely the *inner* and the *outer*, the inner face being frequently called the *back* of the dam.

Calculating Profiles. Sir Guilford L. Molesworth has given formulæ for the calculation of a profile [22] which were published in the "Proceedings of the Institution of Civil Engineers." They are as follow:

$$y = \sqrt{\frac{0\cdot05x^3}{\lambda + (0\cdot03x)}}\,; \quad z = \left(\frac{0\cdot09x}{\lambda}\right)^4;$$

Width of top of dam = 0·4 y, at ¼H

Where H = total height of dam in feet,

λ = limit of pressure allowed on the masonry in tons per square foot,

x = depth below the surface of the water in feet,

y = offset in feet to the outer face of the dam from a vertical line = 0·6x as a minimum,

z = offset to the inner face.

He stated that there was almost an exact agreement between his formula and that of M. Bouvier when the limit of pressure allowed was assumed at 5½, 7½, 9 and 11 tons respectively, and he gave the illustration in 23 to show how closely the formulæ were in agreement when treating profiles with the above limits of pressure.

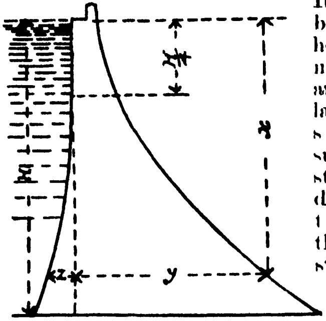
The Molesworth formula is simple, and enables the shape of the cross section to be calculated easily, after which it must be treated graphically to determine the position of lines of resistance.

The conditions of stability for masonry dams are practically two—namely:

1 That the resultant of all forces at any horizontal section must fall within the "middle third" of that section.

2. The stresses in the faces of the dam must not exceed the safe limit.

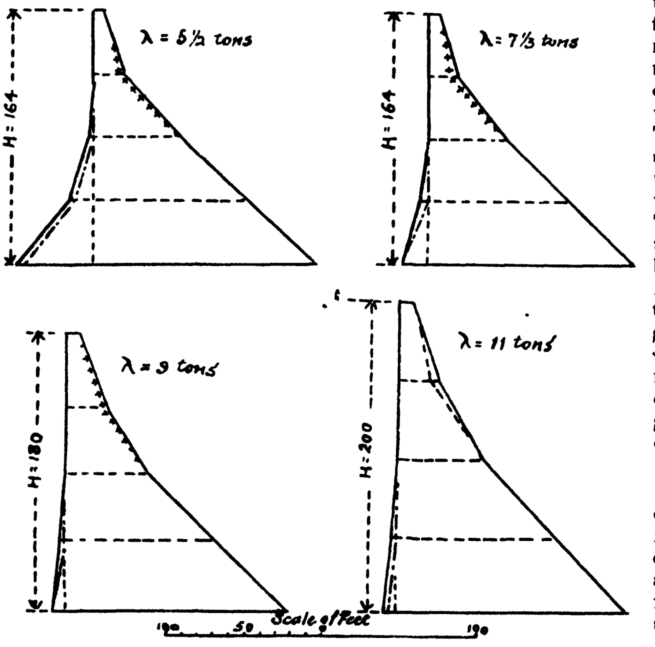
The first of these conditions is intended to prevent any tension taking place in the masonry. It must be borne in mind, however, that internal forces are set up in large masonry structures—such, for instance, as the difference of temperature—that produce stresses which are in no way due to any external forces which the dam has to resist. It must also be remembered that in all theoretical calculations it is assumed that the dam is a perfectly elastic body, which is not true in practice. Such being the case, ample margin must be allowed to ensure safety, and the stresses that have been allowed on existing structures of a similar kind should be studied as the application of a formula must be governed by the results of practical experience.



22 MOLESWORTH'S FORMULA

Dam Foundations. The first consideration is, of course, the foundation upon which the dam is to be built. It is not advisable to build high dams on earth foundations, on account of the mass of material that would be necessary in order to distribute over a sufficient surface the weight for the earth to support. The best foundations are hard, sound rocks, as these prevent unequal settlement, owing to the varying weight of the wall The material of the dam must, to a great extent, be governed by the nature of the foundation. After the head of water behind the dam exceeds 100 ft., it is generally thought best to construct it of masonry. It is necessary to avoid continuous courses in the masonry, and great vigilance is necessary in order that no empty spaces may be left between the blocks.

The resistance to crushing of the materials forming a dam is one of the chief points to be considered. The stresses which are set up by the external forces must not exceed the safe limit. As a general rule, this compressive stress should not exceed 150 lb. per square inch, although in cases more has been allowed. M. Bouvier has stated that, with rubble masonry and good hydraulic



23. COMPARISON BETWEEN MOLESWORTH'S FORMULA AND BOUVIER'S METHOD

Moleswortli's profile shown thus .. .. ————

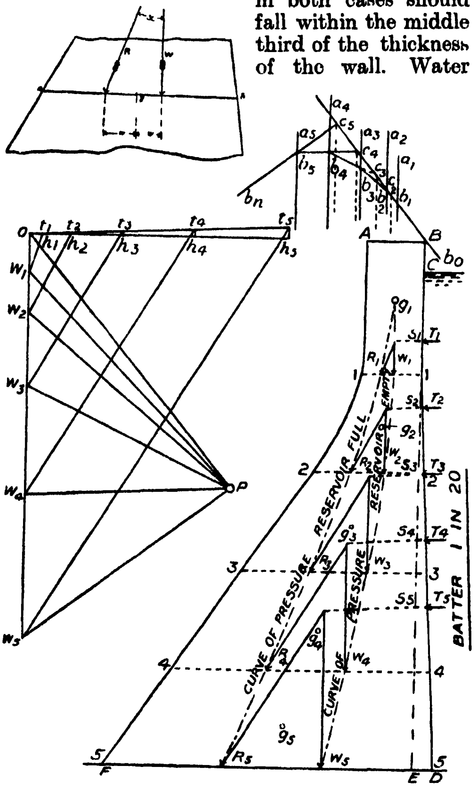
Bouvier's " masonry 135 lb. per cube foot .. .. - - · - - - - - -

Do. " " 150 " " " " .. . ı ı ı ı ı

Bouvier's profile is not shown where the divergence from Molesworth's profile is mortar, the compressive stress may be 140 lb. per square inch at the completion of the works, and 200 lb. later on.

The sides of the dam must be built in, and tied to the impervious strata on the sides of the valley across which the dam is made.

Pressure. A profile having been adopted, it becomes necessary to test it to see if there is sufficient masonry to resist the external forces that will act on it, both when the reservoir is full and when it is empty. The curves of pressure in both cases should fall within the middle third of the thickness of the wall. Water pressure acts normal to the surface of the wall, and therefore, in the case of a curved wall, the pressure is not horizontal, but is inclined downwards. Professor Rankine, in his section for high dams, takes the horizontal pressure, and neglects the vertical component as being on the safe side.

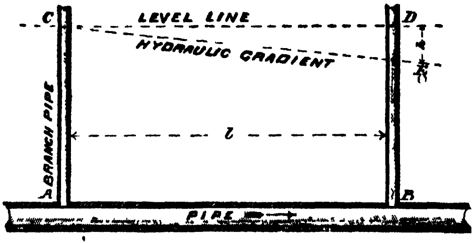


24. COVENTRY'S DIAGRAM

The action of the water tends to overturn the wall on its outer toe. Before this could happen, however, the toe would crush, but if the resultant is within the "middle third," the wall is quite secure from overturning.

In order to test the profile, it is necessary to divide it up into segments, and to test each segment for stability. By this means the curves of pressure for reservoir "full" and "empty" can be drawn, and they must always be within the "middle third" of the section.

In a paper published in the "Proceedings of the Institution of Civil Engineers," Vol. LXXXV., Mr Coventry gives a formula for calculating the section of a profile, and also a graphical method for testing the stability after the profile is drawn. To determine the stresses in the two faces, the following formulæ were given by him :



25. HYDRAULIC GRADIENT

Taking any horizontal section $a\ b$ for reservoir empty,

$$s = \frac{W}{l}\left(1 \pm \frac{6u}{l}\right).$$

The plus sign gives the stress at the edge nearest W, and the minus sign gives the stress at the opposite edge.

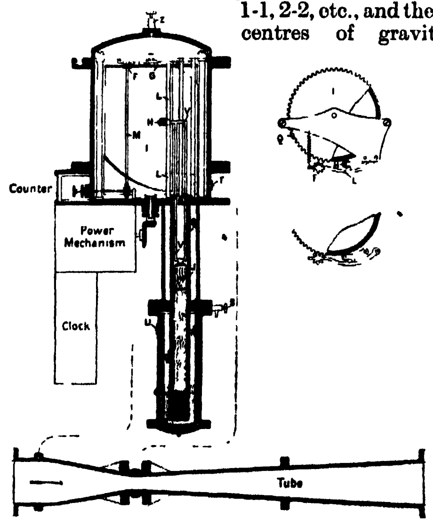
W = weight of the dam above the layer $a\ b$,
l = the length of $a\ b$,
R = the resultant of the water pressure and the weight of the dam,
u = distance of W from the centre of gravity of the section $a\ b$,
u' = distance of R from the centre of gravity of the section $a\ b$,
x = angle the resultant makes with a vertical line,

For the full reservoir:

$$= \frac{R \cos x}{l}\left(1 \pm \frac{6u^1}{l}\right).$$

A useful method for finding these curves is that given by Mr. Coventry, as follows [24]:

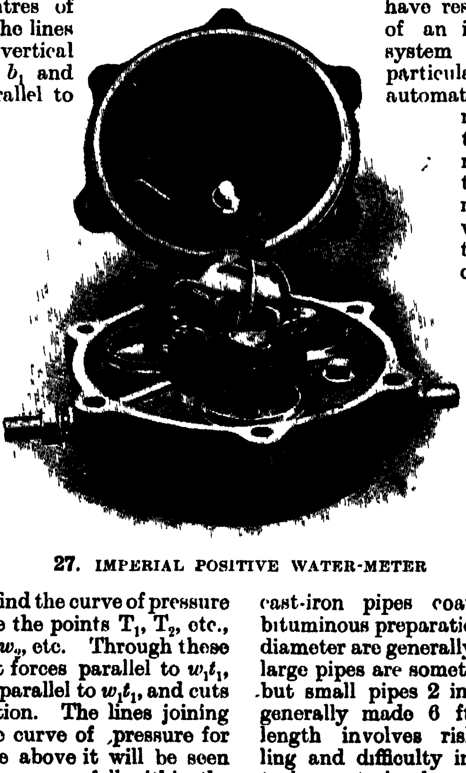
The profile must first be divided up into any convenient number of segments as shown by 1-1, 2-2, etc., and their centres of gravity



26. VENTURI METER

found as shown at g_1, g_2, etc. Next construct a force polygon by setting off on a vertical line to scale, the distances ow_1, w_1w_2 etc., equal to the weights of the corresponding sections 1-1, 2-2, etc. On a horizontal line set off to the same scale distances Oh_1, Oh_2, etc., equal to the water thrusts due to the depths for the various sections. Through the points thus found, draw perpendiculars as h_5 t_5, and from the point where the water thrust first becomes normal to the batter draw a line perpendicular to it, and cutting the perpendicular lines at t_2, t_3, etc. Take any point P and draw the lines Pw_1, Pw_2, etc., and also join w_1t_1, w_2t_2. The position of the water thrusts are shown in the figure at s_1, s_2, etc.. and s_1 is two-thirds of C1, and s_2 is two-thirds of C2, and so on. The magnitude and direction of these forces is equal to w_1t_1, w_2t_2, etc.

To find the curve of pressure for the empty reservoir, from the centres of gravity g_1, g_2, etc., draw the lines a_1b_1, a_2b_2, etc. In the vertical line a_1 take any point b_1 and through it draw b_0b_1 parallel to PO, and produce it indefinitely. Then draw b_1b_2 parallel to Pw_1, and b_2b_3 parallel to Pw_2, and so on, the last line being parallel to the last radial line on the force polygon. Produce the lines b_2b_3, etc., till they cut the line b_0b_1 produced at c_2, c_3, etc., and through the points drop perpendicular lines to the corresponding sections of the profile. Thus w_2 is equal to the weights of the first two sections, and acts through c_2. The lines joining those points will equal the curve of pressure for reservoir empty. To find the curve of pressure for reservoir full, produce the points T_1, T_2, etc., till they cut the lines w_1, w_2, etc. Through these points draw the resultant forces parallel to w_1t_1, and w_2t_2, etc. Thus, R_1 is parallel to w_1t_1, and cuts the base of the first section. The lines joining these points will give the curve of pressure for reservoir full. From the above it will be seen whether these curves of pressure fall within the middle third of the sections, as they should do. The stresses in the faces of the dam can now be calculated by the formula previously given, as the positions of R and w are now fixed.



27. IMPERIAL POSITIVE WATER-METER

Distribution. The sizes of the distributing mains must be large enough to supply the maximum requirements of the community. The sizes of the small branch distributing mains should be 2 in., or 3 in. in diameter. Hydrants for street watering, fire extinction, etc., should be placed at suitable points, and it is desirable to adopt a standard gauge for connecting to them.

In calculating the size of a pipe, the "hydraulic gradient" should be reckoned from the outlet of the reservoir supplying the water to a point about 80 ft. above the highest part of the town, to ensure the delivery of water for fire extinction as well as for ordinary supply to the tops of houses that are, or that may be, built there.

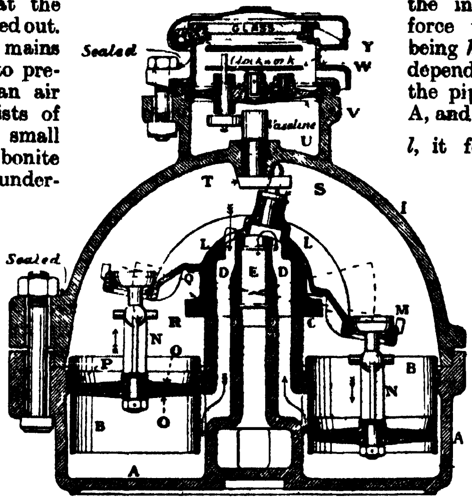
All mains and service pipes should be laid at a sufficient depth in the ground to protect them from the effect of the severest continuous frost. About 2 ft. 6 in. or 3 ft. from the surface to the top of the pipe is the least depth, and the pipes should be tested before being covered. The disregard of this requirement as regards depth has resulted in a few notable failures of the water supply of a district. A very sharp frost for a limited time would not affect the water in the pipes, but a severe frost, lasting for days, does the mischief.

Detection of Waste. Waste-water meters are employed to detect waste, and great savings have resulted. The meter consists of an instrument placed upon a system of water-pipes serving a particular district, and recording automatically and graphically the rate of flow of the water in the pipe. If at a time of night there should be practically no flow, a diagram records the rate of flow, whereby it can be ascertained whether waste is occurring

A night examination of service pipes by applying a stethoscope to them enables any flow of water to be detected, when practically there ought to be none. The waste is generally caused by defective fittings, taps left running all night, etc.

Service Pipes. The usual method of distributing water is by cast-iron pipes coated with Angus Smith's bituminous preparation. Pipes more than 3 in. in diameter are generally cast in 9-ft. lengths. Very large pipes are sometimes made in 12-ft. lengths, but small pipes 2 in. or 2½ in. in diameter are generally made 6 ft. long, because a greater length involves risk of breakage in handling and difficulty in keeping the slender core truly central when casting. The lengths are always reckoned from centre to centre of the joints when laid, but the sockets extend 3 in. or 4 in. beyond. The usual form of joint is the spigot and socket caulked with lead. Some hemp or tarred gaskin is rammed into the socket round the spigot end of the adjoining pipe, and molten lead is poured in through a gap in a clay mould, and when set it is rammed home with caulking chisels.

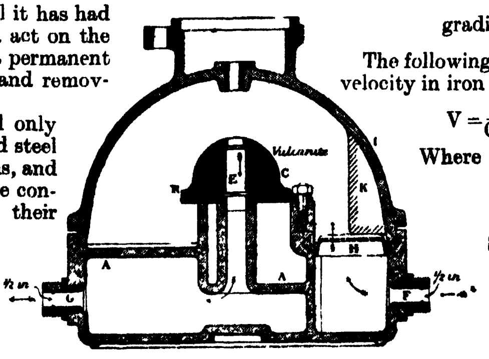
To remove excrescences which form on the inside of pipes, special scraping tools are employed. These are carried on a pair of discs, or loose pistons, attached to flexible arms. The water is run out of the pipes, and the scraping apparatus is put into a section of pipe, which is closed up, and water is let in at the back of the scraper, driving it forward the length of the flexible arm. When this section has been scraped the tool is removed and another section is attacked. Wash-out valves are placed at low-lying points so that the scraped stuff may be flushed out.



28. SECTION OF IMPERIAL POSITIVE WATER-METER

At summits of water mains an air valve is placed to prevent the formation of an air lock. This valve consists of a brass plug, having a small pin hole in it, with an ebonite ball 2½ in. in diameter underneath, held loosely in position by a cradle. When the pipe is full of water under pressure the ball floats up against the pin hole and the pressure of water makes it a tight valve. If air collects, the ball settles down on its cradle and lets the air out, but rises again with the water. A second valve is sometimes used; it has a larger hole to let out the air rapidly when the pipe is being filled after having been emptied for washing out or repairs. As these valves are liable to get out of order, summits should be avoided, especially in pumping mains.

House Services. Service pipes to houses are generally of lead attached to a gun-metal ferrule screwed into the main. If the water is soft, care must be taken not to use the water for dietetic purposes until it has had time to flow through and act on the lead, thereby producing a permanent oxidation of the surface and removing the danger.



29. IMPERIAL POSITIVE WATER-METER
Transverse section

We have so far referred only to cast-iron mains. Mild steel is employed for large mains, and where the pipes have to be conveyed long distances their greater lightness has an advantage. They require to be carefully handled, and if properly coated and protected they have lasted as long as cast iron.

Hydraulic Gradient. In calculating the sizes of water mains to deliver a required amount of water, consideration has to be given to the friction that has to be overcome by the movement of the water through the pipe. Fig. 25 explains this. h represents the loss of head due to friction caused by the flow of water under pressure. If the water in the pipe were at rest, the horizontal line CD would be the level at which it would stand. If there is a flow from A to B then the level at D will fall below that at C and the line CE is what is termed the *hydraulic gradient*. If the velocity is small, h is practically in proportion to the mean velocity v. At high velocities h varies in proportion from $v^{1.70}$ to v^2, according to the smoothness or roughness of the pipe. The smoother the surface is the lower the index of v will be. The force which moves the water being h, and the amount moved depending both on the size of the pipe, the area of which is A, and on the length of the pipe l, it follows that $\frac{l}{h}$ is the cosecant of the angle of inclination of the "hydraulic gradient," and $\frac{A}{P}$ is what is called the *hydraulic radius*, A being the sectional area of the inside of the pipe, and P the *wetted perimeter* or internal circumference of the pipe. The following formula will enable the discharge through pipes to be calculated:

$$Q = \frac{D^{2+x}}{P\sqrt{S}} \times \left(1 + \frac{T-50}{600}\right)$$

Where Q = the discharge in cubic feet per second,
D = diameter of the pipe in feet,
P = a coefficient of roughness,
T = temperature of the water in degrees Fahrenheit,
S = the cosecant of the angle of inclination of the hydraulic gradient $= \frac{\text{length}}{\text{head}}$.

The following formula will enable the velocity in iron pipes to be calculated:

$$V = \frac{R^x}{C\sqrt[n]{S}} \times \left(1 + \frac{T-50}{K}\right)$$

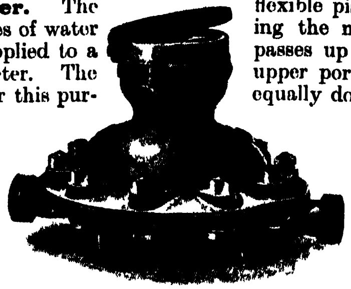
Where V = mean velocity in feet per second,
R = hydraulic radius in feet,
S = the cosecant of the angle of inclination of the hydraulic gradient $= \frac{\text{length}}{\text{head}}$.
C = a coefficient representing the roughness of the surface of the pipe.
T = temperature of the water in degrees Fahrenheit.

The nature of the surface has a large influence upon h independent of its effect upon the index of v. The temperature also has an influence on the discharge.

The values of "x," "n," and C all depend on the roughness of the pipe, and from experiments have been found to be as follows :

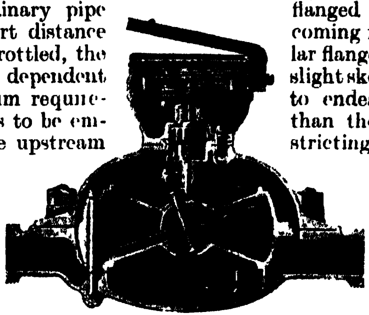
Factor to which coefficient relates. — Description of surfaces	Velocity "n"	Roughness C.	Hydraulic Radius "x"	Temperature K.
Cast-iron pipes (new) medium velocity	1·85	0·005347	0·67	600
Cast-iron pipes (new) high velocity ..	2·00	0·006752	0·63	600
Cast-iron pipes (old)	2·00	0·017115	0·66	600
Cast-iron pipes (cleaned). ..	1·95	0·0074191	0·64	600
Wrought-iron pipes	1·80	0·004787	0·652	600
Riveted sheet iron ..	1·825	0·005074	0·677	600

This subject has been dealt with in great detail in the writer's book on "Hydraulic Power and Hydraulic Machinery."



30. BEE WATER-METER

Measurement of Water. The measurement of large quantities of water either taken from a river or supplied to a town are best effected by meter. The Venturi meter is much used for this purpose. Fig. 26 shows a Venturi meter from a drawing furnished by the maker. The operation of the meter is due to the fact that when fluid in any pipe passes from a state of rest to one of movement, or from one velocity of flow to a greater velocity, a certain amount of pressure against the shell of the pipe disappears, and the disappearance of pressure, or loss of head, is dependent entirely upon the velocities of flow past the points in the pipe at which pressure is taken. From the illustration it will be seen that the meter is in two parts—the tube and the recorder ; there are no movable parts in contact with the flowing liquid. The tube forms part of the ordinary pipe line, differing only for a short distance where it is truncated or throttled, the amount of the throttle being dependent on the maximum and minimum requirements of the place where it is to be employed. The pressure at the upstream end, and at the throat of the meter tube, are transmitted by the small pipes T and U to the recorder, where they are balanced by the displacement of two columns of mercury in the cylindrical tubes, one within the other. The inner mercury column carries a float, JV, the position of which is an indication of the velocity of water flowing through the tube. The position assumed by an idler wheel, H, carried by the float, relative to an intermittently revolving integrating drum, I, determines the duration of contact of gears G and F connecting the drum and the counter, by which the flow for successive intervals is registered. The largest meter-tube that has yet been made is 9 ft. in diameter with a maximum capacity of 200,000,000 gallons in 24 hours.



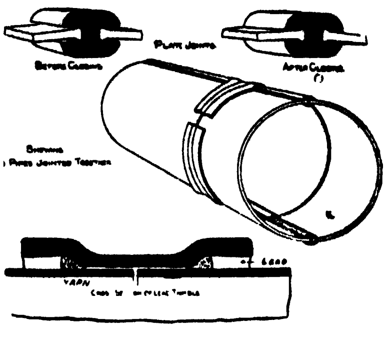
31. SECTION OF BEE WATER-METER

There are numerous meters for measuring small volumes of water, but we shall confine ourselves to two. The Imperial Positive Water Meter is shown by 27, 28, and 29. The lower portion, A, contains three cylinders, B, and the valve-seating, C, with its three ports and passages, D, communicating with the bottom of the cylinders. There is a discharge port and passage, E, and inlet and outlet connections F and G, also a strainer, H ; I is the cover, with the rib K for holding down the strainer. An unequal spacing of the bolt-holes prevents the cover from being wrongly fixed to the lower portion. L is the valve with its three arms, in the ends of which are cup-shaped bushes, M, for receiving the spherically-shaped heads of the piston-rods N, and to these are secured the pistons, composed of upper and lower piston plates, O, nuts, and flexible piston caps, P. The water entering the meter, as shown by the arrows, passes up through the strainer into the upper portion of the casing, and presses equally downwards on all the three pistons, and also on the valves.

According to the position of the valve, the lower end of each cylinder in succession is communicating with the outlet passage E, and its piston is therefore forced down by the superior pressure above, thus discharging the contents of the cylinder. At the same time, one or both of the other cylinders is having its piston raised, whereby water is admitted through the passages, and the lower part is filled. Thus each lower end of the three cylinders B is in due course filled and emptied, one or two pistons always supplying the active force, so that there is no dead point.

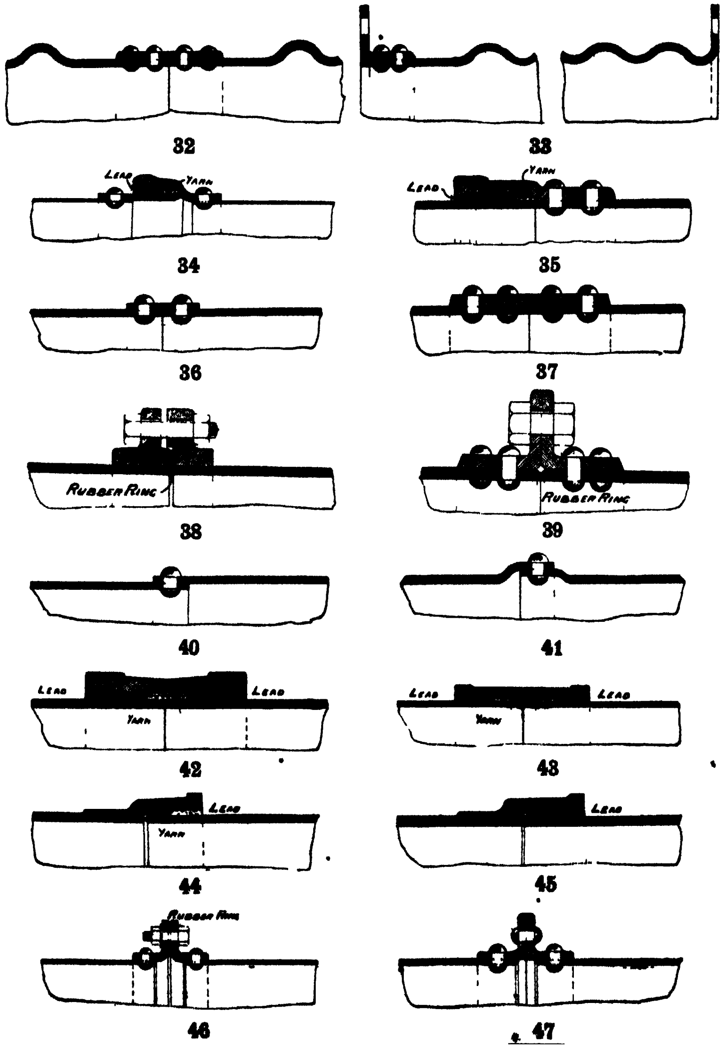
The length of the stroke is regulated by the flanged projection, Q, on the valve L coming into rolling contact with a similar flange, R, on the valve-seating, C. A slight skew of the ports causes the pistons to endeavour to take a longer stroke than they should, the roller paths restricting this tendency. The teeth in the valve and the notches in the valve-seating prevent the valve from turning round on its own axis. The valve-pin, S, engages the crank of the crank spindle, T, which communicates motion to the clockwork in the usual manner. U is the bush in the cover, V the counter-plate supporting the lay-shaft with its worms and wheels. W is the dial-box protecting the clockwork, and Y is the counter.

Figs. 30 and 31 show another good example called the Bee Water Meter. This depends on a disc action piston, a chamber of known capacity being successively filled and discharged. The movement of the passing water is directly and positively transmitted to an oscillating piston or disc, which, for each complete motion, or oscillation, shows that the exact contents of the disc chamber, less the bulk of the immersed portion of the piston or disc, have been received, discharged, and counted, once. For example, let us take a disc chamber with a capacity of 15 cubic in. The portion of the disc immersed is 3 cubic in. Every complete motion of the disc will show that 12 cub. in. of water, or 15 minus 3, has been passed through the chamber. If we divide 1,728 cubic in. (1 cubic ft.) by 12, we find 144 as the number of disc motions required to displace a cubic foot of water, or 6·25 gallons.



48. RIVETLESS STEEL PIPE

Water-pipe Joints. The process of jointing water mains will next be described, and is illustrated in 32 to 47. Figs. 32 and 33 are forms of expansion joints on large steel water mains. Fig. 34 is a welded spigot and socket, riveted on to a steel main, the joint being completed by yarn and lead. Fig. 35 is a modification of the preceding joint. Figs. 36 and 37 are single and double riveted *butt and strap* joints for steel mains. Figs. 38 and 39 illustrate methods of attaching flanges to large steel mains, the joint being completed by a rubber ring between the flanges, and 40 and 41 show the ordinary forms of single riveted lap joint for steel mains; 42 and 43 are types of double collar joints. Fig. 44 is a spigot and socket pipe joint, commonly used on small mains. Yarn is caulked up to the face of the socket, and molten lead is run into the remaining space in the socket, and well caulked with chisels made for the purpose. Fig. 45 illustrates a turned and bored joint for cast-iron pipes. Where the pressure in the main is small, the lead is sometimes omitted, and is not run in as shown by the illustration. Fig. 46 is a method of joining stamped steel flanges steel mains by riveted on to the barrel of the main, the joint being completed by a rubber ring; 47 is another form of riveted joint used on steel mains.



METAL PIPE JOINTS

A rivetless steel pipe is shown in 48. The barrel of the pipe is formed by two semicircular steel sheets jointed by a special metal section, hydraulically compressed into the edges of the sheets, so as to form a rigid and watertight joint.

Continued from page 4110

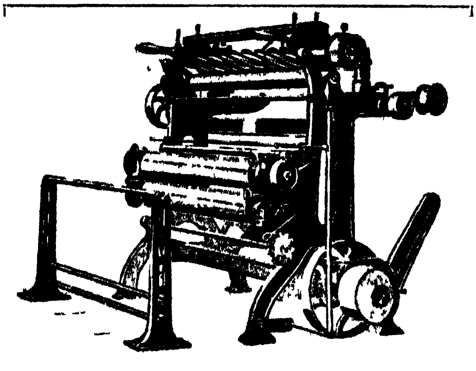
By W. S. MURPHY

THE carpet manufacturer depends very little on the finishing department for the quality of his goods. If the carpet be of good quality and design, and well woven, the finish adds very little to its value. But it must be admitted that the carpet could not pass directly from the loom to the warehouse. Looped-pile and velvet-pile carpets are finished differently, the latter needing the more elaborate finishing.

Viewing. Given an office exactly similar to the burler in the cloth factory, the carpet viewer has a rather difficult task. He must possess a good eye for colour, a knowledge of design, and a practical acquaintance with weaving. Loops or threads may slip, or threads become misplaced without the weaver's knowledge, and as the heavy fabric is unreeled before him, the viewer must spot any and every defect, for upon him at last rests the reputation of the factory. He marks what defects there may be, and sends the carpet on to the darners.

Darning. The work of the darner is to repair the defects of the carpet in such a way that expert scrutiny will not detect the mend. With such a bulky fabric to work upon, the task seems easy, at first sight; but, in reality, imitation of the work of the loom with a needle and thread requires considerable skill. As the darning is purely practical, however, we can do no more than note the theory on which it is based.

Cropping. Axminster, Patent Axminster, Wilton, and Velvet-pile Tapestry carpets have this in common, that they are cropped, or shorn. Up till twenty years ago most carpet manufacturers would have nothing to do with the cropping machine, and at the present day much of the cropping is done by hand; but the machine has been introduced, and steadily makes its way. It is in the velvet-pile tapestry factory that the spiral roller cropping machine has been most largely used. This machine [199] is little more than a large model of the common cloth-cropping machine. The bed is set straight, so as to present a firm surface to the knife, and it crops the surface something in the same way as a lawn-mower crops the grass. The results certainly show well, though the objection of conservative manufacturers that it lessens the wearing life of the carpet may have some truth in it.



199. CARPET-CROPPING MACHINE
(W. Whiteley & Son, Lockwood)

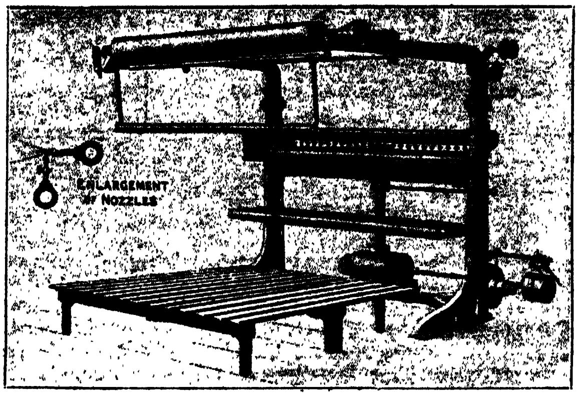
Brushing and Calendering. Carpets are heavy fabrics, and naturally gather a good deal of fluff and stray fibres within them while being woven. Removal of these matters from a Brussels, a Wilton, or an Axminster is a somewhat arduous task; but it is done, and by the simple expedient of brushing rigorously. Brushing machines are variously constructed; but in all we have the combination of fan and brush cylinder such an operation would obviously require. By the fans the dust and fluff are blown into an enclosed receptacle, while the brushes do their work upon the surface of the carpet as it winds round and round. Probably the carpets never experience usage so rough as in this operation. It is amazing what amount of stuff we can take out of a single length of carpet.

When sufficiently cleaned, the carpets are passed through the calender rollers. These are sets of broad rollers hung in a frame, the one above the other, so as to exercise a forcible yet regular pressure on the carpets passed between them.

Sewing and little of technical interest in this department, the work being done chiefly by sewing machines. Carpets woven in strips are carefully joined, and carpet squares are bound with appropriate braidings. It was said of a very clever but unsuccessful manager of a carpet factory that he lost in the ware-rooms what he made in the factory. This is a fact rather more common than is generally supposed. No detail of the industry is too small for the attention of the wise manager.

After the carpets have been sewn and bound, they are again inspected. Any defects apparent are noted and repaired. Then the goods are delivered over to the packers.

Finishing Cotton Fabrics. The number of different cotton fabrics which are finished in the factory is very large. Some plain calicoes are simply passed by the shortest route possible from the loom to the warehouse; cloths that sell at 1¾d. per yard would hardly pay for much finishing. Others, of the same quality, are washed, starched, or



200. DAMPING MACHINE (W. Whiteley & Son, Lockwood)

loaded, calendered, and folded. Fancy fabrics, such as zephyrs, spiders, checks, spots, and check stripes, each comprehending myriads of patterns, are mostly finished in the very simplest style. Fustians, velveteens and moleskins, on the other hand, are elaborately finished both in the factory and elsewhere. Upon the cloths which are bleached, printed, or dyed, we shall not at present touch.

When the cloth, be it plain or fancy, comes off the loom, it is passed into the hands of the viewer, or burler. Over a roller, hung on brackets fixed either in the ceiling of the room or high up on a wall facing the light, the cloth is drawn down by the viewer, who snips off knots and flying threads, and marks faults for repair.

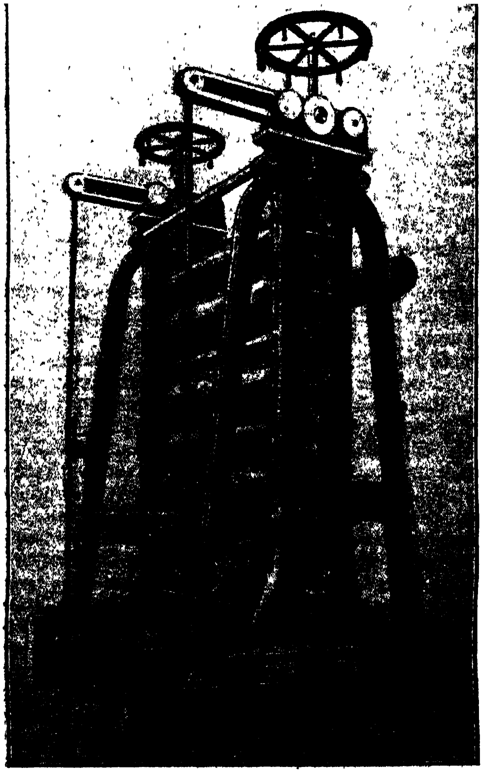
Darning. This work may be very delicate or it may be very simple. To mend a break in fancy cloths woven in figure is a different thing from putting a few threads of plain weft and warp in a common calico or twill. It is purely a matter of practice, however, and is learned in the factory.

Starching. The composition used in starching depends very much on the purpose intended and the fabric to which it is applied. If loading be intended, a mixture of china clay, cereal starch, wax, and some fatty or soapy matters may be used. Care must be taken that the composition has within it preservative elements, and is able to withstand changes of temperature and damp, or else mildew is certain to set in and ruin the cloth. Most export houses have special mixtures of their own. If only the stiffening of the cotton be aimed at, a fine wheaten starch is the best for light goods, and sago, rice, or farina may be used for heavy cloths.

Method. The starching vat is simply one of the many dressing machines. From the cloth beam slung at the end of the machine the cloth is guided down into the starch trough, under a cloth-clad roller revolving in the liquid, up between the clearing rollers, and over the wide, steam-heated drying cylinders.

Starching Fancy Cloths. In dressing faced cloths the starch can be applied only to the back. A simple device effects this very well. Above the roller in the starch vat another roller is placed which receives from the roller below a coating of liquid. This starching roller runs in the direction opposite to the course of the cloth through the machine, and thus presses a coating of starch on the under side of the fabric. Between the clearing rollers and the drying cylinders a number of open reels are placed to harden the starch and keep the drying cylinders clean.

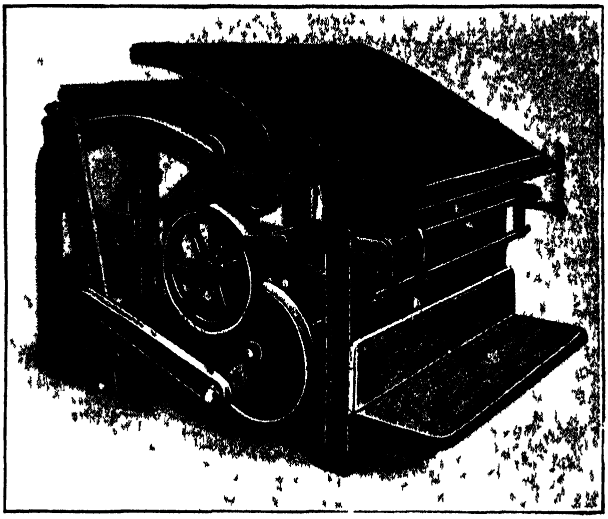
Damping. Dried cloths, whether starched or scoured, are stiff, and do not yield readily to the treatment of the calenders or presses. Most cloths are therefore subjected to damping. Two methods of damping are practised; or, rather, we should say that two kinds of machines are used. On both machines the cloths are run across a space from one beam to another; but it is in the damping apparatus which operates in the intervening space that the differences occur. The older damping machine is a small water tank, with a lid in which a long slit is cut. Within the tank a long-haired brush revolves, sending through the opening in the lid a continuous spray of water on to the passing cloth. The other damper [200] is a spray injector, from the nozzle of which the water is finely distributed. By a curious turn in mechanical development, the newer apparatus is being closely rivalled by an improved model of the older



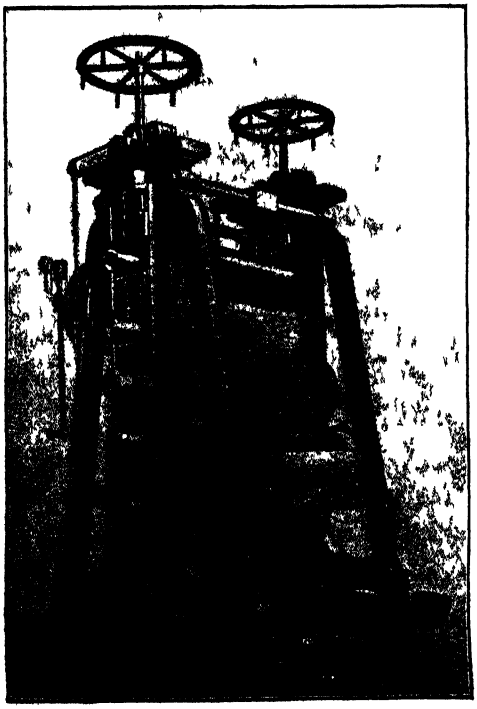
201. CALENDER (W. Whiteley & Son, Lockwood)

machine By a ball-tap feed the water in the brush-trough is regulated, and the volume of spray is governed by screws on the lid, which enlarge or narrow the opening as required

Calendering. No textile factory can afford to do without a calendering machine Many factories employ a large number of various sizes The chief object of calendering is to produce a smooth and lustrous surface on the cloth A calender [201] consists of a series of rollers and cylinders, placed alternately one above the other in a strong frame Calenders may have three, four, five, or six " bowls," as the rollers and cylinders are named The cylinders are generally iron, and always hollow, the rollers are solid, composed of papier mâche pressed to a very dense consistency The six bowl calender is representative of the whole class of such machines Hand screws on the heads of the standards bring the required degree of pressure on the bowls Beside the screws are two levers which put the drive on to all the rollers A gearing is set midway up the machine by which only the three bottom bowls may be driven When a stretching action is desired the top rollers are given a higher speed than the lower section The heating of the hollow cylinders is accomplished either by steam or by the introduction of red hot irons The cloth is wound on to the roller at the foot of the calender, or the web already wound is slung in the same place, and then passes on to the first cylinder, thence round the roller and up through the whole machine, to be delivered at the other side It is all very simple, but the effects on the cloth are very wonderful



202 FOLDING MACHINE (Atherton Bros Preston)



203. MANGLE (W Whiteley & Son Lockwood)

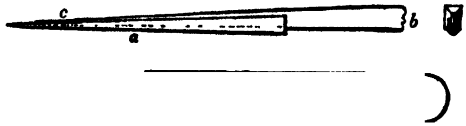
Folding. Mechanical folders have developed very slowly, the inventors seeming to err on the side of elaboration But we have now some good and expeditious folders One of the best is composed of a curved, movable table, over which a folding arm works to and fro [202] The cloth is given out from the beam, and the folder carries it along to the end of the table, where it is clipped, or held, as the arm comes back it makes another fold This machine is also a cloth measurer, the number of yards being indicated on the dial attached to the folder

Hand folders, or lappers, are still needed in many factories, and they are very expert workers The lapper's tool is a long rod named the *broach stick* With this he both measures out and smooths down the cloth, fold by fold

Finishing Fustians. The class of cloths named *fustians* includes velveteens, corduroys, cantoons, and moleskins These are finished by themselves in special ways by experts trained to nothing else Most important are the velveteens, and to them we shall give special attention

Velveteens. When weaving velveteen we send the weft threads floating over seven threads of warp Under a magnifying glass these floating threads are seen to have taken the form of loops, lying in regular rows down the whole length of the web It is obvious that if those little loops can be halved and the severed ends made to stand up straight, a shallow velvet pile will be made This is precisely the aim of the velveteen cutter When the cloth has been taken from the loom, it is stiffened with a kind of gluey paste or dressing. In that condition it is taken to the cutting-room.

Cutting Frames. After being dressed, the cloth is wound on a roller fitted with a ratchet wheel. This roller is slung on one end of a frame at the other end of which is a similar roller. The frames vary in length from 2 ft. to 10 ft., the short ones being operated by women and the longer ones by men. The cloth is drawn across the frame and fixed on the end roller; then it is tightened and the rollers fixed by the ratchets. In this condition it is ready for the cutter.



204. KNIFE FOR CUTTING VELVETEEN

Cutting Knife. The chief tool of the cutter is a knife of peculiar form [**204**]. It is a blade, *b*, 2 ft. long, ⅜ in. square, tapering to a thin point, and set in a strong wooden handle, *d*, thick enough to fill the palm when gripped firmly. Over the point of the blade is fitted an iron cover shaped like a ploughshare, called the *guide*, *a*, which at once keeps the point, *c*, from dipping into the body of the cloth and lifts up the threads [**205**] to be cut.

205. VELVETEEN CUT AND UNCUT

Hand Cutting. Before beginning to cut, the cutter lightly brushes the length of the "race" with a piece of card, to loosen the stiffening. Gripping the knife in the right hand, like a fencing foil, and balancing her body on the right foot, the cutter, having gently insinuated the guide under the first few threads, drives the knife smartly forward in a straight and level line along the surface of the cloth. This is the action for the short-frame and plain velveteen. Longer frames and varied patterns like cords and figures, involve movements so complex and varied as to evade description. In a fine piece of velveteen 27 in. wide there are about 500 races; the cutter must therefore perform the action described 500 times to cut a length of two yards. It is slow and arduous work.

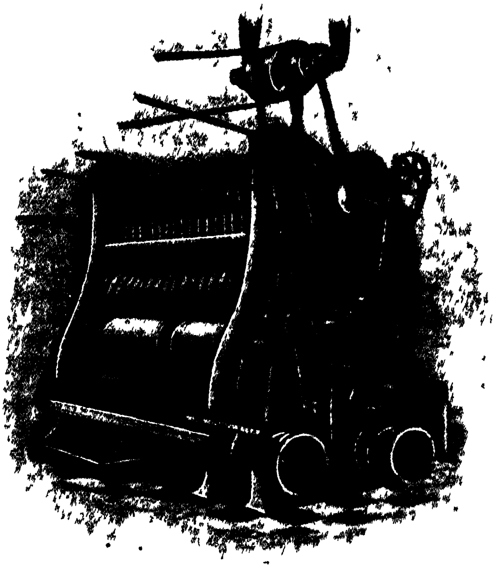
206. SINGEING MACHINE (Mather & Platt, Ltd., Manchester)

Machine Cutting. Fustian cutting by hand is costly, and a machine which could do the work as well, and more quickly, would be a great boon to the trade. The fact that hand cutting is largely practised is proof that no satisfactory machine has yet been invented. There are many machines, however. As early as 1834, two Salford men, William Wells and George Scholefield, took out a patent for a cutting machine which won approval from many competent judges; but something was wanting, and the machine failed to supersede the hand workers. The problems are very delicate and difficult. After the knife has been made a tool of a machine, and the cloth is smoothly fixed, difficulties still remain. The knife and the cloth vibrate under the cutting, and the sensitive nerves of the living cutter respond to the motions. When the knife slips into the cloth, the cutter feels it at once and stops. Here is a double problem for the inventor. In some degree, a solution has been accomplished by the inventor of the machine now used by many velveteen manufacturers. On a frame 14 yards long, with rollers geared so as to remain fixed at any given point, and movable either forward or backward, the cloth is placed. Midway between the two rollers we find the cutting apparatus. The knife has on its guide, but instead of the long blade and handle the short blade is fixed in a steel plate across the bed of the machine, which responds to the vibrations of knife and cloth. The second half of the problem is not so simply solved, though some success has been attained. By a pneumatic piston and a flexible hinge, the knife is rendered sensitive to the lightest obstruction. A knot or a puncture at once throws it out of action. In addition, the knife is watched and set to work by the attendant, who is seated at the point of cutting. The knife cuts at the rate of 2,000 ft. a minute, and at the end of the race the cloth is wound back to the starting point, until the whole breadth has been cut.

Enders and Menders. Small punctures and other faults must be expected to occur, both in the hand cutting and on the machine. When the cutters are done with it, the cloth is handed over to the darners, who are named *enders or menders* in the trade. They carefully inspect the web, and fill up the faults with darns imitative of the rest of the fabric.

Outside Operations. After being darned, the velveteens and corduroys go out of the textile factory into the hands of the bleachers, dressers, dyers, and calenderers. Our duty at this stage, therefore, is simply to inquire into what work we expect from those operators. First, the cloth must be freed from all the sizing and stiffening which have served us in the weaving-shed and the cutting-room. The cloths are soaked, washed, and dried. Secondly, the pile is brushed up on brushing machines. Thirdly, the pile is cropped level on cutting machines with spiral knives. Fourthly, the surface fluff is removed by singeing, either on the hot copper roller or through the gas flame [208]. Fifthly, the cloth is bleached by the common bleaching process. Sixthly, the dyer puts on the colour. Seventhly, the pile is waxed by being passed through between rollers of solid beeswax. Eighthly, the brushing machine again comes into use, to raise the pile. Ninthly, the pile is gently "pegged" on a machine that strokes the cloth with a strip of hard wood. A finishing pegging is given the cloth by hand on tables of stone. The lappers or folders last make up the cloth for the warehouse.

Finishing Linens. Most of our linen fabrics pass through the bleaching process, which is fully explained in the Dyeing section of this course. In several other respects, the finishing operations on linen resemble closely those of the cotton factory. The finishing department of the linen factory, however, has some special features.



207. BEETLING MACHINE (Mather & Platt, Ltd., Manchester)

Beetling. Whoever discovered the secret revealed in beetling made a surprising hit. To change the appearance and character of a cloth by merely beating it with a club, is a wonderfully economical performance. Very probably the inventor was a woman. In olden time, the housewife, when the family linen had been washed, took a flat club, named a beetle, and beat the folded linen flat and smooth, stretching out wrinkles and bringing the fibres up closer to each other.

Beetling Machines. The machine-maker has undertaken no great transformation of the domestic beetles; he has simply made them automatic and power-driven. The wooden pillars are set up on end, with projections fixed on the back of each. A roller behind turns on these projections, and lifts them up in rapid succession, letting the ends of the wooden blocks fall by their own weight. The cloth is wound on a wide roller placed below the beetles, and as it turns, the heavy blocks beat upon the fabric, at the rate of 100 blows a minute. Different effects may be simply brought off on the beetling machine. Imitation of watered silk is produced by the disposition of the cloth in layers, so that the threads are variously pressed. Fine moireens are made in this way. Damasks, fine hollands, tablecloths, and table linens, are smoothly finished in the beetling machine, the threads being flattened and closed up, while a fine lustre is created

Other beetling machines have been brought into use, mostly designed to expedite operations. A rapid machine is that of Mather & Platt [207], the blocks of which are suspended on leather straps attached to semicircular springs, which are worked by a crank from the head of the machine. It delivers about 450 blows a minute.

Mangling. This is another of those finishing operations which, though accepted in many branches of the textile industry, properly belong to the linen trade. The object of mangling is the stretching, smoothing, and lustring of the cloth. Mangling was first mechanically performed by a small waggon heavily loaded with stones running on rollers over a smooth table. This very clumsy appliance has long been discarded. Pressure is obtained by powerful screws, and the to-and-fro motion is accomplished by reciprocating rollers. With the exception of the weight and the reciprocating motion, the mangle [208] is little more than a form of calendering machine. Mangling is variously applied. Sometimes the cloth is taken direct from the beetling machine to the mangle, and in other cases cold calendering precedes the mangling. These are matters of factory practice.

Calendering, viewing, darning, and folding operations in the finishing of linens differ very little from those we have already seen in the other textile factories

Jute. The factory finishing of jute itself is chiefly calendering. The calendering machines are large and heavy, but of the same structure as the common calenders used for lighter fabrics. Jute, however, is the basis of many floorcloths, oilcloths, and linoleums. The manufacture of these fabrics must be studied separately, and in the course of our examination of the processes of manufacture we shall deal with the whole subject of jute yarn and cloth finishing.

PAWNBROKERS. Legal Restrictions. Possibilities of Pawnbroking. Dangers and Risks of the Trade. Disposal of Forfeited Pledges

PERFUMERS. Selling Perfumes as a Department and as an Independent Business. Finance, Capital, Profits and Side Lines

PAWNBROKERS

Of all careers open to a man on fortune bent there is perhaps none less inviting than that pursued by the pawnbroker. For ages he has been covered with obloquy, regarded as a pariah by society, and made a scapegoat of by those whose business it is to restore property to unfortunate persons whom thieves have despoiled.

Pawnbroking appears to have started as a separate trade about the reign of James II. (1685-1688), and from its very beginning its followers have been subjected to the most virulent attacks. Sermons have been preached, speeches delivered from platforms, and articles published in magazines and newspapers, all having for their text the iniquity of pawnbroking and the imperfections of all connected therewith. This prejudice has grown stronger with age, more inveterate from repetition of the attacks, and has been known to culminate in tirades which, it is not too much to say, exceed the bounds of common decency. The whole trade of pawnbroking has been stigmatised as dishonourable, and the pawnbrokers themselves as little better than criminals.

Present Day Pawnbroking. Whatever may have been the truth in the past—and with that we have here nothing to do—pawnbroking is now carried on in the light of day. Its operations are controlled by statute, while its followers are invariably men esteemed by their customers and neighbours. No other tradesman, except, perhaps, the licensed victualler, is surrounded by law as the pawnbroker. The Act of Parliament regulating the trade actually bristles with penalties for the infringement of any of its sections, almost any one of which may be put in motion upon application to a magistrate. It speaks well, therefore, for the members of the trade that so few charges of any importance have been brought home to them. It is claimed for them, and so far has remained undisputed, that more of almost any profession and business have been convicted of serious crimes than there have been pawnbrokers. Still the bad name has stuck to them as to the proverbial dog.

A Dying Trade. It has been stated upon no less authority than that of Mr. John Burns that pawnbroking is one of four dying trades. From what source the President of the Local Government Board derived his information has not been made known, but a long and intimate acquaintance with the trade leads one to believe that he has a strong foundation for the assertion. The number of pawnbrokers is less in proportion to population than any other trade, and, what is more, the proportion shows less and less with each recurring Inland Revenue Report. During the last five years the increase in the number of pawnbrokers in England and Wales was only 33—namely, from 4,280 to 4,313, an average of less than seven per annum, while the population of England and Wales increases at the rate of 350,000 a year. In Scotland the number of pawnbrokers' licences issued in the same period has gone up from 425 to 453. In Ireland there has been an actual decrease. Ten years ago 382 licences were granted; to-day there are only 317. The reason given by pawnbrokers themselves for this restricted growth of the trade is that existing businesses have not been sufficiently remunerative to encourage fresh enterprises. They are constantly complaining that there are too many in the trade, and that it suffers greatly from the consequent competition, although, as before stated, the number is less in proportion than any other trade in London. In many provincial towns there is no pawnbroker's shop to be found. It is only in large industrial and manufacturing centres that the pawnbroker can make a living.

Profits Permitted. Pawnbroking in Great Britain is conducted under the Pawnbrokers' Act, 1872 (35 and 36 Vict. c. 93). The profit fixed by that Act is at the rate of one halfpenny per florin per month up to the sum of £2, or 25 per cent. per annum; above that amount, one halfpenny per half-crown, reducing the rate to 20 per cent. For sums above £2 the Act permits of special contracts being entered into, where the rates are mutually agreed upon as well as the term of the loan, providing it is not less than three months. Every ticket issued by the pawnbroker contains on the back an abstract of the Act setting forth in a clear and precise manner the profit he is entitled to charge, together with other essential information. Any excess upon these charges brings him directly under the penal clauses of the Act. The trade in Ireland is carried on under special Acts of much older date.

Within a radius of ten miles from the Royal Exchange, London, there are 692 pawnbrokers' shops, the average number of pledges taken in per month at each shop being estimated at 5,000, making an aggregate of 3,460,000, or 41,520,000 pledges per year—about seven to each head of the population. The average value of each pledge is 4s., therefore the amount annually advanced to the poor of London is £8,304,000. In these figures pledges of more than £10 are not taken into account, as they do not come within the provisions of the

Pawnbrokers' Act. Yet a very large proportion of the London pawnbrokers, as well as many in the provinces, do a large business in that way.

Present Conditions. With such a turnover it would be thought that the trade of pawnbroking would be prosperous and flourishing; yet such is far from being the case. The good days of pawnbroking are over; competition is too keen, and too much is therefore lent upon the goods. It is a well understood maxim in the trade that the man who makes the biggest advances does the most business, and though in this way, by doing "large numbers," as it is called, ticket money—for a loan of 10s. or under, one halfpenny, and above that sum one penny—amounts to a considerable item, the loss on the realisation of forfeited pledges may easily lead to disaster. It should be remembered that all pledges above 10s. must be sold by auction; goods pledged for 10s. and under become the absolute property of the pawnbroker unless they are redeemed within a year and seven days.

Forfeited Pledges. Many pawnbrokers dispose of their "lows" in bulk—frequently at a discount off the amounts lent—while others utilise them in their own sale department. The latter process is generally the more remunerative, especially if the articles have been carefully "taken in." These statements may not be in accordance with the popular idea regarding a pawnbroker's profits, but they are strictly accurate, and may be verified by reference to the advertisement columns of their trade journal. Few people realise the difficulty of selling second-hand goods. It has been said that one of the finest tests of a salesman's capabilities is to get him to try to sell a second-hand coat A brief experience will teach the novice that it is by no means an easy matter in these days when the market is flooded with cheap and shoddy material, with cut, colour, and fashion constantly changing. The difficulty is quadrupled in regard to women's clothing.

Possibilities of Pawnbroking. In spite of its unpopularity and somewhat unsavoury nature, a good living may yet be made out of pawnbroking. It is anything but a "get rich quick" occupation, for it is a fact, though little understood by the public, that the pawnbroker works for less profit than any other class of tradesman. His "profit"—the word made use of in the Act of Parliament regulating the trade —on every two shillings he turns over is but a halfpenny, far less than is made by the butcher, the baker, the grocer, draper, or any other shopkeeper with whom we have daily dealings. As one of their number puts it, the pawnbroker does not get 25 per cent on his turnover, as is popularly imagined, but his profit or interest is calculated at the rate of 25 per cent. *per annum*, which is a very different thing. Most retail traders price their goods so as to secure 25 per cent. profit upon their turnover, so that it follows that if a tradesman has a turnover of £50 per week he makes a gross profit of £12 10s. If a pawnbroker has a turnover of £50 per week he would not get more than a gross profit of £2 10s. to £3, and that would include his charge for tickets as well as interest.

Qualifications of the Pawnbroker. To succeed in the business a man requires knowledge, ceaseless perseverance, and capital. In the metropolis few pawnbrokers employ in their business less than £2,000, many as much as £10,000, some £20,000, and others considerably more than £30,000. In the provinces there are businesses carried on upon a capital of £500, but under such circumstances it must be a hard struggle to find the wherewithal to meet the demands for wages, rent, rates, taxes, fuel, light, licences, insurance, and the numerous small expenses incidental to all retail businesses, to say nothing of household and personal outgoings. The cost of a pawnbroker's licence is £7 10s., and expires on the 31st of July. Those who make advances on gold or silver articles are also required to take out the higher licence to deal in plate—namely, £5 15s.

As may readily be conceived, the difficulties besetting the business of lending upon portable securities are enormous. The ideal pawnbroker should know the value—that is, the selling price of every article under the sun, anything that has any market value whatever. Needless to say, if such a person exists, he is very difficult to find, and he would probably make a better living in another trade. The pawnbroker deals in everything, and has to exercise his judgment as to the character of the thing offered as well as of the offerer. As a rule, he goes upon the assumption that it will be redeemed, and therefore lends as much as he can upon the article with a due regard to the price it will fetch under the hammer, or, in the case of "low" pledges, in his sale shop. Attention to market value—that is, the price at which any article will readily find a purchaser—is the essential for the man behind the pawnbroker's counter. Experience alone will enable him to attain this desirable qualification. A man can scarcely be at the same time an expert upon precious stones, a judge of silks and satins, and fix the value of an overcoat and a pair of boots. Yet this is the pawnbroker's daily task.

Stolen Property. Apart from these difficulties there are others with which the pawnbroker has to contend He has to avoid taking in pledge property not lawfully acquired, or to which the pawner cannot confer a good title. He must also perpetually be on his guard lest he fall a victim to the wiles of the "duffer." The first is not an easy matter, for the pawnbroker has no more means of distinguishing the thief than has the owner of the stolen property or the policeman who is searching for it. When traced to his keeping, which generally happens through the pawn-ticket issued by the pawnbroker, the latter has, in most instances, to restore the article without compensation. Now and then, by grace of the magistrate, he receives a third or a half of his advance.

"Duffing" the Pawnbroker. "Duffing," or "mosking," is a career pursued throughout the country with considerable success. It consists of purchasing or manufacturing goods, and pledging them at a profit. Numbers are engaged in it, making their way from shop to shop, and from town to town, until they have succeeded in persuading some unwary pawnbroker to advance them the sum they are prepared to accept. This may be considered a legitimate business, but there are other practices which are not so guileless.

There is no royal road to pawnbroking. It cannot be learned or conducted by rule of thumb, but demands from its followers sheer hard work and close application; neither can it be imparted through the pages of a book. The pawnbroker must keep his nose to the grindstone all day long, and the man who succeeds in making a competence at the business would probably do so far more quickly in any other industry. The remuneration is slow, but it is certain. Pawnbrokers nowadays, outside Scotland and Ireland, at least, carry on a sale trade comprising jewellery, clothing, furniture, etc., and the two businesses materially assist one another. It has been advanced as a reason for pawnbrokers getting on so well in the world that they conduct five or six businesses under one roof.

Assistants. It is impossble to state the average wages paid to assistants. Everything depends upon the nature of the business. As in other trades, the West End houses require far more experience and ability in their employees than do those in the East and Southern districts. Experience gained in the East End of London is of very little use in the West, and experience gained in the West is of no use in the East. Of late years the once general custom of apprenticeship has died out. Boys are required for the warehouse where the pledges are stacked, also to write tickets and to book up the day's transactions. After some probation, a smart lad may be employed at the pledge counter, where his real experience begins. The sale shop is generally distinct from the pawnbroking. "Living in" is the rule, and when speaking of wages has to be taken into account. An average London pawnbroker's establishment would comprise a manager or foreman, second and third hands, one or two warehouse boys, and possibly a porter. Boys living in would get from £6 to £9 for the first year, and the porter £30 to £50. Excluding a limited number of very high-class houses, where exceptional ability is demanded and well remunerated, the average pawnbroker's manager living in would get about £100 a year, the other hands receiving from £30 upwards. A proportionate increase would be given to those not living on the premises. In many houses it is customary to allow a commission on sales. Anyone contemplating entering the trade should reflect that, unless he is a man of considerable means of his own, or has some very substantial friends with unlimited confidence in him, the prospects of quickly rising to the rank of a master are not hopeful.

Books on Pawnbroking. The only books dealing with the subject are legal handbooks, the most up-to-date of which is the "Law of Pawnbroking," by Charles L. Attenborough (1897). The trade organ is "The Pawnbrokers' Gazette and Trade Circular," published weekly. The National Pawnbrokers' Association and various metropolitan and provincial societies exist to protect the interests of their members. There are also a number of flourishing charitable and benevolent institutions in connection with the trade.

PERFUMERS

To-day perfumes are sold largely by chemists, hair-dressers, drapers, and in all the departmental stores. The true perfumer—he who keeps open shop for the retail sale of perfumes and toilet articles alone—is not often to be met with nowadays, not so often perhaps as he might be. For there can be no question but that there are many openings, especially in the larger and better-class cities and towns in the country, for a practical perfumer who knows the business thoroughly, and who is prepared to do it well. Of course, perfumes and toilet adjuncts are more or less luxuries. The neighbourhood selected must therefore be a good one, and the shop, stock, and appurtenances must appeal to the æsthetic in mankind, and especially in womankind.

How to Learn. The business is best learned in a chemist's shop. There the manufacture (or blending) and the sale of perfumes is a regular part of the chemist's business. Moreover, the science of chemistry plays a very important part in the modern art of perfume-making, and the youth who is taught the scientific compounding of compatibles and incompatibles in his daily routine is learning the prime essential of the making of agreeable scents. Of course, an apprenticeship of four years to a regular perfumer, either wholesale, manufacturing, or retail, may serve the purpose quite as well, but it is a noteworthy fact that most of the successful perfumers of the day have been chemists first and perfumers afterwards.

What to Learn. The things to be learned during the novitiate are many and various. First, and most important of all, there must be the "cultivation of the nose," as it might be termed. The successful perfumer has so highly trained a nose that he can detect delicacies of smell that elude the ordinary person. This is a matter of experience and application, but primarily of instinct. The business of the novice is, therefore, to become acquainted with the properties and possibilities of the various crude products with which he is brought into contact, so that he can evolve something pleasing to the senses. He is taught how to blend essential oils of lavender, origanum, sandal, orange, lemon, and what not, in certain proportions with rectified spirit or with perfumed waters in such a way as to produce a perfume. He macerates musk, orris-root, ambergris, and so on, to make bases for recognised perfumes, and he learns how to distil flowers for the preparation of the oils they contain, and how perfumes are prepared from fresh flowers by simple absorption in a fatty medium. He comes to know the value—and the worthlessness—of various synthetics which are often employed in the manufacture of cheap perfumes, and the kinds of bottles to buy for bottling certain brands, the style of labelling, capping, and tying with ribbon, packing, and so forth, that is necessary to produce a finished product that will sell. Furthermore, and vitally, he acquires inside information into costs and profits, and the advantages of adequate display. Joined to perfumes and part of the family tree, so to speak, are many toilet dainties in which perfume is an essential, and often the essential ingredient. So the youth who has mastered in a kind of way the art of making a perfume has yet to learn the many ways in which it is adapted to the taste of the dainty lady of fashion. He is taught, or ought to be taught, the mysteries of making perfumed sachets, toilet creams, face powders, pomades, lip salves, cold-creams, cosmetics, bath powders, massage lotions, hair dressings, brilliantines, hair restorers, theatrical grease paints, and a host of allied preparations that are intended to make the plain beautiful and to stave off the ravages of Time. The question of toilet soaps itself is a large one.

Ways and Means. An adequate experience having been acquired, the young man (or woman) with a capital of £500 might essay a new business. As before mentioned, the shop selected must be in a good-class neighbourhood if the adventure is to be made on perfumery and its adjuncts alone. It must be done well, or not at all, for the cheap perfume business is not worth the candle. Those who want cheap perfumery can get all they desire in endless variety from the draper, the hairdresser, or the chemist. So a modest shop in a good-class, busy thoroughfare of a good provincial town, or a flourishing metropolitan suburb, should be secured and fitted up well. It will pay to spend at least £200 on good fittings in an eligible neighbourhood. Light oak, mahogany, or other fancy wood, carved or plain, but in good taste should be chosen. The window should be carefully looked to, and fitted so that it will display in the daintiest manner possible the delicate stock that is to tempt the passer-by. Some tastes run to velvet plush draperies of various shades in the window, while others affect plain oak recessed compartments with brass standards for displaying goods, and mirrored backs, sides, tops, and bottoms. The regulation shop with counter and cases. has given place of late years to the *salon* style of shop interior. A handsome carpet on the floor, a perfume case of one design here, another of a different style there, a profusion of mirrors, palms, and flowers dotted in odd corners, with handsome cut-glass show perfume bottles, perfumed soaps or toilet specialities insinuated in unexpected places, but not obtruding on the general scheme, dainty curtains, a delicate perfume, and a general air of luxury; such is the modern perfume *salon*.

Buying. The young perfumer would not at first attempt to make and bottle his own perfumes entirely. He would probably have a "bouquet" evolved from his inner consciousness, in which he had hopes of great popularity, and this he would manufacture and put up as a send-off. It would require to have a catchy name, and be original and attractive in style of get up. Nowadays, most wholesale perfumers, manufacturers of toilet soaps, and makers of toilet articles, offer perfumes, soaps, and other goods, packed in a selected style and labelled with the retailer's own name and address. The opening stock need not be large; in fact, it should be as small as possible, keeping in consideration the ephemeral nature of the goods and the danger of soiling labels and caskets. The amount expended in stock would not, therefore, be more than £150. For one must remember that crowded perfume cases are neither artistic nor necessary.

What to Buy. First and foremost, the beginner would select about 10 lb. of assorted perfumes in bulk. These would include the more popular perfumes (in triple extracts for reduction with spirit or otherwise), such as jockey club, essence bouquet, heliotrope, Parma violets, lily of the valley, moss rose, musk, myosotis, new mown hay, stephanotis, sweet pea, wallflower, white rose, ylang-ylang, and so forth, which he would order in $\frac{1}{2}$-lb. or $\frac{1}{4}$-lb. quantities at a cost of from 9s. to 10s. 6d. per lb. Then he would carefully choose an assortment of bottled perfumes, in 1-oz., 2-oz., 4-oz., up to 8-oz. sizes. One gross of the 1-oz. size would probably cost about £10, half a gross of the 2-oz. size, about £8, three dozen of the 4-oz. size £5, and so on. It must be distinctly understood that no cheap perfumes should be touched, except in rare instances, and great care and thought should be exercised in the selection, which should not require more than £30 to £40 all told. Beside the bottled perfumes, there are also caskets or cabinets containing bottles of assorted styles, the caskets themselves being works of pictorial art and chaste decoration. A sum of £10 should secure a good display of caskets in designs to suit all tastes. Besides these, there are the proprietary brands to be stocked. Another £15 to £20 would have to be spent on the "creations" of Rimmel, Vinolia, Grossmith, Atkinson, Gosnell, Erasmic, and other British makers who have made their wares popular all over the world; while the staples of Continental perfumers like Roger & Gallet, Piver, and Pinaud, and the celebrated Farina eau-de-Cologne must not be forgotten.

Sundries. This may seem a modest estimate for one aiming at doing a high-class business, but it should suffice, for it must not be forgotten that the balance of the £150 will be required—and perhaps a little more—to cover the necessities that remain. These include toilet vinegars, hair washes, hair pomades, hair oils, brilliantines, mouth washes, and liquid dentifrices, tooth pastes and powders, cosmetics for the hair and moustache, creams, pastes, cosmetics and powders for the skin, toilet milks, perfume sprays, perfumed sachets, toilet powders, smelling salts, incense ribbon, fumigating pastilles, manicure sets, shaving creams, and the important section of toilet soaps. All these must be selected in small, assorted quantities ($\frac{1}{4}$ dozens or $\frac{1}{2}$ dozens), the aim being to have as varied an assortment as possible.

Development. As the business grows, the man with a genius for perfumery will soon evolve new notions, and, provided he can hit on a novelty in perfume, to which he can attach an original and striking cognomen (always taking care to endeavour to be unique in the style and finish of their packing), his success, all other things being favourable, is a foregone conclusion. If a new perfume is evolved—and there are thousands put on the market annually—the usual method is to run a series. That is to say, should he produce a perfume which he names "Eunitia," for instance, he would have besides "Eunitia" bouquet in various sized bottles, "Eunitia" toilet cream, "Eunitia" sachet, "Eunitia" face powder, and even "Eunitia" toilet soap. There is great scope for ingenuity in such an occupation, and to the earnest enthusiast the business is a fascinating one. Then the question of face massage and complexion beautifying is becoming yearly more important. As trade increases, a portion of the shop might be curtained off, or the back shop premises converted into a kind of a boudoir, where Society dames may have their jaded complexions renovated by an experienced masseuse with creams and lotions compounded on the establishment. This once attained and a fair connection secured, the business becomes very profitable indeed, for what will not woman sacrifice to maintain her beauty? Some perfumers have chiropody as a side line, but this requires skill, and generally entails the employment of expert and high-priced operators. The art of manicuring, however, is easily acquired, and well repays the time and trouble spent on it. Detailed particulars regarding "Manicuring" and "Massage" will be found on pages 3738 and 3739. For "Chiropody" see page 1895.

Two Representative Formulas. In the course of his tutelage the young perfumer will become acquainted with many formulas or recipes for the preparation of various perfumes. The aim has been and still is to imitate by the combination of various essential oils the perfume of known flowers. In many cases this imitation is very successful, although the most satisfactory perfumes are undoubtedly made by direct abstraction from the real flowers, either by distillation or by enfleurage. The latter process produces the best results, and is done by placing the petals or leaves on fats, either hot or cold. These processes, however, require a special plant, which the retail perfumer would not possess; so he would buy essential oils from a reputable house, lay in a stock of rectified spirit, and make a "Honeysuckle" perfume, for instance, by mixing the following ingredients:

Oil of pimento	10 drams
Essential oil of almonds	10 drams
Oil of cedrat	5 oz.
Oil of origanum	3 drams
Otto of rose	1 dram
Rectified spirit	4 pints

The usual process is to add the oils to the spirit in a large stoppered bottle, shake, and leave to mature for a week or two before bottling. The most popular of the perfumed waters is "Lavender Water," and every perfumer has his own formula for this. A delightful "lavender," and one which is said to have been prepared for and used by George IV. is made as follows:

Mitcham oil of lavender	6 drams
Essence of musk	6 drams
Essence of millefleurs	6 drams
Oil of bergamot	3 drams
Otto of rose	½ dram
Rectified spirit	48 oz

One of the prime essentials in the preparation of a lavender water is to make sure that a well-matured English oil of lavender is used; and the perfume, after being mixed, should stand for from four to six weeks with occasional shaking, before being filtered through filtering paper. Grey filtering paper of English make should be employed, and the paper should be warmed before the filtering process is begun.

Alluring the Public. A brilliantly-lighted and luxurious window display frequently changed is necessary to attract the public. The vogue of recent years has been to make displays of special perfumes by the use of floral adjuncts, such as baskets of roses, be-ribboned receptacles for perfume bottles, soaps, sachets, etc., palms, greenery, and other elegantly executed pictorial representations of high art, and adjuncts of a like nature, to draw the public to the window. Sprays of honeysuckle in profusion would impress the "Honeysuckle bouquet" on the public mind, and tempt to its sale, while baskets of lilies or twining loops of iris, or other known flower, would be employed for the perfume it represented. The main feature, however, is good taste in all displays, and the lavishly floral or the gorgeously plush may with profit in many instances be replaced with effect by the severely classical, or, as in the case of Old English Lavender, by an old-world touch. On the opening week, tiny sample sachets or sample bottles of a special perfume might be distributed judiciously, and a never-failing attraction and strong incentive to purchase is the practice of having one or two spray bottles containing representative perfumes on the counter or tables in the salon, by means of which the customer may "try before she buy."

Profits. The perfumer will have no difficulty, with a good character and £500 in the bank, in obtaining credit on the usual monthly or three-monthly terms, and he will find, as in most other businesses, that prompt cash brings the largest discounts. Thus, if he pays for his opening stock "on the nail" he will secure from 7½ to 10 per cent. off the list prices—a consideration on a £150 order. The profits on perfumes and toilet articles are good, averaging from 40 per cent. to 50 per cent. on the turnover. Proprietaries do not bear so great a profit—the best-known perfumes and soaps bearing, roughly, 15 per cent. to 25 per cent. profit only. But the bulk perfumes show considerably over 50 per cent. average, and when a formula has been produced that gives a perfume that can be sold in 1-oz. bottles for 2s., for instance, the profits mount up higher still. Taking all things into consideration, however, one might say that a fair average all round may be struck at 50 per cent. on the turnover—a profit by no means to be despised in these times of stores and cut prices.

THE MINOR SOURCES OF SUGAR

Sugar from the Maple, Palm, and Date. Tapping the Trees. Yields. Sugar-making and Refining in India. Sorghum Sugar and Syrup. Maize Sugar

SUGAR
continued from page 4166

Sources of Maple Sugar. Maple sugar is the produce of several kinds of maple-trees, the following being the chief varieties:

Sugar maple, hard maple, or rock maple—botanical names: *Acer barbatum, Michx., A. saccharinum Wang.*

Silver maple, soft maple, white maple or swamp maple—botanical names: *A. saccharinum Linn., A. dasycarpum Ehrh.*

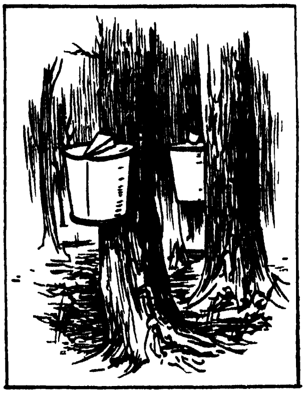
Red maple, soft maple or swamp maple—botanical name: *A. rubrum Linn.*

Black maple—botanical names: *A. barbatum nigrum Sarg., A. saccharinum nigrum T. and G., A. nigrum Mich.*

Production. Maple syrup and sugar have a distinctive delicate flavour, on which account they are much prized in the countries of production—Canada and the United States. The production of maple sugar is looked upon as a remunerative adjunct to other farming industries. The season for tapping begins where winter ends, and is over before the ground is sufficiently thawed and settled for spring work proper. It therefore occupies a period when little other farm work can be done. In Canada some 10,000,000 lb. of maple sugar is made annually, while in the United States the annual production approximates 45,000,000 lb. The bulk of the United States production of sugar and syrup is made in the States of Vermont, New York, Ohio, Pennsylvania, and New Hampshire. The production of maple sugar has been especially encouraged in Vermont, where a bounty was paid on quantities of at least 500 lb. sugar testing 80 degrees or over of the polariscope. The industry was established in Vermont by the Indians, and from them the early settlers learnt the process of manufacture. Between the years 1896 and 1904 the University of Vermont and State Agricultural College conducted a research on maple sugar which has cleared up many doubtful points; this research is the most complete study of the subject that has been made.

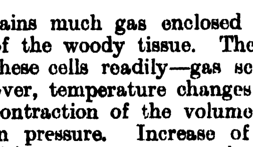
How the Sugar is Obtained. Maple sugar is formed from starch, in the late winter and early spring. This starch is stored in certain sapwood cells during the preceding summer, and is probably transformed into sugar through the action of enzymes (ferments). The starch is formed in the leaves under the influence of sunlight, and a large leaf area and plenty of sunshine conduce to a good sugar yield. As will be explained later, the tree is tapped, and the sap from which the sugar is made flows through the tap into a bucket placed to receive it [16]. The immediate cause of the flow from the tap hole is sap movement under pressure towards the point of least resistance. The exciting cause of the flow seems to be temperature fluctuations backwards and forwards over the 32° F. line, causing alternation of pressure and suction—a pump-like action. The ultimate and absolute cause can hardly be this or any other physical one; it is probably a function of living cell.

The maple trunk rapidly accumulates water during the late winter and early spring. It at all times contains much gas enclosed within the cell walls of the woody tissue. The sap passes through these cells readily—gas scarcely at all. Moreover, temperature changes cause expansion, or contraction of the volume of gas, and change in pressure. Increase of water content and rising temperature produce pressure, pressure induces sap movement, and sap movement means sap flow. Pressure and sap flow come from above and below the tap hole, but little from the side.



16. COLLECTING MAPLE SAP

Season for Tapping. The time for tapping is from the middle of February to late in March, when the nights are still frosty, but sunny and warmer days prevail. If at this time the trunk of the maple be tapped, by boring into it for a depth of 3 in. or less, and a sap spout, or spigot, be inserted, the sap exudes and falls drop by drop, quickly or slowly, according to the weather and time of day, into the bucket. The season lasts well into April The taps used are figured in 17, the top two being the simplest kinds; the fourth, the "Foster" tap, is one much in use, the hook being used for suspending the bucket. The collecting pail should be of tin, and have a cover to keep out snow, rain, and dirt, since much extra fuel is needed to evaporate the sap when it is mixed with rain or snow The pail holds from 16 to 18 quarts of sap



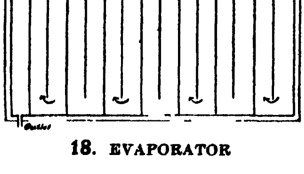
17. MAPLE TAPS

No more sugar is yielded by tapping on the branchy side of the tree than on the side relatively devoid of branches The hole in the tree into which the tap is inserted is made with a sharp bit, about four feet from the ground. The larger the tap hole the more sap and sugar, for a time, at least. It is undesirable, however, so to wound the tree that the hole will not soon heal. A ⅜ to ⅝ in. bit is best for tapping, and care should be taken to free the hole from shavings and borings before the tap is inserted. The sap is at first quite clear, but as the season advances the flow lessens, and the sap becomes thicker and cloudy.

Yield of Sap. A good sap day, of which there are ten or fifteen in a season, occurs only after the air temperature has remained below freezing point for some time. Warm days and frosty nights form ideal sugar weather. Some 63 per cent. of the sap flows before noon. The total sugar content of a tree carrying 135 gallons of 3 per cent. sugar is approximately 35 lb. The average yield of sugar from a small tree is 3 lb., which represents 9 per cent. of the total sugar content. A pound of sugar from each pail of sap is the usual amount, and is amply maintained in practice. The sap ice should not be discarded, as ice removes much sugar. The duration of the sap flow depends on the weather conditions; it may be fairly continuous for some time, but is commonly broken into distinct runs. The swelling of the leaf buds preparatory to bursting marks the end of the flow, or season.

Trees under 25 years old are seldom tapped, as the yield is too small to pay; but once a tree is tapped the process may be continued annually for forty years, without harm to the tree.

Sugar Boiling. The process of obtaining sugar from maple sap is extremely simple on account of its purity and freedom from extraneous matter. The contents of the sap buckets are emptied into a tank in the boiling shop, and from this tank the sap is led to the evaporator, which is heated by prunings of the maple grove. The evaporator [18] is a large iron pan from 10 to 18 ft. long, 4 to 5 ft. wide, and 6 to 8 in. deep, divided by partitions so that the sap, admitted by a tap regulated by a float, takes a devious course before it reaches the far end. The sap boils furiously, and is skimmed all the time by means of shallow tin skimmers. The incoming sap makes a continuous current throughout the evaporator, and by the time the sap reaches the outlet it is a more or less thick syrup. While hot, the syrup is passed through a felt strainer.



18. EVAPORATOR

Maple Syrup. If the maple sugar be required in the form of syrup, which saves much time and fuel, it is evaporated to a density of 1·325 or 11 lb. of sugar to the gallon, and poured while hot into perfectly clean pans or tins, which are then sealed to keep out the air. Syrup of this strength will not granulate under ordinary conditions. The strength to boil can be gauged by a thermometer. When the thin sap begins to boil, its temperature is about 213° F. As it boils down and becomes thicker the temperature at which it boils rises until towards the end it may be 235° to 240° F. A syrup, if consisting only of sugar and water, boiling at 230° F. would test 80°, and at 253° F. 90° polariscope, and each degree over this temperature approximately one per cent. of sugar.

If made into sugar, the syrup is boiled over a brisk wood fire, in a pan smaller than the evaporator, to a concentration which will crystallise into sugar on cooling. There are various methods of determining when this sugaring point is reached, the usual test being to pour a little of the syrup on to snow, when, if ready, it gives a stringy or hairy product. The pan is then removed from the fire, the mass stirred or dipped until graining begins, and transferred to tubs to harden. Variations in the manufacture are practised, a little lime or soda being, in some cases, added to neutralise free acids, and in others white of egg is used to make a crystal white product.

Palm Sugar. In India, besides the sugar cane, several palms are used as sources of sugar. The chief kinds are:

Palmyra palm or crab tree—botanical name, *Borassus flabelliformis Linn.*

Indian date palm—botanical name, *Phœnix Sylvestris.*

Sago palm—botanical name, *Caryota urens*

Coconut palm—botanical name, *Cocos nucifera.*

Neen tree—botanical name, *Melia azadirachta*

The Palmyra Palm. The Palmyra palm constitutes the only species of the genus palmacea, the word *flabelliformis* referring to the fan-shaped leaves. It is very widely distributed, and is found in South America and Australia, and in every part of Hindustan. The average height of the tree in Tinnevelly is 40 to 50 ft., the circumference at the base being often 5¾ ft., and at the top 2½ ft The roots penetrate to a great depth, and hence deep loose soil is best for the growth of the tree. The cultivation is easy, it being required simply to collect and sow the seeds, which germinate readily, and to protect the young saplings from cattle and from villagers, who collect and use the young shoots as a vegetable. The tree cannot stand very much drought, and is best planted in a rather damp locality.

Method of Collecting the Sap. The saccharine juice of the Palmyra palm is obtained by bruising the flower stalk with a wooden instrument resembling a pair of compasses so as to crush the embryo flower or fruit within, and by taking a thin slice off the end for several days. The object of slicing the end of the spathe is to facilitate the exit of the sap, and to prevent it from bursting the spathe. About the eighth day the sap begins to exude, and is received in a little earthen vessel attached to the stalk. The inside of this vessel is smeared with chunam to prevent the juice fermenting. The tree is climbed both morning and evening for bleeding, but the sap which has collected since the last ascent is usually brought away in the morning only. The quantity of juice yielded by a male tree is about two-thirds of that obtained from a female tree. The palmyra season extends from the beginning of February to the beginning of October. Much of the fermenting sap is drunk just as it comes from the tree, and when allowed to ferment forms the intoxicating beverage known as *toddy*. Still more of the juice is boiled into *jaggery*, or converted into *sugar candy*.

The palmyra continues to yield three or four quarts of sap a day for four to five months, but once in every three years the operation of tapping must be suspended, and the fruit permitted to form, otherwise the tree would die. The juice contains more sugar than other palms, three quarts of juice yielding one pound of jaggery. The tree goes on yielding juice for about fifty years, and begins to give sap when about 15 years old, but this depends upon the locality. The production of sugar from the sap is dealt with in the section devoted to the date palm.

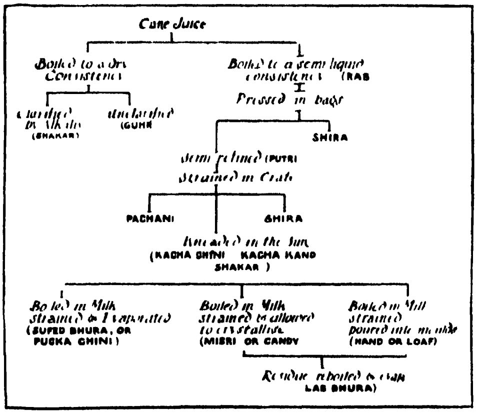
Indian Date Palm. The date palm attains a height of 30 to 40 feet. It grows most abundantly in Bengal, Behar on the Coromandel coast, and Guzeràt. In Jessore and other districts of Bengal, it is extensively utilised as a source of sugar. The higher ground is that chosen for date palm cultivation, and the seed is planted in rows 12 ft. apart. After seven years a tree ready for tapping is obtained, the process being repeated thenceforward every year. There are two series of leaves, the crown leaves, which rise straight from the top of the trunk, and the lateral leaves, which spring out at the side of the top part of the trunk. When the rainy season has completely passed, and there is no more fear of rain, the cultivator cuts off the lateral leaves half round the tree, thus baring a surface measuring 10 to 12 in. each way. This surface, at first white and afterwards turning brown, is not the woody fibre of the tree, but is a bark formed of many thin layers which change colour.

Tapping the Date Palm. After the tree has remained for a few days, the tapping is performed by making a cut into this exposed surface in the shape of a very broad V, about 3 in. across, and ¼ to ½ in. deep. Then the surface inside the angle or V is cut into, so that a triangular surface is obtained from which sap flows. The sap flows to the bottom of the angle of the V, where a small bamboo spout is placed to convey it to a small earthenware vessel. The tapping is arranged throughout the season by periods of six days. On the first evening a cut is made as described, and the juice allowed to run during the night; this juice being the strongest, and known as *jiran* juice. In the evening another slice is cut off the exposed surface, the sap obtained being termed *do-kat*. No new cut is made on the third night, the juice which runs out being called *jarra*. The tree is then rested three nights, and again tapped as described above. In time the tree gets a depth of four inches taken out of the wound. The following season, the opposite side of the tree is tapped, each tree yielding juice for about forty years. The notches are always on the east and west sides of the tree. The clearer and colder the weather, the more copious the flow. Tapping begins in November, the best flows being in December and January. The flow diminishes as the warm weather comes. Each tapping yields five *seers* of juice on the average, and seven to ten seers produce the *seer of guhr*.

The annual yield of sugar from palm-trees in India is estimated at 100,000 tons.

Other Sugar-yielding Trees. The *sago palm* of India is the chief source of palm sugar in Southern Ceylon, and in the Bombay Presidency more sugar is made from it than the palmyra palm. The *coco-nut* palm is used as a source of sugar in Madras, while only a small quantity of sugar is obtained from the *Neem* tree.

Sugar-making in India. The processes followed in making sugar from cane juice are shown in the table prepared by Mr. T. O. Miller for the "Agricultural Ledger." It is given here [**19**] to show the great varieties of sugar which are prepared from one source, and also because some of the methods are followed in preparing sugar from the sap of the Palmyra palm and Indian date palm.



Cane Juice
Boiled to a Dry Consistency
Boiled to a semi liquid consistency (RAB
Pressed in bags
Clarified or White (SHAKAR)
Unclarified (GUHR
SHIRA
Semi refined (PUTRI
Strained in Cloth
PACHANI
SHIRA
Kneaded in the Sun (KACHA CHINI KACHA KAND SHAKAR)
Boiled in Milk strained & Evaporated (SUFED BHURA, OR PUCKA CHINI)
Boiled in Milk strained & allowed to crystallise (MISRI OR CANDY
Boiled in Milk strained poured into moulds (KAND OR LOAF)
Residue reboiled & (LAL BHURA)

19. TABLE OF INDIAN SUGARS

The juice from the palm is boiled at once in large pots placed in a hole on the top of a dome of brickwork which is over a wood fire. The fire is kept burning by using the leaves of the trees with the wood fuel. The juice is clear when put into the pan, but after boiling turns dark brown, and yields a semi-solid mass called *guhr*. This, when still warm, is poured into small earthenware pots. It takes two and a half hours to boil a panful of juice to the guhr condition.

The refining processes of India do not involve the use of charcoal, but consist of eliminating the molasses more or less perfectly by draining, reboiling, and claying. The cane-juice table sufficiently explains the general methods followed in the case of palm sugars. The English system is also followed to a limited extent. It should be noted that the greater purity of the palm juices makes the refining a less troublesome operation than in the case of cane juice, it is also cheaper.

Sorghum Sugar. Broom corn, Chinese sugar cane, Imphee or Sorgho—botanical name, *Sorghum saccharatum Pers.*—is a graminaceous plant which has been the subject of much experiment as a sugar producer [**20**]. Experiments in Kansas have shown that sorghum may be developed in any particular direction by continuous selection of seed from cane which has the qualities desired. In this way the percentage of sugar might be increased and the proportion of impurities in the juice diminished.

20. SORGHUM

No sugar, or only a very little, is produced from sorghum at the present time, but a considerable quantity of sorghum syrup is manufactured. The difficulty has been to get rid of the starch and gummy matters, and the uncrystallisable sugars which prevent the sugar from being prepared in a dry state. The juice of the sorghum contains about 10 per cent. of sugar. A variety of sorghum (*S. vulgare Pers.*) or great millet, also yields sugar.

Cultivation of Sorghum. Sorghum as a source of seed for cattle-feeding purposes is considered by some experts to be superior to maize, and it is probable that future investigation may result in varieties which yield a maximum of sugar as well as fully-matured seeds. The varieties at present best known are the Honduras, early amber or early golden, and white Liberian. The stalk is ¾ in. to 1¼ in. in diameter, and from 6 to 12 ft. long. Sorghum is not affected by drought and can be grown on any good corn land. The land should be deeply ploughed and freed from lumps in the spring by rolling or harrowing. Planting should not be too early, but in warm and moist soil, so that the plants appear in a few days. The plants may be thinned, and are best planted in hills, so as to be able to stand the wind better. Close planting checks the growth of weeds, but exclusion of light is deleterious to the growth.

The time required for maturing varies from 90 days in the case of the early amber, to 140 days for Honduras. The time for harvesting is when the seed has passed the doughy stage and feels hard. The tops are removed by a sickle for the sake of the seed, and sometimes the stalks are stripped for fodder, but there is no difference in sugar yield between stripped and unstripped stalks. It is important to reject immature canes as the larger proportion of glucose they contain prevents the crystallisation of the sugar.

Collier emphasises the following points:

1. A cane that matures quickly and has as long a working period as possible should be selected.

2. The cane should not be worked too early; the seed should be well matured and quite hard, and the juice should have a specific gravity of at least 1·066.

3. After cutting, the canes should be worked up without delay. It is best to draw directly from the field to the mill, as required, to keep the mill going.

The stalks are passed through rollers as in the case of the sugar cane, the juice is then limed, defecated, sulphured, and concentrated in much the same way as for Beet Sugar [page 4160].

Sorghum Syrup. The United States Department of Agriculture has issued in a popular form a pamphlet dealing with the production of sorghum syrup, of which the following is an abstract of the practical portions. The juice as it comes from the mill is treated with sufficient cream of lime to render it slightly alkaline when tested with litmus paper. Excess of lime should be avoided. The addition of fine clay at this stage is also recommended The clay, in very fine powder, is stirred in water to make it into a thin batter, and a small quantity of this is stirred in after the lime. The lime and clay gradually subside and take down with them the impurities of the juice. The vessel containing the juice is allowed to remain undisturbed until the juice is cleared The clear juice is then drawn off, heated nearly to boiling point, and a little superphosphate of lime added to make the liquor distinctly acid to litmus paper. About a gallon of concentrated superphosphate of lime is sufficient for from 400 to 500 gallons of juice, the quantity depending upon the amount of lime that was used. Excess of superphosphate must not be added, as it affects the taste of the product. The mixture settles out a precipitate from which the clear juice is separated and rapidly concentrated in an evaporator. Bright and brilliant clarified juice is essential to success. After evaporation to a suitable density the syrup is cooled, and when it reaches the temperature of the air it is put into barrels. If no clay be used in the process of manufacture, the juice is slowly heated after the addition of lime and the scum that forms removed by a skimmer. The juice may have a little bisulphite of lime added at this stage as a preservative and colour improver. After the juice has been thoroughly skimmed it is allowed to settle for from one to two hours, the clear juice being drawn off from the sediment and evaporated very rapidly into a syrup.

Maize Sugar. The stalks of Indian corn, *zea mays*, contain from 9 per cent to 12 per cent. of sugar, and have been used as a source of sugar by the Mexicans in ancient times. The taste of the syrup or sugar obtained from maize resembles that of maple sugar.

Sugar cannot be made from maize to compete profitably with that of the beet, but it is quite possible that a systematic selection of seed according to the sugar yield would give better results. It would be an ideal state of things if the corn could be grown both for its seed and sugar.

LITTLE BOYS' SUITS

The Drafting and Making of a Man-o'-war Suit. The Jumper and Whole-fall Trousers. Sleeves and Pockets

CHILDREN'S CLOTHING
continued from page 4176

By AZÉLINE LEWIS

THE shape of the first small shirt cut on manly lines is shown in **37**, and is made in practically the same way as the grown-up model, for which we must refer the maker to Shirtmaking, where full directions are given. The yoke is of double material, cut selvedgeways, and is stitched to the gathered back, as the notches indicate. The button stand is stitched to the right side of front opening, and the mitred wrap on the left, as it must be remembered that men's garments fasten over from left to right, and not right to left, as those of the other sex. This shirt will take 1 yd. of 36-in. material, either of flannel or shirting.

The pattern can also be utilised for the French shirt shown in (*b*) of **36**, the lower portion being merely elongated and cut leg-fashion. As already mentioned, if these be further extended, and the garment made larger, it forms an excellent sleeping suit.

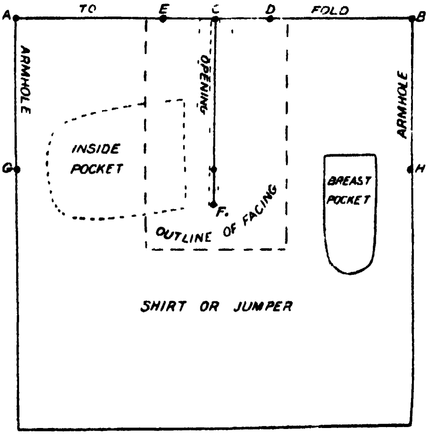
Man-o'-war Suit. The drafting and making of this suit are given in full, as they present a few variations, and the style is always popular. Besides this, the small trousers can be adapted to several shapes. The measurements are as follows: Breast, 26 in.; neck, 12 in.; sleeves, 14 in.; wrist, 6 in.

This drafting will do for four years, as already observed, by cutting without inlays. The materials and accessories required for this suit are 2¼ yd. of 27-in., or 1⅛ yd. of 50-in. material; ⅜ yd. flannel for singlet; lanyard and whistle; black silk square; man-o'-war hat.

Diagram **38** shows the jumper, which is drafted as follows: A to B, two-thirds of breast (about 17¼ in.); make C in the centre. Draw two parallel lines from A and B, 18 in. in length (or longer if desired).

C to D, and C to E are each one-sixth of the neck measure, plus ¼ in. (2¼ in.); C to F, one-fourth of breast, plus 1½ in. (8 in.); A to G, and B to H, are each one-fourth of breast (6½ in.).

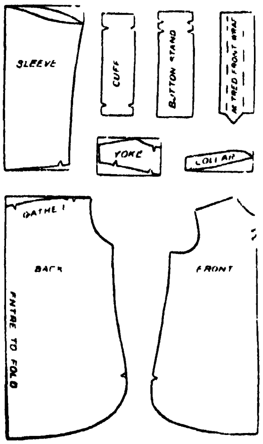
The Collar. A to B, the neck measure, less 1 in.; C midway between; the depth of collar is one-fourth of breast plus 1 in. (7½ in.), or deeper if desired. [See diagram **29** (2)]



38. JUMPER

Sleeve. A to B, one-fourth of breast plus 2 in. for pleats (8½ in.); A to C, the length of sleeve (14 in.); C to D, half wrist plus 2 in. for pleats; connect D to B; B to E, 1 in; connect E to A [**41**].

The Singlet. A to B and A to C are each one-sixth of neck, less ¼ in., to make it fit well round the neck; A to D, 1½ in. Curve from B through D to C. D to E and D to F are each 5 in.; D to G, 10 in.; H and I are each 2½ in. from G. Draw lines from I to F on to C, and from H to E on to B. A represents the back, and D the front [**40**].



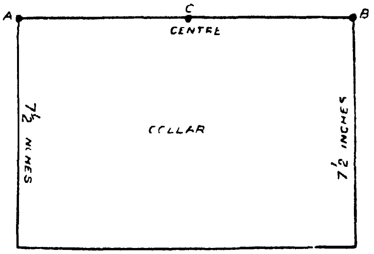
37 SHIRT

In cutting out the pattern, allow ¼ in. turnings. The shirt, or jumper, as the sailors call it, is cut in one piece—*i.e.*, it has no shoulder seams, these being placed to the fold of material.

The Making. Chalk-mark the armholes, as at G and H; then slit the neck from E to D, and mark the opening from C to F, or longer if required, to allow plenty of room for the head to go through, and avoid splitting. The opening must be faced with a strip of the same material 6 in. wide and 1½ in. longer than opening. Chalk-mark the centre of facing, as from C to F [**38**].

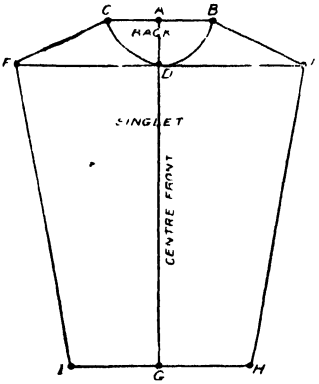
The making of the jumper is very simple. The facing is stitched to the inside of front, as shown by the broken lines, using a long stitch for coarse material, and well pressed. Make a small pocket and sew on the inside of right fore part on the edge of facing [**38**], and another on the outside of the left fore part for whistle, etc.

For the collar, two pieces must be cut out, and ¼ in. turnings allowed all round. It is made in the same manner as a pocket-flap, for which see Boys' Tailoring [page 1292]. Insert the neck of jumper between the collar, placing centre of neck to centre of collar; baste on carefully and stitch along the neck and all round the collar, quite close to the edge, and ¼ in. beyond. Press well on the wrong side, over a damp cloth. The seams can now be basted together and stitched; remove the basting and stitch again on the right side through both turnings—*i.e.*, without opening the seam—¼ in. from the seam, to keep them flat and neat; turn up the bottom, baste, and stitch.



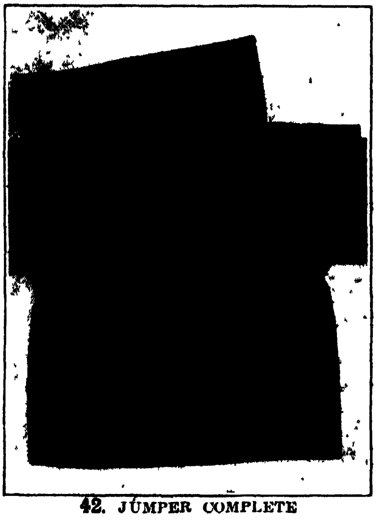
39. COLLAR

The sleeve should have a box pleat in the centre of top, and one on either side, reversed—*i.e.*, one facing front, the other back; 2 in. are allowed for the pleats, and they should be stitched down 2 in. or more to keep in position. The wrist is made in the same manner. After the pleats are stitched, the bottom should be turned in ¼ in. and faced with a piece of material or lining, and the opening of sleeve hemmed—about 3 in. will be sufficient. Then stitch up the seam to match the sides, place a button on the under part, and work a buttonhole in the top. The sleeve can be made without an opening if preferred; in this case, the seam must be stitched before the facing is put on.



40. SINGLET

Diagram **42** shows the shirt finished and the position of pockets. To insert the sleeve, place the seam to the underarm seam, baste and stitch; turn the shirt on the right side, and stitch again, to match the other seams. Sew two pieces of ribbon on the opening, about 1 in. from the bottom.



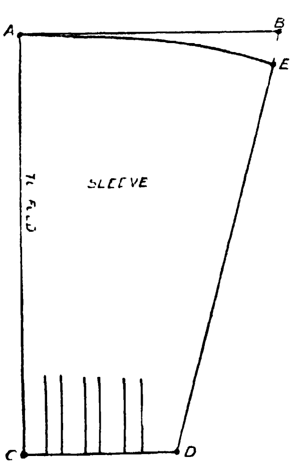
42. JUMPER COMPLETE

Drill collars to wear over these jumpers are sold ready-made, or can be made as shown.

The singlet is cut in two pieces. Join the right shoulder, turn in the edges of the left, work two buttonholes or loops on the front, and sew two buttons on the back; the neck should be bound round with a strip of drill or linen, cut on the cross, whilst the edges can either be bound, or turned in and herringboned. Sew tapes at each corner, to keep the singlet down when worn. An anchor on the centre of front is a great improvement, and can be bought woven ready to sew on.

Drafting "Whole-fall" Trousers. These are the measurements: Inside leg, 16 in.; waist, 26 in.; seat, 28 in. Working scale, half seat, 14 in. [**43**]. These trousers are cut without an outside seam, so the paper for drafting must be folded in half lengthwise.

A to B, the inside leg measure, 16 in.; B to C, half scale, 7 in.; C to D, one-fourth, 3½ in.; C to E, half the distance from C to D, 1¾ in.; E to F, 1 in.; C to G, half scale plus 1½ in., 8½ in.; square a line from G to the fold, and make H. H to I, 4 in. (for the opening); H to J, 2 in.



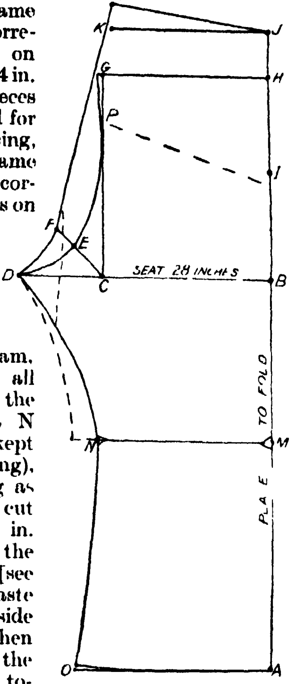
41. SLEEVE

Square out from J half the waist measure, 6½ in., and make K; K to L, 1 in.; connect J to L. Draw line from L to F, and curve from F to D; curve gradually from ½ in. to the left of G, through E to D. We must now consider the leg. A to M, half the inside leg measure plus 1½ in., 9½ in.; M to N, half the seat measure, 7 in., more or less as desired; A to O, 1 in. more than M to N [**43**]. Curve from O through N to D. The bottom should be slightly rounded.

Cut out the pattern from L, through F to D, thence through N to O, and on to A [**43**]. Next, slit down the opening from J to I, cut along the fall from H to G, and ½ in. to the left of G, through E to D.

It must be remembered that the pattern is drafted double, no seam being required at side, so care must be taken in cutting-out the upper front portion when the slit for the fall has been made not to cut the back part too.

Two pieces are required to go under the fall, which correspond with the upper part of front; these are joined on at the sides, to finish the waist part; and to this the fall is buttoned. They are cut as shown in diagram **44**. I to J and J to K must be the same measure as corresponding letters on drafting. K to P, 4 in.



43. "WHOLE-FALL" TROUSERS

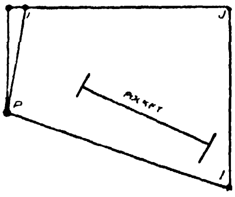
Two small pieces are also required for the fall-front facing, and are the same measure as the corresponding letters on the drafting.

Open the pattern of trousers on to the material, each leg being cut without a side seam, chalk-mark all round, as also the knee-marks at N (these are to be kept together in making), and the opening as at H and I, and cut out, allowing ¼ in. turnings. Face the forks with lining [see TAILORING]. Baste and stitch the inside leg seams; then baste and stitch the two back parts together, beginning two inches from the waist and terminating at the top of fall, as at G, taking care to keep the forks together, as at D. This part must be faced with two pieces of lining. [For shape see broken line in the drafting.]

Cut two pieces of material or lining (in many cases the latter will prove much less clumsy), join the centre and hem the lower edge; place the facing on the fall, face to face; baste and stitch round the edge, turn it over to the wrong side, work out the corner, baste again, and stitch ¼ in. from the edge. Join the small pieces to the sides, placing J and I together; turn in the top of waist ¼ in., and face with a straight piece of lining; this must be slip-stitched all round.

Turn back the 1½ in. for buttons and buttonholes, and hem along the bottom. Stitch all round the top of waist and edge of fronts, ¼ in. from the edge; secure the openings with a double row of stitching. Work four buttonholes on the fall, one at either corner (on the slant), and one about 1½ in. on either side of the seam, and three on the left under part [see A in diagram **45**].

As the blouse in this suit is tucked inside the trousers, no braces can be worn. The absence of this support, is, however, arranged for by drawing them together at the back by means of ribbon, or a lace passed through eyelet-holes. For this, the back seam is left open a few inches from the waist, and firmly fastened off to prevent tearing. For woollen material, it is best to stitch the opening about ¼ in. from the edge, but for drill or cotton it is not necessary. Two eyelet-holes are then worked with twist on each side of the opening. [For the method of working, see DRESSMAKING.] Now baste a piece of lining or material on the inside of the opening, about 4 in. square, and rounded at the lower part, forming a pocket-shaped piece, which stitch round twice [see B in diagram **45**]. This facing is to prevent any discomfort or pressure from the ribbon or lace used to draw it in the waist. For this last purpose a short silk or mohair bootlace answers admirably, but ribbon can be used if preferred. For the position of the facing, see diagram **45**, which shows the waist part of the trousers complete. In A we have the fall-front showing facings and buttonholes; also position of buttons on the pieces which go under the fall. In B, the back part is shown finished.



44. FRONT WRAP

Turn the fall over the front and mark position for the buttons, also for those on the right front; sew them on; turn up the bottom and fell and press.

45. TROUSERS COMPLETE

If a pocket is wanted, it should be jetted; for position see diagram **43**. Full directions for making pockets were given in TAILORING FOR WOMEN [page 1844].

This drafting can easily be converted into knickers, if required, by cutting pattern to the knee-line, and widening the leg part, as shown by the broken line.

If made a little fuller at the knee part, which can easily be done by placing J of the drafting to the fold of material, and M ½ in. in from this, the pattern will do for the gathered knickers worn with the tunic suits. If required with openings in front, we must refer the maker to the section on BOYS' TAILORING [pp. 1461, 1551], although, of course, the correct pattern to be worn with this suit is that illustrated on this page.

VERBS—continued

Reflexive Verbs

THE reflexive form of the active verb is obtained by the addition of the conjunctive forms of the personal pronouns *mi, ti, si, ci, vi.* [See page 3784, Position of the Conjunctive Forms.] The reflexive verbs are conjugated with the auxiliary *èssere*. The past participle must always agree in gender and number with its subject.

Lavarsi, to wash oneself

INDICATIVE MOOD

Present

io mi lavo, I wash myself
tu ti lavi, thou washest thyself
egli si lava, he washes himself
noi ci laviamo, we wash ourselves
voi vi lavate, you wash yourself, -selves
essi si làvano, they wash themselves

Past Indefinite

io mi sono lavato, -a, I have washed myself
tu ti sei lavato, -a, thou hast washed thyself
egli si è lavato, he has washed himself
noi ci siamo lavati, -e, we have washed ourselves
voi vi siete lavato, -a, -i, -e, you have washed yourself, -selves
essi si sono lavati, they have washed themselves

Imperfect

mi lavavo, I washed myself
ci lavavamo, we washed ourselves

First Pluperfect

mi ero lavato, -a, I had washed myself
ci eravamo lavati, -e, we had washed ourselves

Past Definite

mi lavai, I washed myself
ci lavammo, we washed ourselves

Second Pluperfect

mi fui lavato, -a, I had washed myself
ci fummo lavati, -e, we had washed ourselves

Future

mi laverò, I shall wash myself
ci laveremo, we shall wash ourselves

Future Perfect

mi sarò lavato, -a, I shall have washed myself
ci saremo lavati, -e, we shall have washed ourselves

IMPERATIVE

Present

làvati, wash thyself
laviàmoci, let us wash ourselves
Third person: *si lavi* (sing.); *si làvino* (plur.).
Second person plural: *lavàtevi*.

SUBJUNCTIVE MOOD

Present

che io mi lavi, that I wash myself
che noi ci laviamo, that we wash ourselves

Perfect

che io mi sia lavato, -a, that I have washed myself
che noi ci siamo lavati, -e, that we have washed ourselves

Imperfect

se io mi lavassi, if I washed myself
se noi ci lavàssimo, if we washed ourselves

Pluperfect

se mi fossi lavato, -a, if I had washed myself
se ci fòssimo lavati, -e, if we had washed ourselves

CONDITIONAL MOOD

Present

mi laverei, I should wash myself
ci laveremmo, we should wash ourselves

Perfect

mi sarei lavato, -a, I should have washed myself
ci saremmo lavati, -e, we should have washed ourselves

INFINITIVE MOOD

Present

lavarmi, -ti, -si, -ci, -vi, to wash myself, etc.

Perfect

èssermi, -ti, -si, -ci, -vi lavato, -a, -i, -e, to have washed myself, thyself, etc.

GERUND

Present

lavàndomi, -ti, -si, -ci, -vi, washing myself, etc.

Perfect

essèndomi, -ti, -si, -ci, -vi lavato, -a, -i, -e, having washed myself, etc.

PARTICIPLE

Present

lavàntemi, -ti, -si, -ci, -vi, washing myself, etc. (unused).

PAST PARTICIPLE

lavàtomi, lavàtami, etc.; *lavàtici, lavàteci, lavàtisi*, etc., having washed myself, etc. (of little use).

Many verbs in Italian may be conjugated with *mi, ti, si, ci, vi* in the same way as the reflexive verbs, in order to give more strength to the expression. Such verbs are called Pronominal Verbs, and must not be confounded with the reflexive verbs. Examples: *Avevo tanta fame che mi son mangiato* (instead of *ho mangiato*) *un pezzo di pane intero*, I was so hungry that I ate a whole loaf of bread; *Mi son comprato* (instead of *ho comprato*) *un bel vestito*, I have bought (myself) a nice suit.

When the verb conjugated with *ci*, *vi*, *si* expresses the action of two or more subjects, acting the one on the other, the verb is called *reciprocal*. Examples: *Noi ci amiamo*, We love one another; *Esse si scrivono tutti i giorni*, They write to one another every day.

It should be noted that many verbs which are reflexive in Italian are used in English as intransitive verbs. Examples: *Io mi rallegro*, I rejoice; *Io mi maraviglio*, I wonder.

The following are some of the most important verbs which are reflexive in Italian but not in English:

accòrgersi, to perceive, *mi accorgo di*
addormentarsi, to fall asleep, *mi addormento*
affrettarsi, to make haste, *mi affretto a*
avvicinarsi, to approach, *mi avvicino a*
dimenticarsi, to forget, *mi dimèntico di*
fidarsi, to rely upon, to trust, *mi fido di*
farsi, to become, *mi fàccio*
fermarsi, to stop, *mi fermo a*
indirizzarsi, to apply to, *m'indirizzo a*
informarsi, to inquire, *m'informo di*
lagnarsi, to complain, *mi lagno di*
levarsi, to get up, *mi levo*
pentirsi, to repent, *mi pento di*
sedersi, to sit down, *mi seggo* (*su*)
servirsi, to use, *mi servo di*
andàrsene, to go away (from somewhere)
Io me ne vado, I go away (thence)
andiàmocene, let us go away (hence)
se ne sono andati, they have gone away (from here, there)

EXERCISE XXXIII.

1. Vestìtevi sùbito, perchè dobbiamo andàrcene. 2. Vi divertiste ieri sera a teatro? 3. Non vi avvicinate troppo alla gàbbia 4. Incomìncio a stancarmi; fermiàmoci un poco. 5 Se vuole lavarsi le mani, le darò dell' acqua calda. 6. I signori del secondo piano si sono lagnati del servìzio. 7. Svegliàtemi alle sette e mezzo domani. 8. A che ora si leva ordinariamente? 9. Si levi; è molto tardi. 10. Vi ricordate di quella signora che era con noi in campagna l'estate scorsa? 11. Me ne ricordo benìssimo. 12. Non bisogna mai pèrdersi d'ànimo nella sventura. 13. Si segga, signora, e mi racconti tutto apertamente; lei sa che di me può fidarsi. 14. Mi ascolti, signore, e vòglia il cielo che non venga un giorno in cui si penta di non avermi ascoltato (m.).

IRREGULAR VERBS

Second Conjugation

Verbs in **-ere** (long)—continued

Cadére, to fall

Ind. Pres.—Cado, cadi, cade, etc.

Past Def.—Caddi, cadesti, cadde, cademmo, cadeste, càddero.

Future.—Cadrò, cadrai, cadrà, cadremo, etc.

Subj.—Cada, cada, cada, cadiamo, etc.

Condit.—Cadrei, cadresti, cadrebbe, cadremmo, etc.

Past Part.—Caduto.

Conjugate like *cadére*: *accadére* (imp.), to happen; *decadére*, to decay.

Sedére, to sit down

Ind. Pres.—Siedo and *seggo, siedi, siede. sediamo, sedete, sièdono* and *sèggono.*

Imperf.—Sedevo, sedevi, etc.

Past Def.—Sedei and *sedetti, sedesti*, etc.

Future.—Sederò, sederai, etc.

Imperat.—Siedi, sieda and *segga*, etc., *siedano* and *sèggano.*

Subj. Pres.—Sieda and *segga*, etc., *sièdano* and *sèggano.*

Past Part.—Seduto.

NOTE. When the accent falls on the first *e* of this verb, this *e* is changed into *ie*: *siedo, sièdono*; but *sedète, sederò.*

Conjugate like *sedére*: *possedére*, to possess; *soprassedére*, to supersede.

Rimanére, to remain

Ind. Pres.—Rimango, rimani rimane, rimaniamo, rimanete, rimàngono.

Imperf.—Rimanevo, rimanevi, etc.

Past Def.—Rimasi, rimanesti, rimase, rimanemmo, rimaneste, rimàsero.

Future—Rimarrò, rimarrai, etc.

Imperat.—Rimani, rimanga, etc., *rimàngano*

Subj. Pres—Rimanga, rimanga, rimanga, rimaniamo, rimaniate, rimàngano.

Subj. Imperf.—Rimanessi, etc.

Condit.—Rimarrei, rimarresti, etc.

Past. Part.—Rimasto.

Persuadére, to persuade

Ind. Pres—Persuado, persuadi, etc.

Past Def.—Persuasi, persuadesti, persuase, persuademmo, persuadeste, persuàsero.

Future.—Persuaderò, etc.

Past Part.—Persuaso.

Conjugate like *persuadére*: *dissuadére*, to dissuade.

Tacére, to be silent

Ind. Pres.—Tàccio, taci, tace, taciamo, tacete, tàcciono. (The forms *tàcio, tàciono* are incorrect.)

Imperf.—Tacevo, tacevi, etc.

Past Def.—Tacqui, tacesti, tacque, tacemmo, taceste, tàcquero.

Imperat.—Taci, tàccia, etc.

Subj. Pres.—Tàccia, tàccia, tàccia, taciamo, taciate, tàcciano.

Subj. Imperf—Tacessi, tacessi, etc.

Past. Part.—Taciuto.

Piacére, to please

Ind. Pres.—Piàccio, piaci, piace, piacciamo piacete, piàcciono.

Imperf.—Piacevo, piacevi, etc.

Past Def.—Piacqui, piacesti, piacque, piacemmo, piaceste, piàcquero.

Subj.—Piàccia, piàccia, etc.

Past Part.—Piaciuto.

The compound tenses are formed with *èssere*: *sono piaciuto*, I have pleased.

Conjugate like *piacére*: *dispiacére*, to displease.

The verbs *piacére* and *dispiacére* are generally used as impersonal verbs, thus: *Mi dispiàce*, I am sorry; *ci dispiace*, we are sorry, etc. *Mi piace*, I like; *gli piace*, he likes; *Le piàcciono questi fiori?* Do you like these flowers? etc.

Giacére, to lie down

Ind. Pres.—Giàccio, giaci, giace, giaciamo, giacete, giàcciono.

Past Def.—Giacqui, giacesti, giacque, giacemmo, giaceste, giàcquero.

Imperat.—Giaci, giàccia, etc.

Subj. Pres.—Giàccia, etc., *giaciamo, giaciate, giàcciano.*

Past Part.—Giaciuto.

Valére, to be worth

Ind. Pres.—Valgo, vali, vale, valiamo, valete, vàlgono.

Imperf.—Valevo, valevi, valeva, etc.

Past Def.—Valsi, valesti, valse, valemmo, valeste, vàlsero.

Future—Varrò, varrai, varrà, varremo, etc.

Imperat.—Vali, valga, valiamo, valete, vàlgano.

Subj. Pres.—Valga, valga, valga, valiamo, valiate, vàlgano.

Condit.—Varrei, varresti, etc.

Past Part.—Valso and *valuto.*

Conjugate like *valére*: *equivalére*, to be equivalent; *prevalére*, to prevail (*past part., prevalso*); *invalére*, to become prevalent (*past part., invalso.*)

EXERCISE XXXIV.

1. Questo quadro non vale niente. 2. Tacete, le vostre parole non vàlgono la pena di èssere ascoltate. 3. Io tàccio sùbito, ma è certo che voi non mi persuaderete a fare quello che non mi piace di fare. 4. Mi dispiacque tanto che lei non rimase con noi l'altra sera. 5. Cadde, ma non si fece male. 6. Non vada così presto, rimanga ancòra un poco. 7. Non posso dare di più, ecco tutto ciò che posseggo. 8. Sappiamo quanto vàlgono le vostre promesse. 9. Lo persuasi di accettare l'impiego che gli fu offerto. 10. Se questa càmera non le piace, gliene darò un' altra.

ESERCÍZIO DI LETTURA – continued

Quel brav' uomo aveva lasciato un figliuolo di stampa ben diversa[1]. Or dunque, alla raccolta[2], il cercatore andò per riscòtere la metà ch'era dovuta al convento; ma colui se ne fece nuovo affatto[3], ed ebbe la temerità di rispòndere che non aveva mai sentito dire che i cappuccini sapèssero far noci. Sapete ora cosa avvenne? Un giorno (sentite questa), lo scapestrato[4] aveva invitato alcuni suoi amici dello stesso pelo[5], e, gozzovigliando[6], raccontava la stòria del noce, e rideva dei frati. Quei giovinastri ebber voglia d'andàr a vedère quello sterminato mùcchio di noci; e lui li mena su in granàio[7]. Ma sentite: apre l'ùscio, va verso il cantùccio[8] dov'era stato riposto il gran mùcchio, e mentre dice: guardate, guarda egli stesso e vede . . . che cosa? Un bel mùcchio di fòglie secche di noce. Fu un esèmpio questo? E il convento, invece di scapitare[9], ci guadagnò; perchè, dopo un così gran fatto, la cerca delle noci rendeva tanto, tanto, che un benefattore, mosso a compassione del pòvero cercatore, fece al convento la carità d'un asino, che aiutasse a portàr le noci a casa. E si faceva tant'òlio, che ogni pòvero veniva a prènderne, secondo il suo bisogno; perchè noi siamo come il mare, che riceve acqua da tutte le parti, e la torna a distribuire a tutti i fiumi.

NOTES. 1. Of a quite different character. 2. Harvest. 3. But he pretended to know nothing at all about it. 4. Scatter-brains 5 Brother spirits. 6. To carouse. 7. Garner. 8. Corner. 9. Instead of losing.

CONVERSAZIONE

A che ora si leva abitualmente?

Alle sette sono già in piedi; mi levo sempre molto presto.

Io invece sono molto pigro, lo confesso. La mattina non so come decìdermi a saltàr giù dal letto. Se devo uscire alle nove, per esèmpio, alle otto e mezzo sono ancòra lì; e quindi appena ho il tempo di lavarmi e vestirmi.

È una gran brutta abitùdine la sua. Oltre a rovinarsi la salute, perde le più belle ore del giorno. Le ore del mattino hanno l'oro in bocca, dice il provèrbio.

Lei ha ragione, e le prometto di corrèggermi.

Ma si segga, signore.

Gràzie; non posso fermarmi di più.

Ripasserò di qui questo dopo pranzo e le porterò i due romanzi di cui le parlai.

Non se ne dimèntichi, perchè non ho niente da lèggere.

KEY TO EXERCISE XXXII.

1. We were speaking of you. 2. You are very kind. 3. Be so kind as to give me that pin. 4. Excuse me for not having sent them to you earlier. 5. I assure you that I shall do something regrettable if you do not tell me at once the name of that man. 6. You are wrong, my friend; ask your sister; is it not true, Miss N., that you are informed of everything? 7. You are very ready to speak without being questioned. 8. You are the most genial person I have ever known; how do you manage to be always so cheerful? 9. Your brother told me that you had returned to town, and I have hastened to come to shake hands with you. 10. Have you enjoyed yourself these long winter months? 11. Why do you stand at the door in the cold? Come in. 12. You do not know, and never will know how sincere my friendship for your son was. 13. Have the kindness to put this letter into the post, when you go out. 14. I thank you very much for the beautiful flowers you have sent me. 15. You believe that everything can be done offhand; but time is wanted for everything. 16. Your friends beg you to go down in the garden, if you don't mind. 17. I will show them to you (m. and f. sing. and plur.).

FRENCH

Continued from page 4218

By Louis A. Barbé, B.A.

VERBS—continued

Impersonal Verbs

1. Impersonal, or unipersonal verbs (*verbes impersonnels ou unipersonnels*) are intransitive verbs used only in the third person singular, or in the infinitive and participles, which are not personal tenses.

2. The following verbs are always impersonal:

Infinitive	*Indicative Present*
pleuvoir, to rain	*il pleut*, it rains
neiger, to snow	*il neige*, it snows
grêler, to hail	*il grêle*, it hails
tonner, to thunder	*il tonne*, it thunders
geler, to freeze	*il gèle*, it freezes
dégeler, to thaw	*il dégèle*, it thaws
bruiner, to drizzle	*il bruine*, it drizzles
venter, to be windy	*il vente*, it is windy
importer, to matter	*il importe*, it matters
falloir, to be necessary	*il faut*, it is necessary

3. There are a great many verbs which, though not essentially impersonal, are often used impersonally. Of these, the following occur most frequently:

Infinitive	*Indicative Present*
sembler, to seem	*il semble*, it seems
paraître, to appear	*il paraît*, it appears
convenir, to be suitable	*il convient*, it is suitable
arriver, to happen	*il arrive*, it happens
s'agir de, to be the question	*il s'agit de*, the question is
se trouver, to be found	*il se trouve*, it is found

4. The third person singular of *être*, to be, is used to form impersonal expressions: *Il est vrai que je suis son ami*, It is true I am his friend. *Avoir*, preceded by *y*, is used impersonally, with the meaning of "to be": *Il y a un Dieu*, There is a God. *Faire*, to make, is used impersonally, with the meaning of "to be," in a number of expressions chiefly referring to the state of the weather: *Il fait beau*, It is fine; *Il fait mauvais temps*, It is bad weather; *Il fait froid*, It is cold.

Pleuvoir, to rain

Principal Parts: *Pleuvoir, pleuvant, plu, il pleut, il plut.*

INDICATIVE

SIMPLE TENSES	COMPOUND TENSES
Present	*Past Indefinite*
il pleut, it rains	*il a plu*, it has rained
Imperfect	*Pluperfect*
il pleuvait, it was raining	*il avait plu*, it had rained
Past Definite	*Past Anterior*
il plut, it rained	*il eut plu*, it had rained
Future	*Future Anterior*
il pleuvra, it will rain	*il aura plu*, it will have rained

CONDITIONAL

Present	*Past*
il pleuvrait, it would rain	*il aurait plu*, it would have rained

SUBJUNCTIVE

Present

qu'il pleuve, that it may rain

Past

qu'il ait plu, that it may have rained

Imperfect

qu'il plût, that it might rain

Pluperfect

qu'il eût plu, that it might have rained

Falloir, to be necessary

Principal Parts: *falloir* (no pres. part.), *fallu*, *il faut*, *il fallut*.

INDICATIVE

SIMPLE TENSES	COMPOUND TENSES
Present	*Past Indefinite*
il faut, it is necessary	*il a fallu*, it has been necessary
Imperfect	*Pluperfect*
il fallait, it was necessary	*il avait fallu*, it had been necessary
Past Definite	*Past Anterior*
il fallut, it was necessary	*il eut fallu*, it had been necessary
Future	*Future Anterior*
il faudra, it will be necessary	*il aura fallu*, it will have been necessary

CONDITIONAL

Present	*Past*
il faudrait, it would be necessary	*il aurait fallu*, it would have been necessary

SUBJUNCTIVE

Present	*Past*
qu'il faille, that it may be necessary	*qu'il ait fallu*, that it may have been necessary
Imperfect	*Pluperfect*
qu'il fallût, that it might be necessary	*qu'il eût fallu*, that it might have been necessary

Uses of Falloir. 1. *Falloir* is frequently equivalent to the English verb "must." In that case the subject of "must" becomes the subject of the following verb, which requires to be in the subjunctive: *Il faut que je réponde à sa lettre*, I must answer his letter; *Il faut que les enfants soient obéissants*, Children must be obedient.

2. When the statement made is general, or when the person on whom the obligation falls is sufficiently indicated by the context, the second verb may be in the infinitive: *Il faut obéir aux lois*, We must obey the laws; *Mes enfants, il faut vous coucher*, Children, you must go to bed.

3. With the infinitive construction, the person indicated by the subject of "must" may be indicated by an indirect object, or dative: *Il me faut sortir*, I must go out.

This construction is not, however, a very common one, and can be used with a pronoun only, not with a noun.

4. In the past and future, *falloir* cannot be translated in English by "must," but may be

rendered by the suitable tenses of "to have to." *Il faudra nous dépêcher,* We shall have to make haste; *Il a fallu qu'il me le donnât,* He had to give it to me.

5. When *falloir* is followed by a noun, it means "to want," "to require." In that case, the subject of the English verb is expressed by an indirect object, or dative, and is placed before *falloir,* if it be a personal or relative pronoun, but after it if it be a noun: *Il me faut d'autres livres,* I require other books; *Voici l'élève à qui il faut une grammaire,* Here is the pupil who requires a grammar; *Il faut une nouvelle robe à ma sœur,* My sister requires a new dress.

6. *Falloir* is used idiomatically in the following expressions:

(*a*) *S'en falloir de beaucoup,* To be far from; *Il s'en faut de beaucoup que la somme y soit,* The sum is far from being complete; *Il ne s'en faut pas de beaucoup que la somme n'y soit,* The sum is not far from being complete (lit., from being there).

(*b*) *S'en falloir de peu,* or *peu s'en falloir,* not to be far from, to want but little, to be near. *Peu s'en fallut qu'il n'en mourût,* He was near dying of it.

(*c*) *Tant s'en faut,* so far from, far from it, by a long way. *Tant s'en faut qu'il consente, qu'au contraire il fera tout pour l'empêcher,* He is so far from consenting, that, on the contrary, he will do everything to prevent it; *Ils ne nous ont pas payé tout ce qu'ils nous devaient; tant s'en faut,* They have not paid us all they owed us; far from it (by a long way).

7. *Comme il faut* (pronounced ko-mi-fô) is used as a qualificative, with the meaning of "respectable," "gentlemanly," "ladylike"; and also as an adverbial phrase signifying "suitably," "properly": *Ce sont des gens très comme il faut,* They are very respectable people; *C'est un homme tout à fait comme il faut,* He is quite a gentleman. *Elle a l'air très comme il faut,* She looks very ladylike.

EXERCISE XXX.

1. The earth is warmed (*échauffer*) by the sun.
2. The egoist (*égoïste*) is loved by (*de*) nobody.
3. Figures (*le chiffre*) were invented (*inventer*) by the Arabs (*Arabe*).
4. The woman was deceived by the serpent (*le serpent*).
5. Thunderstorms (*un orage*) are foreseen (*prévu*) and announced by the swallows
6. America (*l'Amérique*) was discovered (*découverte*) by Christopher Columbus (*Christophe Colomb*) in 1492.
7. Printing (*l'imprimerie,* f.) was invented by Gutenberg in the fifteenth century.
8. The Cape of Good Hope (*le cap de Bonne-Espérance*) was doubled (*doubler*) for the first time by the Portuguese (*Portugais*).
9. When did you come back from Paris ?
10. What day did your friends leave (*partis*) for London ?
11. Since the comet (*la comète*) has (is) appeared (*apparue*) a crowd (*la foule*) of people pass the night (*à*) looking at it.
12. When we arrived at the station (*la gare*) the train (*le train*) had already started.
13. It seems that the sun turns (*tourner*) around (*autour de*) the earth, when, on the contrary (*au contraire*) it is certain that it is the latter which turns around the sun.
14. If it freezes (in) the morning, it is often fine all day (*journée,* f.).
15. A door must be open (*ouverte*) or closed, says a French proverb.
16. I have told you everything. What (of) more do you want ?
17. That is just what I require; thanks (*merci*).
18. His friends are very respectable people.
19. He was very near being killed (*tuer*).
20. To (*pour*) speak well, it is necessary to say what is required, all that is required, nothing but (*rien que*) what is required, and to say it suitably.

IRREGULAR VERBS

Amongst the verbs classed as irregular there are some of which all the tenses are formed quite regularly from the principal parts, but in which these principal parts themselves present some peculiarities. As regards these verbs, it will be sufficient to give the principal parts, together with the three persons singular of the present indicative. No such verbs occur in the first conjugation, and the third has only two.

Second Conjugation. 1. ASSAILLIR, to assail, *assaillant, assailli, j'assaille, tu assailles, il assaille, j'assaillis.* Some grammarians give an irregular future, *j'assaillerai,* instead of *j'assaillirai.*

2. BOUILLIR, to boil, *bouillant, bouilli, je bous, tu bous, il bout, je bouillis.* This verb is intransitive, and its use is consequently practically limited to the third person. "To boil" as a transitive verb is *faire bouillir,* "to make boil."

3. COUVRIR, to cover, *couvrant, couvert, je couvre, tu couvres, il couvre, je couvris.*

4. DORMIR, to sleep, *dormant, dormi, je dors, tu dors, il dort, je dormis.*

5. FUIR, to flee, *fuyant, fui, je fuis, tu fuis, il fuit, je fuis.*

6. MENTIR, to tell a lie, *mentant, menti, je mens, tu mens, il ment, je mentis.*

7. OFFRIR, to offer, *offrant, offert, j'offre, tu offres, il offre, j'offris.*

8. OUVRIR, to open, *ouvrant, ouvert, j'ouvre tu ouvres, il ouvre, j'ouvris*

9. PARTIR, to set out, *partant, parti, je pars, tu pars, il part, je partis.*

10. SENTIR, to feel, to smell, *sentant, senti, je sens, tu sens, il sent, je sentis.* The reflexive verb *se repentir,* to repent, is conjugated like *sentir.*

11. SERVIR, to serve, *servant, servi, je sers, tu sers, il sert, je servis.*

12. SORTIR, to go out, *sortant, sorti, je sors, tu sors, il sort, je sortis.*

13. SOUFFRIR, to suffer, *souffrant, souffert, je souffre, tu souffres, il souffre, je souffris.*

14. TRESSAILLIR, to start, to shudder, is conjugated like *assaillir.*

15. VÊTIR, to clothe, *vêtant, vêtu, je vêts, tu vêts, il vêt, je vêtis.*

Third Conjugation. 3. POURVOIR, to provide, *pourvoyant, pourvu, je pourvois, tu pourvois, il pourvoit, je pourvus.*

2. PRÉVOIR, to foresee, *prévoyant, prévu, je prévois, tu prévois, il prévoit, je prévis.*

EXERCISE XXXI.

1. Our brigade will attack (*assaillir*) the enemy in his retrenchments (*le retranchement*) to-morrow morning.

2. A few shots (*coups de feu*) are fired (go off); at this noise Napoleon starts. The Russian (*de Russie*) campaign (*la campagne*) is opened.

3. Everybody (*tout le monde*) knows (*sait*) that it was Christopher Columbus who discovered America.

4. He never opens his mouth without saying some foolish thing (*la sottise*).

5. The noise that was made (*se faisait*) in the meeting (*une assemblée*) covered the voice of the speaker (*orateur*).

6. It is certain that the sea formerly covered a great part of the inhabited (*habiter*) earth.

7. The water would boil more quickly if you lighted (*allumer*) a good fire.

8. Francis (*François*) I. slept on a gun-carriage (*un affût*) the night of the battle (*la bataille*) of Marignano (*Marignan*).

9. We fall asleep (*s'endormir*) every evening whilst he reads (*lit*) the paper (*le journal*) to us.

10. When we were young we used to sleep twelve hours without awakening (*se réveiller*).

11. Isaac having asked his father where the victim (*la victime*) was which was to be sacrificed (*immoler*), Abraham answered: "God will provide for (to) it."

12. Charles the Bold (*Téméraire*) perished (*périr*) before Nancy, betrayed (*trahir*) by a Neapolitan mercenary (*un mercénaire napolitain*) and killed whilst (*en*) fleeing after the battle by a gentleman of Lorraine (*gentilhomme lorrain*).

13. Let us flee together to the depths (*le fond*) of the forests; it is better to trust (*se fier*) to tigers than to men.

14. There are people (*gens*) who lie simply for the sake of (*pour*) lying.

15. Satire (*la satire*) lies about (on) men of letters (*gens de lettres*) during their life, and praise (*l'éloge*) lies after their death.

16. He has been offered a situation (*une place*) in Paris, but he does not wish (*désirer*) to leave (*quitter*) London.

17. It is useful for (to) the proud (*le superbe*) to fall, because their fall opens their eyes.

18. We (*on*) are usually (*ordinairement*) less grieved (*fâché*) when we go away than when we see (*voit*) (others) go away.

19. We ought to have started for the country yesterday, but we shall start to-morrow only.

20. When you (sing.) tell a lie, does not your conscience (*la conscience*) reproach (*reprocher*) you (with) something, and do you not repent immediately?

21. The judge who is faithful to his duty (*le devoir*) feels neither regrets (*le regret*) nor anger (*courroux*, m.).

22. There are people who seem to think (*croire*) that the happiness of serving them is a sufficiently (*assez*) high reward (*la récompense*) for those who serve them.

23. Go out when you like (*voudrez*), but I warn you (*avertir*) that I shall go out only after you (shall) have (be) gone out.

24. Is it worth while (*la peine*) to live (*vivre*) when we (one) suffer? Yes, for we always hope that we shall not suffer to-morrow.

25. The misfortune (*le malheur*) of those people who know all (it) is that they never foresee anything.

KEY TO EXERCISE XXIX.

1. Il me semble que j'ai déjà vu cette dame. Comment s'appelle-t-elle?

2. Les vaincus ne se sont pas moins bien battus que les vainqueurs.

3. L'ennemi s'est emparé de la ville après un long siège, pendant lequel les habitants se sont défendus aussi courageusement que les soldats.

4. Nous nous défions trop des autres, et nous ne nous méfions pas assez de nous-mêmes.

5. Il y a des hommes qui se glorifient plus de leurs défauts que de leurs bonnes qualités.

6. Aide-toi, le ciel t'aidera, dit le proverbe.

7. Elles se sont aperçues de leur erreur, mais il était trop tard.

8. Un écrivain a dit que si nous nous vantons souvent de ne point nous ennuyer, c'est parce que nous sommes si glorieux que nous ne voulons pas nous trouver de mauvaise compagnie.

9. A quelle heure vous levez-vous ordinairement? Nous nous levons ordinairement à sept heures, et nous nous couchons rarement avant onze heures et demie.

10. De grands motifs peuvent nous engager à nous humilier, aucun à nous avilir.

11. Les Romains, après s'être emparés de la Gaule, lui donnèrent en peu de temps leur civilisation.

12. Il vaut mieux s'exposer à l'ingratitude que de laisser sans secours un malheureux.

13. L'histoire nous dit qu'il y a eu des rois qui se sont dévoués à la mort pour le salut de leur peuple.

14. Il y a bien de la différence entre se plaire à un travail et y être propre.

15. Nous sommes si accoutumés à nous déguiser aux autres, qu'enfin nous nous déguisons à nous-mêmes.

16. Il est aussi facile de se tromper soi-même sans s'en apercevoir, qu'il est difficile de tromper les autres sans qu'ils s'en aperçoivent.

GERMAN

Continued from page 4222

By P. G. Konody and Dr. Osten

XCV. Principal Rules of German Punctuation. The full stop (.) is employed at the end of a complete sentence, and after inscriptions, abbreviations and numerals, as in English. Examples: Der Vater kommt heute. Er bat mich ihn zu beſuchen, The father is coming to-day. He asked me to call on him, etc.; u. ſ. w. (abbreviation of und ſo weiter, and so forth); z. B. (zum Beiſpiel, for example); der 15. Auguſt.

The mark of interrogation (?) is put after an interrogative sentence; and the mark of exclamation (!) after expressions of command, desire, joy, grief, and after addressing persons in letters (Lieber Freund! etc.).

The comma, the semicolon, the colon, and the full stop indicate pauses in the sentence. The shortest pause is denoted by the comma, the longest by the full stop. The use of the comma in German differs from the English. It is employed (*a*) in enumerations. Example: Männer, Frauen, Mädchen, Knaben eilten umher, Men, women, girls *and* boys were running about. (*b*) Between principal sentences and subordinate clauses. Examples: Er bat mich, daß ich kommen möge, He begged me to come. Dies iſt der Mann, der mir den Weg zeigte, This is the man who showed me the way. (*c*) When a co-ordinate or subordinate clause contains a new subject and predicate. Examples: Der Vater ſagte mir nichts, und auch die Mutter ſchwieg. Father said nothing to me, and mother, too, kept silent. (*d*) With quotations. Example: Hier bin ich, ſagte er, Here I am, he said.

The semicolon and the colon are used for indicating longer pauses in complicated compound sentences, for the sake of the clearer articulation of the sentence; and the colon is also used to introduce enumerations.

All other signs are used exactly as in English.

XCVI. German Correspondence.

The mode of address in German business letters differs from the English form in so far as it is customary to use only the name of the addressee's firm, and not the additional address of civility, „Sir," or „Dear Sir," or „Gentlemen". On the other hand the signature is frequently preceded by expressions of courtesy, which would sound ridiculous if literally translated into English: Hochachtungsvoll (full of high esteem); Ergebenſt (most devotedly); Mit dem Ausdrucke aufrichtiger Wertſchätzung (with the expression of sincere valuation); Mit der Verſicherung vorzüglicher Hochachtung (with the assurance of excellent high esteem); etc. In private letters without distinct commercial character, the style of address is: Sehr geehrter Herr! Dear Sir (very honoured sir); Werte gnädige Frau! Dear Madam (esteemed gracious madam); Sehr geehrtes gnädiges Fräulein! Hochgeſchätzte Frau! etc. This address is always followed by a note of exclamation. The signature is again preceded by the customary terms of courtesy, as in business letters. It is not considered very good form to begin private letters with the personal pronoun „Ich".

KEY TO EXERCISES IN EXAMINATION PAPER XXIII. (PAGES 4220–1)

EXERCISE 1 (*a*). Ich kaufte den Hut in dem Geſchäfte, das (or welches) ſich nebenan befindet. Dies widerfuhr mir, der ich doch, etc. Er ſtellte mir ſeine Frau vor, die (or welche) ich vorher, etc. Dies iſt der Mann, deſſen Sohn, etc. Dies iſt die Bäuerin, deren Tochter, etc. Das war Alles, was ich erfahren konnte Das ſagen Sie, der dies doch beſſer wiſſen ſollte? Das ſagte der Mann, der (or welcher) dies hätte beſſer wiſſen müſſen. Das Klügſte, was wir tun können, iſt, abzureiſen. Es gab nichts, was er nicht wußte.

(*b*) Ich kaufte den Hut in dem Geſchäfte, das ſich nebenan befindet. Alle Mühe, die daran gewendet wurde, war vergeblich, or Alle Mühe war vergeblich, die daran, etc. Ich befolgte den Rat, der mir erteilt worden war (or wurde). Sie ſchenkte ihm eine Roſe, welche wunderbar duftete. Er zeigte mir den Weg, welcher der kürzeſte war.

EXERCISE 2. Ich fühlte mich ſo wohl, wie ein Fiſch im Waſſer. Ich fühlte mich wohler, als ein Fiſch im Waſſer. Wie die Sonne aus den Wolken bricht, ſo trat die Fee, etc. Unſer Garten iſt weit ſchöner als der ſeine. Er liebte ihn, wie ein Bruder den andern.

Private Letters.

Lieber Freund! Sehr geehrter Herr!
Werteſte gnädige Frau! Lieber Guſtav! Liebſte Karoline!

Zu meinem lebhaften Bedauern iſt es mir infolge eines unvorhergeſehenen Zwiſchenfalles unmöglich geworden, unſere Verabredung einzuhalten. Ich wäre troſtlos, wenn dadurch in Ihre Einteilung eine Störung getragen würde, allein es iſt mir beim beſten Willen nicht möglich, an der Partie teilzunehmen. Ich hoffe, daß Sie eine angenehme Fahrt und einen zufriedenſtellenden Aufenthalt haben werden.

In alter Herzlichkeit

Dear Friend. Dear Sir,
Dear Madam. Dear Gustave, Dear Caroline,

To my greatest regret, unforeseen circumstances make it impossible for me to keep to our arrangement. I should be sorry if this were to upset your plans, but I cannot possibly make one of the party, much as I should like to do so. I hope that you will have a pleasant journey and a satisfactory holiday.

Most cordially yours,

. . . .

Sehr geehrter Herr!

Meine Frau und ich würden uns aufrichtig freuen, wenn Sie uns das Vergnügen machen wollten, mit uns am nächſten Sonntag, den 12., um 1 Uhr, zu ſpeiſen. Wir haben einige Freunde eingeladen, die es ſich zur Ehre anrechnen werden, Ihre Bekanntſchaft zu machen.

In aufrichtiger Ergebenheit

Dear Mr. . . . . . ,

My wife and I would be delighted if you could give us the pleasure of dining with us next Sunday, the 12th, at 1 p.m. We have invited a few friends who will feel honoured to make your acquaintance.

Most sincerely yours,

. . . .

Herren A. & B.!

In höflicher Erledigung (Beantwortung) Ihrer geſchätzten (geehrten) Zuſchrift vom 4. d. M. (dieſes Monats [vom 4. v. M. (vorigen Monats)] beehre ich mich, Ihnen mitzuteilen [anzuzeigen, Sie zu benachrichtigen, Sie in Kenntniß zu ſetzen], daß die mir zu-

Messrs. A. & B.,

In [courteous] reply to your favour [esteemed letter] of the 4th inst. [of the 4th ult] I beg to [have the honour to] inform you that the goods forwarded to me are only partially up to sample. The sizes, as well as the quantities and qualities,

gemittelten Waren nur zum Teile muſtergemäß ſind. Sowohl die Maße, als auch die Nummern und die Qualitäten entſprechen nicht meiner Ihrem Reiſenden erteilten Ordre de dato 2. Mai d. J. (dieſes Jahres). In der Anlage [Beigeſchloſſen] finden Sie eine Kopie meines auf Grund Ihrer Muſter erteilten Auftrages nebſt Aufſtellung der tatſächlich gelieferten Waren. Wollen Sie demnach umgehend das Fehlende nachliefern und über das Nichtbeſtellte und Muſter-Ungemäße disponieren. Die Zahlung erfolgt naturgemäß erſt, ſobald die Ordre komplett und auftragsgemäß effektuirt iſt.

Durch die Ungenauigkeit in der Ausführung meiner Beſtellung ſind mir Unannehmlichkeiten erwachſen und es wäre, wenn unſere Verbindung aufrecht erhalten werden ſoll, wünſchenswert, wenn ſolche Irrtümer [Störungen] in Zukunft vermieden würden.

Ihren geſch. (geſchätzten) Nachrichten entgegenſehend
Hochachtungsvoll und ergebenſt

. . . .

Herren . . . . . .

In den Beſitz Ihrer geſch. Zuſchrift vom . . . . . gelangt, haben wir von der uns darin aviſirten Entnahme von £287.16.10 o/ (Ordre) Bruder Hellwald & Co., Berlin, drei Monate à dato, Notiz genommen, und wir werden Ihre Ziehung zulaſten Ihrer w. (werten) Rechnung zur Zeit einlöſen.

In Ihren Dienſten ſtets gerne bereit, zeichnen wir
Hochachtungsvoll

. . . .

Herren P. Winkelmann & Co., Berlin.

Von der Deutſchen Bank in Berlin iſt uns heute für Ihre w. Rechnung ein Check £648.14.11 zugegangen, den wir zum Ausgleiche Ihres Kontos verwendet haben. Ihren gefälligen weiteren Aufträgen mit Vergnügen entgegenſehend, zeichnen wir
Hochachtungsvoll

. . . .

Herrn Dr. chem. Joſef Lippmann, Frankfurt a. M.

Wir empfingen Ihr geſchätztes Offert vom . . . . und ſind nicht abgeneigt, der Frage Ihres Engagements für unſere Fabriken näher zu treten. Wie aus den uns zugemittelten Zeugniſſen erſichtlich, haben Sie in unſerer Spezial Branche ſchon gearbeitet, und demnach dürfte Ihre Qualifikation für die Bedürfniſſe unſeres Betriebes im Großen und Ganzen außer Zweifel ſtehen. Abgeſehen von der Honorirung, die den Gegenſtand weiterer Verhandlungen zwiſchen uns zu bilden hätte, ſcheint uns die Frage von der Dauer des Engagements von beſonderer Wichtigkeit. Wir legen auf eine drei bis fünfjährige Engagements-Dauer Gewicht und erbitten uns Ihre freundliche Mitteilung, ob Sie geneigt ſind, ſich für eine derartige Periode zu verpflichten. Die in Ihrem Offertſchreiben dargelegten Wünſche hinſichtlich der Ihnen beizuſtellenden wiſſenſchaftlichen Laboratorium Behelfe etc. werden nach Tunlichkeit Berückſichtigung finden.

Hochachtungsvoll und ergebenſt

. . . .

Herren . . . . .

Ihren werten Auftrag de dato . . . . , können wir zu unſerem Bedauern erſt in der zweiten Hälfte des nächſten Jahres ausführen, da der Aufſchwung in der Textilwaren-Induſtrie im Inlande unſere Produktion bis zu dieſem Zeitpunkte vollſtändig in Anſpruch

do not conform to the order given by me to your traveller on the 2nd of May last. Enclosed you will find a copy of my order based on your samples, together with a list of the goods actually delivered. Will you [in accordance with this list] make up the deficiency and dispose of the goods not ordered? Payment will, of course, only follow when the delivery has been completed according to order.

The irregularity (inexactness) in the execution of my order has caused me some unpleasantness, and if our relations are to be continued (kept up) it would be desirable if such errors were avoided in future.

Awaiting the favour of your esteemed reply,
[I am]
Yours very truly,

. . . .

Messrs . . . . .

We beg to acknowledge receipt of your favour of the . . . . inst. in which you advise us of your draft on us of £287 16s. 10d. to the order of Brothers Hellwald & Co., Berlin, three months from date, which will be duly honoured and debited to your account

[Always at your service] we remain
Yours very truly,

. . . .

Messrs. P. W. & Co., Berlin.

We have received to-day from the Deutsche Bank, Berlin, a cheque £648 14s. 11d. in full settlement of your account. Anticipating the favour of your further esteemed orders,
We are,
Yours faithfully,

. . . .

Dr. Josef Lippmann Frankfurt-a.-M.

We are in receipt of your esteemed application of the . . . . inst., and are not disinclined to consider the question of your engagement for our factories. It appears, from the testimonials you have sent us, that you have already worked in our special line, so that your qualifications for the requirements of our works appear to be on the whole beyond doubt. Apart from the question of salary, which would have to be discussed at a later date, the duration of the engagement seems to us an essential point. We attach great importance to a three to five years' engagement, and shall be glad if you will kindly let us know whether you feel disposed to bind yourself for this term. We shall give due consideration to the wishes expressed in your application regarding the scientific appliances to be supplied by us

Yours very truly,

. . . .

Messrs. . . . . . .

We are sorry to inform you that your esteemed order of . . . . . . cannot be executed before the second half of next year, as the boom in the textile industry for home consumption will fully absorb our output up to that date. Should your nimmt. Falls Ihr Bedarf nicht unmittelbare Deckung nötig macht, wird es uns freuen, Ihnen ab Ende Juni 1907 dienlich ſein zu konnen.

Ihrer gef. Meinungsaußerung entgegenſehend
Hochachtungsvoll und ergebenſt

. . . .

Herren . . . . .

Mit Gegenwartigem erlauben wir uns die ergebene Anfrage, ob Sie in der Lage waren, den Ihnen mit ſeparater Poſtſendung zugehenden Artikel in größeren Quantitäten herzuſtellen. Wir erbitten uns in dieſem Falle Gegenmuſter mit genaueſter Berechnung des Preiſes und Angabe des Liefertermines. Wir haben in dieſem Artikel einen bedeutenden Umſatz und konnten konvenirenden Falles große Ordres erteilen. Wir legen, wie jetzt ſchon ausdrucklich erwahnt werden mag, auf ſtrikteſte Einhaltung der Qualitat nach Muſter, ſowie auf prompte Lieferung das großte Gewicht. Die Zahlung erfolgt gegen Ladeſchein.

Ihrer freundl. poſtwendenden Verſtandigung entgegen
ſehend Hochachtungsvoll und ergebenſt

. . . .

Herren S. Winkler & Co., Leipzig.

In hofl. Beantwortung Ihrer Anzeige in der Deutſchen Handels-Zeitung vom . . . . . erlaube ich mir hierdurch, Ihnen meine Dienſte als engliſcher Korreſpondent anzubieten. Ich habe, wie Sie aus den beifolgenden Abſchriften meiner Zeugniſſe gutigſt erſehen wollen, in deutſchen Hauſern als engliſcher Korreſpondent bereits ſerviert und bin beider Sprachen in Wort und Schrift vollkommen machtig.

Ihrer geſchatzten Meinungsaußerung ſieht entgegen
Hochachtungsvoll und ergebenſt

. . . .

demand not require immediate supply, we shall be pleased to be at your service after the end of June, 1907.

In anticipation of your esteemed reply,
We are, Yours very truly,

. . . .

Dear Sirs,

We take the liberty of asking you whether you are in a position to produce large quantities of the article sent to you in a separate parcel, in which case we shall be glad to receive sample with lowest quotations and date of delivery. We have a large turn-over in this line, and are in a position to place large orders if suited We may mention at once that we attach the greatest importance to the goods being up to sample, and to prompt delivery. Payment on bill of lading.

Awaiting your reply by return of post,
We are,
Yours very truly,

. . . .

Messrs. S. Winkler & Co., Leipzig.

Gentlemen,

In reply to your advertisement in the “Deutsche Handels-Zeitung” of the . . . . . I beg to offer you my services as English correspondent. As you may see from the enclosed copies of my testimonials, I have already served with German firms as English correspondent, and can speak and write both languages fluently.

In anticipation of your esteemed reply,
I am, Yours very truly,

. . . .

SPANISH

Continued from page 4224

By Amalia de Alberti & H. S. Duncan

IRREGULAR VERBS

The Spanish irregular verbs are very numerous, but excepting a few, which are not classifiable, they may be divided into several classes, following easily definable rules.

Class I. Verbs of this class expand the radical vowels *e* and *o* into *ie* and *ue* when the stress falls upon them and not upon the verbal ending. The radical vowel is that which lies nearest the end of the verb stem, found by suppressing the infinitive ending; thus, in *acord-ar*, to agree, the radical vowel is *o*, which becomes *ue* whenever the stress is laid upon it. In all these verbs the accent falls on the radical vowel throughout the Indicative Present, the Subjunctive Present, and the Imperative, always excepting the first and second persons plural. In all other tenses, the accent falls on the verbal ending, so that, with the above exceptions, these verbs follow the rule of their regular conjugation. Examples:

Cerrar, to shut

Ind. Pres.—cierro, cierras, cierra, cerramos, cerrais, cierran.

Subj. Pres.—cierre, cierres, cierre, cerrémos, cerreis, cierren.

Imperat.—cierra, cierre, cerremos, cerrad, cierren.

Perder, to lose

Ind. Pres.—pierdo, pierdes, pierde, perdemos, perdeis, pierden.

Subj. Pres.—pierda, pierdas, pierda, perdamos, perdais, pierdan.

Imperat.—pierde, pierda, perdamos, perded, pierdan.

Acordar, to agree

Ind. Pres.—acuerdo, acuerdas, acuerda, acordamos, acordais, acuerdan.

Subj. Pres.—acuerde, acuerdes, acuerde, acordemos, acordeis, acuerden.

Imperat.—acuerda, acuerde, acordemos, acordad, acuerden.

Morder, to bite

Ind. Pres.—muerdo, muerdes, muerde, mordemos, mordeis, muerden.

Subj. Pres.—muerda, muerdas, muerdas, mordamos, mordais, muerdan.

Imperat —muerde, muerda, mordamos, morded, muerdan.

Remarks. All verbs of this class observe the euphonic changes in spelling already given for the regular verbs. Thus, *rogar* (to beseech), besides expanding *o* into *ue*, follows the ordinary

rule for verbs ending in *gar*, changing the *g* into *gu* before *e*, thus:

Ind. Pres.—ruego, ruegas, ruega, rogámos, etc.

Subj. Pres.—ruegue, ruegues, ruegue, roguemos, roguéis, rueguen.

Imperat.—ruega, ruegue, roguemos, rogad, rueguen

When in verbs of this class the radical vowel *o* is preceded by *g*, the expansion into *ue* takes a diaeresis wherever it occurs. Example:

Degollar, to behead. *Ind. Pres. degüello, degüellas, degüella, degollámos, degollais, degüellan.*

The verbs *oler*, to smell; *desosar*, to bone; and *desovar*, to spawn, take an *h* wherever the *o* is expanded into *ue*, thus:

Ind. Pres.—huelo, hueles, huele, olemos, oleis, huelen.

In the verb *errar*, to miss, wherever the *e* is expanded into *ie*, *i* becomes the initial letter, and is therefore written and pronounced *y*, thus:

Ind. Pres.—yerro, yerras, yerra, erramos, errais, yerran.

NOTE. *I* is also changed into *y* in other verbs when the stress falls upon the verbal termination beginning with the diphthongs *ie* or *io*. Example: *creer*, to believe; *creyendo*, believing.

The verb *jugar*, to play, formerly spelt with an *o*, is included in this class.

Class II. This class consists of verbs of the third conjugation only, with the radical vowels *e* and *o*.

Besides expanding these vowels into *ie* and *u* when the stress falls upon them, these verbs shorten *ie* and *ue* into *i* and *u* in the first and second persons plural of the Subjunctive Present, the first person plural of the Imperative, and throughout the conjugation whenever the verbal ending contains the diphthongs *ie* or *io*. Example:

Sentir, to feel; Gerund, *sintiendo*

Ind. Pres.—siento, sientes, siente, sentimos, sentis, sienten.

Past Def.—sentí, sentiste, sintió, sentimos, sentísteis, sintieron.

Imperat.—siénte, siénta, sintámos, sentid, sientan.

Subj. Pres.—sienta, sientas, sienta, sintamos, sintáis, siéntan.

Subj. Impf. (1) *sintiera, sintieras, sintiera, sintiéramos, sintiérais, sintieran.*
„ „ (2) *sintiese, sintieses, sintiese, sintiésemos, sintiéseis, sintiesen.*

Subj. Fut.—sintiere, sintieres, sintiere, sintiéremos, sintiéreis, sintieren.

The imperfect and future of the Indicative and the Conditional are regular.

Dormir, to sleep. Gerund, *durmiendo*

Ind. Pres.—duermo, duermes, duerme, dormimos, dormís, duermen.

Past Def.—dormí, dormiste, durmió, dormimos, dormísteis, durmieron.

Imperat.—duerme, duerma, durmamos, dormid, duerman.

Subj. Pres.—duerma, duermas, duerma, durmamos, durmais, duerman.

Subj. Impf. (1) *durmiera, durmieras, durmiera, etc.*
„ „ (2) *durmiese, durmieses, durmiese, etc.*

Subj. Fut.—durmiere, durmieres, durmiere, durmiéremos, etc.

NOTE. A few verbs of the third conjugation ending in *quirir*, expand the radical *i* into *ie* when the accent falls on it, but are otherwise regular. Example:

Adquirir, to obtain *Ind. Pres.—adquiero, adquieres, adquiere, adquirimos, adquiris, adquieren.*

The following is a list of the irregular verbs of the first class likely to be required in ordinary use:

First Class

Verbs with radical *e* expanding to *ie*, and radical *o* expanding to *ue*.

absolver, to absolve
acordar, to agree
acostar, to put to bed
acrecentar, to increase
alentar, to encourage
almorzar, to breakfast
alongar, to lengthen
amueblar, to furnish
amolar, to grind
apretar, to press
aprobar, to approve
arrendar, to rent
ascender, to ascend
asosegar, to calm
atender, to attend
atraer, to attract
atravesar, to cross over
avergonzar, to shame
calentar, to warm
cegar, to blind
cimentar, to lay a foundation
cocer, to cook
colgar, to hang up
comenzar, to commence
componer, to compose
comprobar, to prove
concertar, to concert
concordar, to agree
condescender, to condescend
condolerse, to condole
confesar, to confess
conmover, to move
consolar, to console
contar, to count
contender, to contend
costar, to cost
defender, to defend
demoler, to demolish
demostrar, to demonstrate
denegar, to deny
desacertar, to mistake
desacordar, to disagree
desalentar, to discourage
desapretar, to loose
desaprobar, to disapprove
desasosegar, to disturb
desatender, to neglect
desatentar, to perplex
descender, to descend
desenterrar, to unearth
deshelar, to thaw
desmentir, to give the lie
desolar, to desolate
despoblar, to depopulate
desterrar, to exile
desvergonzarse, to become shameless
detener, to detain
devolver, to give back
discordar, to disagree
disolver, to dissolve
despertar, to awake
doler, to ache
empellar, to impel
empezar, to begin
encender, to light
encentar, to cut
encerrar, to shut up
encomendar, to commend
encontrar, to meet
enmendar, to correct
enterrar, to bury
envolver, to wrap up
esforzar, to endeavour
extender, to extend
forzar, to force
fregar, to scour
gobernar, to govern
helar, to freeze
herrar, to shoe a horse
holgar, to rest
invernar, to winter
jugar, to play
llover, to rain
manifestar, to manifest
moler, to grind
mostrar, to show
mover, to move
negar, to deny
nevar, to snow
pensar, to think
perder, to lose
plegar, to fold
poblar, to populate
probar, to prove
proponer, to propose
quebrar, to break
recomendar, to recommend
recordar, to remember
reforzar, to fortify
regar, to water
remendar, to mend
remorder, to cause remorse
reprobar, to reprove
reventar, to burst
revolver, to stir
rodar, to roll
sembrar, to sow
sementar, to sow
sentarse, to sit down
sentar, to establish
sonar, to sound
soñar, to dream
sosegar, to calm
temblar, to tremble
tender, to stretch out
tentar, to tempt
tostar, to toast
transcender, to transcend
transponer, to transpose
trascordarse, to forget
travesar, to cross
trocar, to exchange
tronar, to thunder
tropezar, to stumble
verter, to spill
volar, to fly
volver, to come back.

NOTE. Only one meaning is given here; a good dictionary should be consulted for the further meanings of each verb.

Second Class

Verbs of the third conjugation with radical *e* and *o*, expanding to *ie* and *ue*, or changing to *i* and *u* :

adherir, to adhere
adormirse, to fall asleep
asentir, to assent
conferir, to confer
convertir, to convert
deferir, to defer (show deference)
desadvertir, to act rashly
diferir, to defer (put off)
digerir, to digest
discernir, to discern
disentir, to dissent
divertir, to divert
entregerir, to intermix
entremorir, to die away
herir, to wound
hervir, to boil
inferir, to infer
ingerir, to interfere
invertir, to invert
malherir, to wound badly
morir, to die
pervertir, to pervert
preferir, to prefer
premorir, to predecease
proferir, to pronounce
referir, to refer
reherir, to repel
reherrar, to re-shoe (a horse)
rementir, to lie frequently
sentir, to feel
subvertir, to subvert
sugerir, to suggest
transferir, to transfer
zaherir, to censure

EXERCISE XV. (1)

Translate the following into Spanish :

1. We have shut all the doors ; now you shut the windows.

2. It is not worth while to beseech them to pardon him ; you beseech, if you like.

3. The smell of those flowers is a real perfume.

4. It is difficult to acquire fame, and even more difficult to preserve it after it is acquired.

5. It is well to encourage youth ; I always encourage it.

6. It is difficult to approve when a friend criticises us with truth ; the approbation of those who surround us is necessary to our happiness.

7. It is necessary to attend to our business.

8. Let us be careful in crossing the square ; I cross it always looking to the right and to the left.

9. The proverb says that there is no one more blind than he who will not see. To be blind to our defects is natural.

10. The foundation of our friendship was laid years ago when we suffered together. Troubles are calculated to lay the foundation of friendly intercourse.

11. This room needs to be warmed, and the breakfast must also be warmed.

EXERCISE XV. (2)

Translate the following into English :

1. El destierro politico á que fué condenado hizo su fortuna, cuando su partido volvió al poder.

2. Despertar la ira de una persona apasionada es peligroso, una vez despierta es dificil de apaciguar.

3. Es mas dificil al hombre gobernar sus pasiones que gobernar una nacion.

4. Niego absolutamente haber dicho semejante cosa, y cuando me confronten con él no lo podrá negar.

5. Se dice que mas vale remendar su capa á tiempo, que dejar que el remiendo sea mas grande que la capa.

6. El que siembra espinas no puede esperar que salgan flores, mas vale sembrar buena semilla que sementar abrojos.

7. El tonto sueña loque quiere, y el sabio lo que puede. El soñar no se manda.

KEY TO EXERCISE XIV. (1)

1. ¿ Quiere Vd jugar al ajedrez ? No sé jugar tan bien como Vd. No importa, le daré la reina y el peon.

2. Muy bien ; pero despues de concluido el juego de ajedrez, tendrémos uno de damas. Creo que conozco ese juego más bien. Aquí está el tablero.

3. Tome Vd un cigarro ; son buenos ; son habanos. Gracias, no fumo. ¿ Y su hermano fuma ? Mi hermano fuma cigarros, cigarillos, y la pipa.

4. Los escoséses tocan la gaita, y son los únicos en el mundo entero que pueden tocarla.

5. Esa agua que vé Vd aqui es un manantial de agua dulce.

6. Este es un arroyo en verano, y un rió caudaloso en invierno.

7. La calma viene antes de la tormenta.

8. ¡ Dice que es buen jinete, y no sabe manejar su caballo !

9. ¿ Usa Vd espuelas ? Nunca.

10. Esa silla es vieja. Deberia Vd comprar otra nueva y permítame que le diga que los estribos son demasiado largos.

11. Ese caballo es muy brioso ; necesita domarse. Eso es fácil ; tengo en mi caballeriza un buen picador.

12. El aparejar se hará pronto.

13. No es bueno alabarse tanto, pues el que se alaba corre el riesgo de que se burlen de él.

14. ¡ Dejárlos burlarse ; no me importa !

15. Se me alegra el corazon al ver á Vd.

16. Nos alegrámos mucho de su buena fortuna.

KEY TO EXERCISE XIV. (2)

1. The war was very sanguinary ; many soldiers died.

2. On receiving the sad news the poor woman fainted.

3. May I open that letter ? It has been opened since this morning.

4. The sky is overcast ; they must cover the flowers, as it will surely rain.

5. I have written to your father giving him news of our engagement ; we shall see if he deigns to write.

6. Those words are printed on my heart.

7. This manuscript must be printed.

8. America was discovered by Columbus.

9. Upon discovering the statue, they threw it on the ground.

10. It thunders, rains and freezes at the same time.

11. It is going to thunder.

12. We left the town incognito at dawn.

13. Day breaks at five in the morning.

14. We reached our destination at nightfall ; it was a long journey.

15. Is it true that it is twelve miles from here to San Juan de Luz ?
